It would occupy too large a space of the present article to attempt a detailed account of even the principal expeditions and occurrences, in the course of this contest for existence, between the rival colonies; but it may be remarked in general, that a very accountable circumstance, the province of Canada, which was so thinly inhabited and so poorly provided, should have been able to withstand, for such a length of time, the whole power of the English settlements; which, in addition to their decided superiority by sea, were able to bring five times the number of fighting men into the field. The frequent discontinuance and tardy progress of the British forces, may be ascribed chiefly to the inexperience of their commanders in the American mode of warfare, to the endless dissensions between the provinces and their governors, and to the prevalence of personal animosities and of private interests among those who should have united in the service of their country. About the year 1738, however, the arms of Great Britain began to be attended with better success in North America; and it ought to be recorded, that Sir William Johnson, by his good conduct as a commander, as well as by his extraordinary influence with the Indians as a negotiator, was eminently instrumental in giving this favourable turn to the state of affairs, and in preparing the way for the final subjugation of Canada. The operations of the campaign, for this purpose, were directed in three different quarters, so as gradually to approach each other, and at length to unite in one point. General Wolfe, with 8000 men, was appointed to undertake the siege of Quebec. General Amherst, at that time commander in chief of the forces in America, was directed, with 12,000 men, to reduce Ticonderago and Crown-point, and then crossing lake Champlain, to co-operate with General Wolfe. Brigadier General Prideaux, assisted by Sir William Johnson’s abilities and advice, was commissioned to attack fort Niagara, and thence to proceed, to form a junction with the other commanders, for the siege of Montreal. These three different divisions, by a wonderful concurrence of favourable circumstances, accomplished their respective objects; and actually met at the walls of Montreal, within 24 hours of each other. A more particular account of their progress and exploits has already been given in the article AMERICA; and we have only to mention the general result in this place. By the capitulation of Montreal on the 7th of September 1760, the reduction of Canada was completed; and it was finally ceded to Great Britain, by the definitive treaty of peace in 1763. The province was found by the conquerors in a very impoverished condition; and the inhabitants, in many places, were supplied with provisions from the stores of the army. For several years after the conquest, the country continued in a very unsettled state; and presented innumerable obstacles to the British traders. The Indian tribes, either not considering the French government as sufficiently authorised to transfer their allegiance to Great Britain, or excited against their new masters by the Popish missionaries, who resided among them; carried on, for some time, a desultory and destructive warfare; rendered all intercourse with the interior extremely hazardous; and prevented the extension of settlements, either for the purposes of trade or cultivation. The most formidable confederacy of the natives was directed by a celebrated Indian warrior named Pontiac, who had always been strongly attached to the French interest. In the year 1763 he took by surprise fort Michilimackinac, which is situated between the lakes Huron and Mihigan; but treated the garrison with considerable humanity. In the following year, he made a similar attempt against fort Detroit, between lake Erie and lake St. Clair; but having been thwarted in his designs, and the garrison having received a considerable reinforcement, he proposed an accommodation, concluded a peace, and received a pension from the British government, as the purchase of his friendship. The confederate Indians soon after returned to their different provinces, and gradually became reconciled to the conquerors of the country.

Previous to the year 1664, the supreme authority was in the hands of a governor in Canada. Through the whole of the latter’s time, a council was given to the colony, and a council of state was established in the capital. This council consisted of the governor, the bishop, the intendant,
four counsellors chosen by these three, a procurator general, and a chief secretary. This constitution afterwards underwent various alterations. The number of counsellors was gradually increased to twelve, and the subaltern judges to so great a multitude, that a litigious spirit began to prevail among the colonists, from the influence of which they have continued to suffer even to the present day. During the first four years after the conquest of Canada by the British, it was divided into three military governments, and the officers of the army acted in the double capacity of commanders and judges. The laws of England, however, were soon established in the province; and its criminal code, particularly, was speedily experienced to be an inestimable benefit, in comparison with the tyrannical and summary proceedings of the French system. But the English civil laws were not received with equal approbation by the old colonists; and, in 1774, an act of the British legislature restored in their place the old coutume de Paris.

A council was at the same time appointed, consisting of the lieutenant-governor, the chief justice, the secretary of the province, and 20 other members, chosen indifferently from the French and British residents, invested both with a legislative and executive authority, and possessing power to perform every act of government, except that of imposing taxes. This plan, however, was not greatly relished, either by the British emigrants, who thus found themselves deprived of some of the most valuable privileges which they had enjoyed in their own country, or by the Canadian inhabitants, who had begun to relish the advantages of a free government. Hence, in 1791-2, all the benefits of the British constitution were extended to this part of the empire. The colony was divided into two distinct provinces, called the Upper and Lower. A legislative council and an assembly were constituted in each, having power, with the consent of the governor, to make laws, which should not be contrary to the acts of the British parliament; but the king has a right to declare his dissent at any time within two years after receiving the bill. The legislative council of the upper province must consist of at least seven members, and that of the lower of 15; which numbers, however, may be augmented at the king's pleasure, and has been recently increased to twenty-one. These are summoned by the governor under the royal authority, and are nominated for life, unless they forfeit their seats by an absence of four years, or by paying allegiance to a foreign power. The house of assembly in Lower Canada consists of 50 members, and in Upper Canada of 16, who are chosen by the freeholders in the towns and counties. In the counties, the electors must be possessed of landed property to the clear yearly value of 40 shillings or upwards; and, in the towns, must possess a dwelling-house and lot of ground to the yearly value of £5 sterling; or must have paid, for one year at least, a rent of £10 per annum. These councils must be assembled once, at least, every twelve months; and the houses of assembly continue four years at most, but are subject to be dissolved before the termination of the full period. The governor, together with such of the executive council as may be appointed by the king, for the affairs of each province, are to act as a court of civil jurisdiction for hearing and determining appeals; subject, however, to such appeals from their sentence as existed previous to the passing of the act appointing this constitution. The whole is superintended by an officer styled Governor General of the four British Provinces in North America; but each of them has a lieutenant-governor, who, in the absence of the governor-general, has all the powers of a chief magistrate.

It has been questioned, with considerable appearance of justice, whether the inhabitants of Canada were sufficiently prepared for such a full extension of the British constitution. The majority of the assembly in each province, especially in the Lower, are always of French descent; and have thus the power of passing such regulations, as may be most agreeable to their views; while, at the same time, they are in general very far from being properly qualified, by their degree of education, or habits of life, to discharge the office of legislators. The counties, though large, are so thinly inhabited, that they can very seldom furnish persons fitted to represent them. The few who might be competent to undertake the office, cannot easily leave their habitations and employments, without great detriment to their private interests. Hence it happens, that more than one half of the members of assembly, at least in Lower Canada, is composed of merchants, shopkeepers, lawyers, etc., residing in Quebec and Montreal. The Canadians themselves opposed, at first, the introduction of the present form of government; and it was procured chiefly by the application of British residents. But in order to have given the latter what they wished, the superiority in the government, as well as upon every principle, which renders a union desirable, there ought to have been only one house of assembly for both provinces.

For the more regular administration of justice, courts of Lower Canada was, in 1794, divided into three districts: that of Trois Rivieres, in which there is only one judge; that of Quebec, in which there is one chief justice, three puisne judges, and a solicitor general; and that of Montreal, in which there is the same number as in Quebec, with an attorney general; but both the solicitor and attorney general are competent to attend the several courts throughout the province; and, unless prevented by unavoidable absence, the attorney general conducts all criminal suits in each of the districts. The upper province is considered as only one district; and has one chief justice, with three puisne judges. The chief justices are always British.

There are about 60,000 militia in Canada, but they are neither well clothed nor trained. The English establishment of the Canadians also are distributed into separate corps, while the latter are both officered by their own people and taught their exercise in French, so as to be utterly incapable of acting in the same brigade with British troops.

The revenues of Lower Canada, consist of the casual and territorial revenue of the crown prior to the conquest, which has been given up by his majesty in aid of the civil expenses of the province. This arises from ledroit de quinte les blés et venes, (du-
ties paid upon the sale of property), rent paid for the king’s posts on the Labrador coast, and for the forges of St Maurice. To these are to be added certain permanent and moderate duties, (imposed either by acts of the British parliament prior to the constitutional act of the year 1791, or by those of the provincial legislature,) on wine, spirits, tea, and a few other articles imported into Canada. The whole taken together, produce from £50,000 to £35,000 a year; and nearly suffice for the ordinary expenses of the civil government, any deficiencies being made good from the military chest. Duties, to nearly the same amount, are also collected under temporary acts of the provincial legislature, and applied to particular purposes, such as the building of court houses, gaols, &c. The expenses of the Indian department of the two Canadas, including the salaries of the officers, and what is paid in England for goods sent out as presents to the Indians, (who are treated by the British government as military allies,) amount, on an average, to about £25,000 per annum; and are regularly included in a vote of parliament, and defrayed out of the army extraordinaries. But the surplus expense of Great Britain in supporting Canada is well repaid by the consumption of her manufactures, the employment given to her seamen, the supplies afforded to her West India islands, and the variety of useful productions which she imports from the colony.

The external appearance of Canada, like that of North America in general, is altogether of the majestic character; and inanimate nature is there exhibited on the grandest scale. Every thing is vast and sublime. Lakes, that can be compared only to seas; rivers of immense and amazing velocity; cataracts of inconceivable magnificence; mountains and forests apparently interminable, are every where presented to the view, in continued succession and inexhaustible variety. In the districts of Upper Canada there are plains of great extent and beauty; but the general and ordinary prospect throughout the country is that of mountainous ridges, rising behind each other, stretching in all directions, and completely covered with wood; so that the cultivated parts appear like a few islands scattered upon the surface of the ocean; and are almost wholly lost to the view, except in the neighbourhood of the towns, where the scenery is rich and pleasing, presenting a beautiful mixture of cottages and corn fields, of villages and country residences. On entering the St Lawrence, a continued forest appears down to the very brink of the water; but the trees are there rather dwarfish and scrappy, more like brushwood than timber. On both sides, are mountains of immense height, which frequently terminate in acute pointed capes; and from the bottom of these to the edge of the river lies a level tract of land gradually advancing to general cultivation.

The great river of Canada, the St Lawrence, is universally regarded as the second, and may even be affirmed to be the first, on the face of the globe. Its length, if reckoned from the egress of lake Ontario, is 700 miles; but if computed from lake Superior, is not less than 2500. But the greatness of its breadth, and the extent to which it is navigable, form its distinguishing characteristics. It is 90 miles wide at its mouth, where it is divided into two channels by the island of Anticosti, which is 120 miles long and 30 broad, barren and of little value, and occupied only in winter by a few savages for the purposes of the chase. It is navigable for ships of the line nearly 400 miles from its mouth; for ships of considerable size, as high as Montreal; while ships of the largest class may be navigated on the lakes, through which it flows, at a distance of 2000 miles from its junction with the ocean. It receives in its progress an innumerable multitude of smaller rivers, and several of considerable magnitude. These tributary waters flow chiefly from the north; and the most remarkable are, the Saguenay, a very deep and impetuous torrent, about three miles in breadth, except at its mouth, bounded by high and precipitous banks, sometimes 600 and even 1000 feet in height, taking its rise from lake St John, flowing through a course of 150 miles, interrupted by numerous falls in its progress, and falling with a contracted stream, but with a powerful impulse, into the waters of the St Lawrence at Tadoussac; the Montmorenci, which also flows from the north, abounds in cascades, and meets the St Lawrence, about eight miles to the eastward of Quebec; the Chaudiere, which flows from lake Megantic, through a course of 120 miles, and falls into the St Lawrence about eight miles to the south west of Quebec, where its mouth is completely confined by thick woody banks; the St Ann, a stream of considerable size, flowing from the north coast, and abounding in falls; the Jacques Cartier, which falls in about 30 miles above Quebec, and which sweeps its broken current with great impetuosity over a very rocky bed; the Sorel, or Champlain, arising from lake Champlain, and flowing through a very fertile tract of country; the Otonais, or Ulass, or Grand river, the largest of all these tributary streams, issuing from various lakes in the centre of Upper Canada, rushing over a bed of remarkable declivity, and pouring its waters, of a bright greenish colour, into the muddy bosom of St Lawrence, a few miles above Montreal.

The numerous and magnificent cataracts, which are to be found in this country, are its greatest natural curiosities. In most of these falls, there is indeed a considerable similarity in point of effect, as the precipices, over which they are thrown, are nearly perpendicular; but, still, each of them is distinguished by some peculiar features of the sublime, the wild, and the picturesque. The cascades and rapids are innumerable; and are to be found, in all the variety of romantic beauty, in almost every stream that flows into the St Lawrence. The following appear to be the most worthy of particular notice:—The falls of St Thomas, which are extremely beautiful, and about 25 feet in height;—of St Charles, a very romantic cataract of 30 feet, near the lake of the same name;—of Saguenay, at the mouth of that river, about 50 feet high, forming an immense sheet of waters, which is so perpetually broken in its descent, as to assume a resplendent white appearance;—of St Ann, which are seven in number, very near to each other, the largest of which is about 130 feet high, and is surrounded with remarkably rugged steep woody banks;—of La Puace, the chief of which is 112 feet.
in height, and is so completely clothed with wood, to the very summit of the precipice; as to produce a very deep and solemn gloom;—of the **Chaudière**, about four miles from the mouth of the river, about 360 yards broad, descending from a height of 120 feet, in three distinct cataracts, surrounded with wood, and abounding in the wildest and most picturesque scenery;—of **Montmorency**, exactly at the confluence of that river with the St Lawrence, about 200 feet in breadth, falls in one undivided mass from a perpendicular height of 216 feet, and having few trees on its steep and lofty banks, is more remarkable for grandeur than for beauty;—and of **Niagara**, between lakes Erie and Ontario, 600 yards wide, divided by two islands into three distinct cataracts, one of which is 142 and another 160 feet high, the noise of which is heard to the extent of 15 miles, and the cloud of vapour, which they throw up, is said to be frequently observable at a distance of 90 miles. Those who have witnessed this stupendous cataract, declare that no power of words can convey an adequate idea of its sublimity. "The lofty banks and immense woods," says Mr. Heriot, "which crown this stupendous scene, the irresistible force, the rapidity of motion displayed by the rolling clouds of foam, the uncommon brilliancy and variety of colours and shades, the ceaseless immenseness and swift agitation of the dashing waves below, the solemn and tremendous noise, with the volumes of vapour darting upwards into the air, which the simultaneous report and smoke of a thousand cannon could scarcely equal, irresistibly tend to impress the imagination with such a train of sublime sensations, as few other combinations of natural objects are capable of producing."

See also **Niagara**, and Weld’s *Travels in Canada*, vol. ii. p. 123.

The lakes of Canada are astonishingly numerous, and the waters still cover so large a portion of its surface, as almost to afford a proof of its being more recently deserted by the ocean, than the rest of the American continent. Those in the direction of the St Lawrence, are by far the largest; and the first of these, that meets the navigator, as he ascends the stream, is that of **St Peter**, which, is, properly speaking, nothing more than an expansion of the waters of the St Lawrence, over a level country, which is about 20 miles long, and 15 broad, receives a number of considerable rivers into its bed, and yet is so extremely shallow, that the ship-channel, at some seasons, is not in more than 11 or 12 feet deep.—

**Lake Ontario**, or **Cataraguy**, the smallest of the five great lakes, is of an oval figure, 160 miles in length, and about 450 in circumference. Its depth, in many places, is not ascertained; and it has frequently been sounded with a line of 350 fathoms, without finding the bottom. It contains an immense number of islands, and is very liable to be agitated by stormy winds. The soil around its borders is very much intermixed with rocks, and yields several valuable quarries of a durable white stone. Various volcanic productions are found on its banks; and this circumstance, in conjunction with its immeasurable depth, has given rise to a conjecture, that its basin was once the crater of a volcano. See Volney’s *View of the United States*, p. 120.—**Lake Erie**, or **Oswego**, is 300 miles in length, 40 at its utmost breadth, 710 in circumference, and about 50 fathoms at its greatest depth. At its northern extremity, it is much exposed to violent gales, and its navigation is both tedious and dangerous. It contains, towards the west, a number of beautiful islands, in which are many remarkable caverns abounding in curious stalactites. These islands are also full of reptiles, especially rattlesnakes; and the margin of the lake is in many places completely covered, for many acres, with the large leaves of the pond lily, upon which, in the summer season, myriads of water snakes are seen basking in the sun. The bottom is a blueish limestone rock, and its banks are clothed with wood, abounding in game and wild animals.—**Lake Huron**, the second in point of magnitude, is of a triangular form, 250 miles in length, and 1100 in circumference. It contains a number of islands, among which, one called Manataulin, signifying the place of spirits, and held sacred by the Indians, is nearly 100 miles long, and 8 in breadth. It has also numerous and extensive bays, one of which, **Sagguina**, or **Saganaum**, is 15 miles long, and 18 wide; and another about 9 miles broad, called **Thunder Bay**, because it is scarcely ever free from tremendous thunder storms. The storms on this lake are extremely dangerous, and its waves both rise higher, and break quicker than those of the ocean. It contains abundance of large white fish, and particularly a rich and delicate trout, some of which are four or five feet in length, and frequently 70 lb. in weight.—

**Lake Michigan** is situated entirely within the American territories, but as, together with lakes Huron and Superior, it forms what has been called the *Sea of Canada*, it seems entitled to a short notice in this sketch of the principal lakes of that country. It is about 280 miles long, 70 at its greatest breadth, and 945 in circumference. On its eastern coast it receives a number of rivers, the banks of which abound in *ginseng*. On its northern coast is the Green bay, or **bay des Puans**, 120 miles long and 30 wide, the waters of which have a considerable flux and reflux; and the quantity of mud which they leave behind causing an unpleasant vapour, when exposed to the sun, has occasioned its French name *Puanite*. From this bay there is a short and easy communication with the Mississippi. It communicates also with **Lake Huron**, by the straits of Michillimackinac; and though no diurnal ebb or flow is perceptible in the waters of this passage, yet it is affirmed, that a periodical alteration takes place in their height; that in the course of seven years and a half, they gradually rise about three feet, while, in the same space of time, they as imperceptibly fall away to their former state.—**Lake Superior**, or **Tracey**, or **Condé**, is the largest body of fresh water on the face of the earth, being 400 miles in length, 100 at its greatest breadth, and nearly 1600 in circumference. It receives the waters of nearly 40 rivers, some of which are of considerable magnitude; and contains a number of islands, one of which, **Isle Royale**, is about 100 miles long and 40 broad. Its bed is covered with large uneven rocks, and is in many places beyond the reach of soundings. Its northern banks are very high and rugged, and abound in virgin copper; but its eastern shore is low and shallow, covered with stunted trees and brambles, and
producing an amazing quantity of currants, strawberries, whortleberries, and raspberries, of extraordinary size and delicious flavour. The soil, however, around the greater part of the lake, is extremely barren, yielding indeed abundance of meadow hay, but scarcely bearing any other kind of crop than potatoes. It abounds in sturgeon and long trout, from 50 to 70 pounds in weight; and, owing to the unequalled transparency of its waters, these fish are seen to an astonishing depth from its surface. It is subject to tremendous storms; and there is a swell upon its coast resembling the flow of the tide. Its waters have been observed to vary in their height at particular periods from five to six feet; which is supposed to be occasioned by the greater or smaller quantity of snow in the adjacent regions, by the dissolution of which its tributary streams are supplied. This lake may be considered as the grand reservoir of the river St Lawrence, as no other large river flows from its bosom; but as it does not appear that one tenth part of the waters, which are conveyed into it by 40 channels, are carried off at this one point of evacuation, it remains yet to be ascertained by what cause, whether by evaporation, or by subterranean cavities, the superabundant fluid is removed. It communicates with Lake Huron by the Straits of St Mary, which are rendered impassable for boats of any burden by the rapids. The North West company, however, have cut a canal along the northern bank, for the purpose of facilitating their commerce, and have here a considerable establishment; but their principal fort and storehouses are situated at Kamenistiquia, upon the banks of a river which flows into the north-west of Lake Superior, and which affords them an easy communication with the interior.

Of the immense multitude of smaller lakes which cover the inland parts of Canada, it is only a very short view of the most remarkable that can here be given. Farther west are the Lake of the Woods, which has its name from the quantity of wood on its banks, is of an oval form, about 75 miles long and 40 broad, with a muddy bottom, and in some places of great depth; Lake Winnebago, or Quinipique, the reservoir of several large rivers which discharge themselves into Hudson's Bay, is about 200 miles long and 100 broad, full of small islands, and well stored with fish, bounded on the north side with banks of black and grey rocks, and on the south with a low and level country; Lake Bourbon, formed by the waters of the river Bourbon, which runs a great way southward, near to the northern head of the Mississipi, is about 80 miles long, and nearly as much in breadth; Lake of the Hills, or Lake Athabasca, or Great Slave Lake, from which Mackenzie's river extends its course to the Arctic Ocean, is about 200 miles in length, and 100 in breadth, and scarcely within the boundaries of Canada. On the north of the St Lawrence, the principal lakes are, Lake Manikagamick, at the head of the black river, which falls into the St Lawrence to the east of Saguenay, near the coast of Labrador, and which is about 60 miles in circuit; Lake St John, on the river Saguiney, about 90 miles in compass, and bordered with pine trees; Lake Mississin, at the head of Rupert's river, very irregular in its shape, but nearly 200 miles in circumference; Lake Temiscaming, on the Utawau river, which falls into the Cataragui; and Lake Nipissing, on the French river, which runs into Lake Huron, about 100 miles each in circumference. On the south of the St Lawrence, the only one worth mentioning is Lake Champlain, at the head of the river Chamby or Sorel, and almost entirely within the territories of the United States. It is 120 miles in length and 15 in breadth, well stored with fish, and situated in the midst of a beautiful and fertile country.

The mountains of Canada have never been properly examined, either with a view to describe their range, and mines, or to ascertain their structure. The principal ridge is in the northern part of the province, in the direction of south-west and north-east, giving rise to many rivers, which flow chiefly to the south-east. There are few mountains towards the south west of the colony; but between Quebec and the sea, they are more numerous. The whole extent of Canada may be considered as a granitic country, occasionally accompanied with calcareous rocks of a soft texture, and in horizontal strata. The region of the calcareous stones seems to extend in a line north-west, beyond Lake Michigan, as far as the sources of the Mississippi, and thence to those of the Saschachawin, joining at length the great chain of the Stony or Chipewyan mountains, which again may be considered as a continuation of the Cordilleran of the Andes. All the great lakes of Upper Canada are placed in the line of contact between those two vast chains of granite and limestone. At the narrowest part of Lake Winnipeg, for instance, where it is not more than two miles broad, the west shore is skirted by calcareous rocks, about 30 feet high, while, on the opposite shore, there are still higher rocks of a dull grey granite. In the lower province, particularly, the granite predominates. A calcareous stratum, indeed, found under the St Lawrence at the fall of Niagara, seems to proceed along the bed of the river as far as Quebec; the isle, on which the city of Montreal is built, is of a calcareous nature; the immediate bed of the fall of Montmorency is a horizontal shelf of a black grey limestone, of the kind called primitive or crystallized; and the banks of the St Lawrence, as also of the other rivers in Lower Canada, are chiefly composed of a schistous substance, generally in a decayed and mouldering condition. But still in every quarter, even among these other substances, the granite is found in strata, more or less inclined to the horizon, but never parallel with it. There are veins of lead ore near the bay of St Paul, north-east of Quebec, which yield a few grains of silver. A considerable quantity of iron ore is found in the neighbourhood of Trois Rivieres; and copper on the south-west of Lake Superior. No coal has yet been discovered in Canada, but it is supposed to exist in the environs of Quebec, and is known to abound in Cape Breton.

The soil of lower Canada consists of a light and soil loose blackish earth, ten or twelve inches deep, lying upon a stratum of cold clay, very fertile, but soon exhausted, unless regularly recruited by a supply of manure. The best of it is generally found on the banks of those rivers, which flow into the St Lawrence, especially the Quelle, de Sud, Chamby, and
de Loop. That of the upper province, however, is greatly superior, and the country much more level, and better adapted for cultivation. In Canada there can scarcely be said to be more than two seasons of the year, summer and winter. The snow has scarcely disappeared, when the heat of summer is experienced; and the season of vegetation is prolonged through the autumn months, till suddenly checked by the rapid return of winter. The range of the thermometer is very extensive, seldom less than 120 degrees, generally rising in summer to 95, and frequently falling in winter to 25° below zero; that is, from 60° above to 60° below the freezing point. At midsummer it has been observed occasionally as high as 96, and in winter as low as 40 degrees below zero; but the medium temperature in December and January is 22 below the freezing point. In the month of July and August, the heat is peculiarly oppressive; and in September the weather is most pleasant. In October and November, the snow begins to fall, and the frost becomes daily more severe. In December and January, winter reigns in all its majesty, and the cold is very intense; but the air, by means of the congelation of its aqueous particles, is uncommonly dry; and has not nearly so severe an effect upon the feelings as a moist atmosphere with a higher temperature. When the cold dry air enters a heated apartment, its drying power is astonishingly increased, and its effects upon the furniture are very surprising. In the course of a winter, the panels of the doors frequently shrink so much, as almost to fall out of the frame, while the frame itself shrinks to such a degree, that the bolt loses its hold. In the month of March, the sky is clear, the sun shines bright, and his heat begins to be felt. In April, the influence of his rays is very considerable; and, in the first week of May, the snow has nearly disappeared, the ice on the rivers and lakes is broken up, the ground sufficiently soft for farming operations, and vegetation remarkably vigorous. In the settled parts of Upper Canada, the climate is greatly milder, and the winter of shorter duration, frequently passing without much frost, and sometimes with scarcely any snow, Neither Lake Ontario, Lake Erie, Lake Huron, nor Lake Michigan, are subject to be frozen to any great distance from their coasts; but Lake Superior, from its more northerly situation, is usually covered with a solid body of ice for an extent of 70 miles from land.

In the region to the north-west of Lake Superior, extending to the Stony Mountains, and then northwards to the latitude of 72°, the climate and soil are completely Siberian. The ground is generally flat, bare of trees, (unless here and there a few of stunted growth,) interspersed with lakes, marshes, and an infinite number of streams, and incessantly swept by stormy icy winds from the northwest. From the latitude of 46° the earth is frozen throughout the whole course of the year; and at several trading posts, between 50° and 56°, it was found impracticable to dig wells, even in the month of July, the earth being thawed only to the depth of three feet. In what may be called cultivated Canada, however, in the upper province, and especially towards the west, the climate bears a nearer resemblance to that of Europe, in the same latitudes; and there is very little difference to be found, except such as may proceed from the vicinity of high mountains covered with snow. The longer continuance of frost and snow in Lower Canada, for nearly six months in the year, has been attributed to the immense desert regions, which stretch towards the north; and it is chiefly when the wind blows from the north-east quarter, where the mountains of ice are found, that very great quantities of snow fall in that province. The utmost depth of snow in the woods, when it is not drifted by the winds, is usually six or seven feet; and the ice on the rivers generally acquires a thickness of two feet and upwards; but, on the borders of St Lawrence, it sometimes exceeds even six feet. The climate of the lower province, however, has been observed to be rapidly ameliorating; and by a meteorological table it has been ascertained, that in the space of fifty-eight years, the medium cold of its winter has lost eight degrees of its wonted severity in the neighbourhood of Quebec. The period also, at which the river St Lawrence is shut up by the ice, is nearly a month later, than when Canada was first colonized. This has been ascribed to the clearing and cultivating of the lands, and it is not improbable, that this cause may have had some small influence; but the tracts thus improved bear so small a proportion to the whole extent of the country, and this amelioration of the climate has also been so conspicuous even in those districts, which are still in an absolute state of nature, that it seems more rational to refer it to some more extensive and predominating operation in the system of nature. (See this subject discussed more fully in Volney's View of the United States, p. 266.) It has been mentioned also, (but whether to be considered as a cause or as an effect of this improvement of the climate, it is not very easy to ascertain,) that the inland waters are decreasing, and that many lakes are draining and filling up by the earth, which is carried down by the rivers from the higher grounds.

When the French commenced their settlements in Canada, the country presented the appearance of one vast unbounded forest; and great privileges were bestowed to encourage the colonists to attempt its improvement. The lands on each side of the St Lawrence, and of the rivers, which fall into its channel, for a space of nearly 300 miles in length, extending from 90 miles below Quebec to 30 above Montreal, were granted by the French king, in extensive lots, called seigneuries, to officers in the army, to companies or associations, and to such other individuals as possessed interest to procure them, and who thus became seigneurs or lords of the territory. These tenures were entirely of a feudal nature, held immediately of the king; and, upon every transfer of the property, the new purchaser paid a fifth part of the value to the receiver-general, who gave a receipt upon the title, and by this act invested him with the possession. These seigneuries occupied from 100 to 500 square miles; and the proprietors were bound to concede them in smaller lots to the settlers, upon certain conditions. These lots were very narrow in front, seldom extending along the course of the river more than three acres; but they stretched a considerable way, generally 80 acres, into the country.
These grants, or concessions, were also of a feudal character; and the grantees were the vassals of their lords, as the lords were the vassals of the king. For these lots there is seldom superiority given by way of purchase money; and the rent paid by each tenant is very inconsiderable, frequently not more than three lives (2s. 6d.) a year, besides a bushel of wheat and a couple of fowls; but the seigneurs, who have many inhabitants on their lands, derive a handsome revenue, partly from these trifling rents, from the fees received at his mills, to which his tenants are bound to bring their grain, and from the fine which is due to him upon every transfer of the lots by sale or long lease. There are about 100 of these seigneuries in Lower Canada, all subject to French law; and the proprietors might have attained considerable influence, had the estates been allowed to remain entire; but, according to the old French law, which is still in force in the colony, the property of every individual, who dies intestate, descends in certain proportions to his widow and children; and thus both the seigneuries themselves, and estates of much smaller extent, held in rotation, have been so frequently subdivided, that many of the proprietors of the former retain little more than their title; while the greater part of the holders of the latter are so miserably poor, as to have neither capital nor spirit for agricultural undertakings. This law has been found to have a very hurtful effect, also, in a moral point of view, tending very much to weaken the natural affection, which should subsist between parents and children, as well as to introduce a general spirit of litigation into families. Since the conquest of Canada by the British arms, all those parts of the lower province, which had not been previously granted as seigneuries, have been surveyed by order of government, and divided into townships, which are about ten miles square, and are granted to individuals to be held by the English tenure of free and common socage. These are situated in the more retired parts on the south bank of the St Lawrence, between the rivers Chaudiere, St Francis, Yamasca, and Chambly, extending to the 45th parallel of latitude, and subject, like the upper province, to the law of England. The persons to whom these townships are granted, are bound to cultivate a certain number of acres within a given time. The greater part of these lands lie contiguous to the territories of the United States; and are chiefly occupied by emigrants from thence, who, before obtaining their grants, have taken the oath of allegiance to his Britannic majesty. They hold in general above 200 acres each; and are bound to keep open the high ways passing through their possessions. The first step in the process of cultivation is to build a log-hut, and open a road of communication with the nearest neighbours. They next proceed to clear the land of the wood, and this is done in various ways. One mode is, to cut down the timber, to dig out the roots, and then to burn the whole in heaps upon the ground; which, when thus laid open, is soon covered with vegetation, and capable of grazing cattle; but this method, besides being very tedious, is attended with great expense, and costs about thirty shillings per acre. The Americans have introduced a more simple and economical, and, at the same time, equally successful plan, viz. to cut down and burn the trees; and, after turning up the earth with a hoe or harrow, to sow the spaces between the standing roots. A third method is to set fire to the growing wood; to stop the growth of the larger trees, by cutting a deep circle in the bark, to sow the interstices with grain, and to remove the decayed timber at leisure. In these cases, when the underwood is thick, the blaze of the burning forest is truly awful, continues for weeks together, and often extends its progress far beyond the intended space. In clearing the ground, however, a certain portion of wood is always left standing, for supplying fuel and other domestic purposes; and these stripes of forest, while they serve as boundaries between the different lots, contribute to give even to the cultivated districts, a wild and woody appearance. The usual condition upon which farms are let, are, that the proprietor furnish the cattle, supply the utensils of husbandry, and incur the expense of clearing, ditching, and fencing: the produce is then equally divided between the tenant and himself.

With the exception of a few cases, the Canadians are very deficient in agricultural skill. In consequence of the law before mentioned, their farms are small, and their capitals limited, so that they are not at all able to attempt experiments. They are also destitute of education, and ignorant of recent improvements; much inclined to indolent habits; and, like the peasantry of most countries, strongly averse to admit any innovations. It is only of late years, and to a very small extent, that they have begun to adopt the application of manure, the rotation of crops, and the use of artificial grasses. They have begun particularly to employ the mlar, which is found in considerable quantities on the shores of the St Lawrence; but the general practice is to plough the same field, and sow the same grain, twenty times over; while the only remedy for land exhausted in this manner, is to leave them fallow for a few years. Seed-time commences about the 20th of April, and harvest early in August. The average produce of the soil in Lower Canada has been estimated at 25 to 1 for oats; 12 for barley; 6 for pease; and 11 for summer wheat. Barley, oats, Indian corn, and other ordinary kinds of grain, are produced in considerable quantities for home consumption, but seldom in such abundance as to supply exportation. It is but very lately indeed that barley has been known in Canada; and was introduced, with great difficulty, by a gentleman who had established a distillery at Quebec. That which is now produced, makes excellent malt; and considerable quantities of ale are exported to the West Indies. The soil and climate of Canada are very favourable to the growth of hops, of which enough is raised to supply the wants of the brewers, and which might easily be rendered an article of exportation. Hemp has begun to be cultivated with much success; and government has greatly encouraged the growth of that article. See on this subject, a paper by William Bond, Esq. in the 26th volume of the Transactions of the Society for the encouragement of Arts, &c.

At the time when Canada was first discovered, the inhabitants of Europe were so entirely engrossed with the acquisition of those precious metals, which had been imported from Mexico and Peru, that no
Canada.

Commerce.

Canada, in which these were not produced, was considered as deserving of any attention. It was soon understood, that no mines were to be found in that quarter of North America; and hence the colony of New France fell into complete disrepute, before a proper knowledge could be acquired of its soil and productions. This early prepossession to its disadvantage was the principal source of the future discouragements and obstacles, with which its commerce had to struggle; and it never attained any degree of prosperity, as long as it remained in the hands of the French. It sustained very great injury, also, by the frequent alterations which took place in the medium of exchange, especially by the inconveniences which resulted from the introduction of card or paper money. In 1706, the whole trade of the colony was carried on with a fund of 650,000 livres, distributed among a population of 30,000 inhabitants. During seven years of its most flourishing period, previous to its conquest by the British, its annual imports were valued only at L.160,000, sometimes at L.240,000; while its exports seldom exceeded, and frequently did not reach, the sum of L.80,000. The balance was supplied by the sums, which the French government expended in paying the troops, building ships, raising fortifications, &c.; but the bills drawn upon the treasury of France on these accounts were not long very punctually paid. For a few years after the reduction of the colony, the British traders derived considerable assistance from the quantity of furs which had been previously collected, and from the sums of money which were regularly remitted for the payment of the large military force then supported in the country; yet the commerce of Canada was still rather in a declining than increasing state; and, in 1769, the quantity of produce exported amounted only, according to Heriot, to L.163,105; but, according to Lambert, to L.345,000, and was shipped in 70 vessels belonging to Great Britain and her colonies. During almost thirty years longer, its commerce continued in a state of great fluctuation, according to the varying degree of demand in Europe for its productions; but, in the year 1795, it was very considerably augmented by the scarcity of grain, which prevailed about that time in Great Britain and most of the European countries; and not less than 123 vessels (19,953 tonnage) arrived that year in the river of St. Lawrence. At that period, also, the construction of vessels at Quebec was begun by a company of London, and very considerable profits were drawn from that branch of employment. In 1799, 1800, 1801, and 1802, an immense quantity of grain was exported; and, in the last of these years, it amounted to 100,000 bushels of wheat, 38,000 barrels of flour, and 93,000 casks of biscuit. The vessels employed in the transportation of these and other productions, were not fewer than 211, and the amount of tonnage nearly 36,000. As the crops in Canada, however, are extremely precarious, and the demand for its grain equally irregular, the surest statement of its commerce must be taken from an average of several years.

During the space of five years, ending in 1805, the average amount of exports from Canada to Great Britain and British settlements, according to Gray, was L.767,703:17:8 Sterling, and were conveyed in 193 vessels, equal to 53,996 tons. They consisted chiefly of wheat and other kinds of grain; beef, pork, and fish of various sorts; timber in the form of planks, staves, mast, oars, &c.; pot and pearl ashes; flax-seed, apples, and essence of spruce; butter and tallow, soap, beer, and castoreum; horses, cattle, and hides; stoves, manufactured at Trois Rivieres; vessels, built at Quebec; and furs and peltry, equal in value to more than one third of the whole.

The imports from Britain and British settlements, which pay duty, amounted to L.204,105:17:6, consisting principally of wines, spirits, sugar, molasses, salt, coffee, tobacco, cards; while those which pay no duty are calculated to have nearly equalled the difference between the above sum and the value of the exports, namely, L.563,600, consisting chiefly of cloths, linens, muslins, silks, furniture, tools, hardware, crockery, coals.

In consequence of the late improvements of the country, and the embargo on the American trade, the commerce of Canada has recently increased in a very astonishing degree. The unusual and growing demand for its productions, especially since the year 1808, has greatly increased the price of every article; and hence a considerable portion of the exports, such as timber, staves, pot and pearl ashes, and provisions of every description, have, in spite of the embargo-law, found their way across the boundary line of the United States into Canada, and been shipped for Europe and the West Indies with great advantage to the Canadian merchants. In 1806, the tonnage of the shipping employed in the trade of the colony amounted to 83,896; in 1807, to 42,293; in 1808, to 70,275; in 1810, to 143,893; and in 1811, to 223,762. The following tables, from Lambert, will afford a clearer view of the progressive and amazing increase of this commerce since the year 1754.

Besides the trade, which Canada maintains with Britain and her dependencies, a very considerable traffic is carried on with the American states. The legal channel of this trade is by St John's, on the river of Champlain, where there is a custom-house for its regulation; and the imports by this course, in 1806, amounted to £75,546: 11: 6, consisting principally of teas, chocolate, coffee, tobacco, spirits, butter, fish, pork, leather, shoes, and boots; nankeens, stockings, mahogany, pot-ash, hogsheads, and hops: but, by other channels, cottons, silks, cambrics, and groceries, are annually smuggled into the country, to the amount of £100,000. The exports, by this communication, are more correctly known; and amounted, during the same year, to £66,566: 8: 2, consisting chiefly of hides, salt, fish, and especially of furs.

Ever since the year 1796, the Americans have been permitted, under authority of the 3d article of Mr Jay's treaty, to import into Canada, East India goods, groceries, and several other commodities, duty free; and as, by a variety of advantages attending a neutral flag, they are able to transport East India articles into America, and thence into Canada, much cheaper than can be done by British merchants, they have gained almost exclusive possession of this branch of trade in the colony. The money sent out of Canada to the United States in payment of their goods, besides creating a greater scarcity of specie, which lowers the rate of exchange, occasions an increase of price upon every article of Canada produce, and thus enables the American to undersell the Canadian merchant in Europe, as he does the European in Canada. Besides restricting the American trader from such privileges, there are many obvious reasons for securing to the British North American colonies the exclusive right of supplying the West India islands with lumber, fish, bread, flour, &c. for which they at present depend so entirely upon the United States.

The provinces of Canada, especially if encouraged by bounties from the British government, as the Americans are by theirs, could soon be enabled to furnish the West Indies with sufficient quantities of all these articles, so as to preclude them completely from suffering any great inconvenience from American embargoes and non-intercourse acts.

The articles of Canadian traffic comprehend almost every necessary of life; but the principal productions which it supplies for commercial purposes, are grain, timber, fish, and furs.

The only grain that is exported, is wheat, which is of an excellent quality, and yields a greater proportion of flour, than that which is brought from the Baltic. That of Upper Canada is superior to what is produced in the Lower province, and is usually exported in the form of flour; as it is thus more easily conveyed by the navigation on the lakes and rivers, more secure against damage in the voyage, and more beneficial to the country by the profits and wages of labour arising from its preparation. It is even frequently converted into biscuit, which is both of a good quality, and cheaper than what is procured from Britain; and which is sent to supply the shipping at Newfoundland and Halifax. The timber of Canada is also a principal article of exportation, and can be furnished for every purpose of the dock-yard, house carpenter, and cabinet-maker. Its oak is next to that of Great Britain in point of quality; its pines can furnish masts 120 feet in length; its staves are peculiarly excellent, and daily rising in demand; its forests, in short, could easily render the mother country independent of every other foreign supply of timber. This branch of trade has greatly increased in late years. It is said, that, in 1810, not less than 600 vessels arrived in the St Lawrence for this single article, and regulations have been made by the British government, to favour the importation of Canadian timber to a still greater extent.

The fisheries of Canada have not been prosecuted to their extent of which they are capable, and have received very little encouragement from government. There is a seal and porpoise fishing on the St Lawrence, which produces a considerable quantity of skins and oil; and on the Labrador coast an establishment has been formed, which sends chiefly to the West Indies large cargoes of cod, mackerel, shad, herring, salmon, and a fish about the size of salmon, called bass.

But the fur-trade of Canada may be considered as the chief peculiarity in its commerce; and though not so valuable a branch of traffic to the colony as grain, or to the mother country as timber, is at least next to either of these in importance, yielding a duty...
of £20,000 annually; and is most of all entitled, from its nature, to a more particular description in this place. In this trade, the French settlers engaged with great eagerness, at the first establishment of the colony; and, as the Indians were not then acquainted with the value of the articles, large quantities of the richest furs were procured, in exchange for the most trifling wares. The accumulation of skins in the magazines soon became so immense, and the demand so inadequate to carry off the supply, that the merchants were unwilling to purchase more, and the abundance of the article nearly ruined the trade in Canada. The adventurers, who explored the Indian territories in quest of furs, and who were stiled Coureurs de Bois, naturally sought a market among the English settlers in the neighbouring colonies, and many of them fixed their residence in the country of New York. The attempts, which were made by the governors of New France to prevent such desertions, and to recall those fugitives, were long attended with little success. Many of them became attached to a wandering life, and took up their abode among the savages, from whom they could be distinguished only by their superior licentiousness of manners. As the conduct and example of such characters occasioned the greatest obstacles to the exertions of the Catholic missionaries, an order was at length procured, that no one should be permitted to traverse the country for the purpose of trafficking with the Indians, without a license from government. These permissions were at first granted only to persons of known respectability, to officers of the army, or to their widows. Such, however, as did not choose to make use of the licences personally, were allowed to sell them to the merchants, who again employed the Coureurs de Bois in quality of agents, and these again soon furnished occasion for renewed complaints from the missionaries. Military forts or settlements were at length established at the confluence of the rivers with the larger lakes, which served at once to protect the trade, and to check the improper conduct of the more profligate adventurers; while, on the other hand, a number of respectable men, who had retired from the army, prosecuted the trade in person, under their respective licences; and, with the assistance of the missionaries, extended their excursions as far as 53 north latitude, and 102 west longitude.

For some time after the conquest, the fur trade was in a great measure suspended, partly because the conquerors were not sufficiently acquainted with the country, and with the language of the agents; and partly, because they were exposed to great personal hazard among the Indians, whom the French had inspired with the utmost hatred against the British. But these obstacles were gradually surmounted; and a very keen competition was excited among the traders. This spirit of rivalry, however, gave rise to endless contests and innumerable irregularities; and, with the exception of a very few individuals, the agents in general conducted themselves in so imprudent and disorderly a manner, as to draw upon themselves the determined hostility of the Indians. A resolution was actually adopted by the principal tribes to free themselves from such troublesome neighbours, by a general massacre of the traders; and they were prevented from putting their plan into execution only by one of the most dreadful calamities, that could have befallen a people; by the fatal ravages of the small-pox, which raged among them with the fury of a pestilence, spread its baneful influence with the rapidity of a conflagration, swept away whole tribes at once, and rendered immense tracts of country entirely desolate.

The country being thus depopulated, and the traders also reduced in number, the merchants in Canada formed a junction of interests in the year 1784, under the denomination of the North West Company; the traders forgot their animosities, and engaged with great spirit in the service of the new establishment; but it was not till the year 1799, when the demand for furs, as an article of dress, became more general, that the speculation was productive of much profit. The number of persons who hold shares in this company amounts to more than forty; and the clerks, voyageurs, and Indians employed in their service are upwards of three thousand. The business in the north-west territory is conducted by young men in the service of the company, who are chiefly composed of adventurous young Scottish Highlanders, and who have under them a body of Canadians, hunters, and canoemen. These repair to the country of the Indians, and establish trading posts among them, frequently at so great a distance, that it requires more than one summer to send them the goods, with which they are to traffic, and to procure the furs, which they have collected. In these distant regions they remain for several years, subject to numberless privations, and subsisting in a great measure by hunting; while those who manage the concerns of the company, and who have the principal shares in the undertaking, generally reside at Montreal. To these posts more than fifty canoes are sent annually, loaded with merchandise, and navigated by nearly 1000 people. The persons, employed for this purpose, styled voyageurs, are a very peculiar set of mortals, of a most robust nature and thoughtless character, and said in these respects to bear a striking resemblance to British seamen. Though they know, that, for the space of 2000 miles, their exertions must be unremitting, and their living miserably poor, yet they pursue their tedious and toilsome occupation with the utmost cheerfulness. Sometimes they save their wages, and, returning to their native parishes, spend the remainder of their days in the labours of agriculture; but they generally acquire habits of dissipation, squander their gains as speedily as possible, and are thus compelled to set out upon a new excursion.

In this trade, the capital, which is employed in goods alone, is said to exceed £100,000. The goods are made up in packages, about 80lbs. each, for the purpose of being more easily removed and carried, when the loaded canoe is not able to pass along the stream. The canoes in which these goods are conveyed to such a distance, are exceedingly light and frail, but constructed with wonderful ingenuity. The frame is formed of thin slips of wood, covered with the bark of the birch tree, sewed together with the filaments of a particular root, and rendered water-
Canada.

Manufactures.

The manufactures of Canada, though daily increasing, are still very limited in their number and extent. Previous to its conquest by the British, and during several years after that event, the inhabitants easily provided, by their own industry, the few necessary articles, which their simple mode of living required; and every family then prepared for their own use, druggets, coarse linens, stockings, worsted caps, hats, bonnets of straw, &c. As their wants increased, they imported, chiefly from Great Britain and the United States, a great variety of articles for domestic purposes, but the greater part of those they have of late years begun to manufacture for themselves. Among their principal manufactures for the purpose of exportation may be mentioned the conversion of their wheat into flour and biscuit, which gives employment to a great number of hands; the building of ships, which is peculiarly useful in the country, as it is almost the only occupation, which can be followed, during the six months of winter; bar-iron, stoves, cooking utensils, for which there are two considerable iron forges in the province, near Three Rivers, which was established by the French king, and another near St. Anns, on the road from Quebec to Montreal, with others of less importance. Potash, of which the country could easily supply any quantity, though the inhabitants prepare little more than what is necessary for the manufacture of the soap, which they make in every family. Soap, candles, and snuff, for the manufacture of which last article Canada has long been celebrated, and the use of which is remarkably common among the females of the country, of all ranks and ages; while the men, and even boys, on the other hand, are seldom without a tobacco pipe in their mouths, from the moment that they awaken in the morning till they return to bed at night. Among the articles, which they prepare for their own consumption may be particularly mentioned, hats, of which, however, the bodies, as they are called, are still chiefly imported from England, where they can be procured at a cheaper rate, than they can be made in Canada; leather, for the preparation of which several considerable tan-works are lately established; and sugar from the maple tree, of which so much is made as nearly equals two-thirds of the whole consumption of that article in the country, and which might be prepared for trade and exportation, if the West India sugars were not so abundant and cheap in the province. In March and April, when the sap begins to rise, those, who wish to make sugar, provide themselves with the proper apparatus; make an excursion into the woods, where maple trees abound; collect the sap from incisions made in the trunk; erect their boilers on the spot, and return in a few days with sugar ready for use, which, when properly purified, is of an excellent quality. There is a large distillery established at Quebec, and several breweries in the lower province, which export considerable quantities of ale.

In addition to the principal products of agriculture, which have been already particularly noticed, in a preceding paragraph, it may here be mentioned, that various other kinds of grain and pulse are raised in Canada, especially rye and beans; the last of which are of a smaller size than the European, and are much used by the Indians, who eat them when boiled, as an accompaniment to bear's grease and lard. Gourds, and water melons, are cultivated, as field crops; and are used, as bread, by many of the native tribes. The orchards and gardens, especially in the neighbourhood of Montreal, abound in a great variety of fruits and vegetables of the finest quality. The apples are particularly good, and yield an excellent cyder. Peaches, plums, gooseberries, raspberries, and currants, are found in the greatest perfection and abundance; and, with the protection of glass, grapes may be raised for the table equal to any in Portugal. The natural and indigenous productions of the country are remarkably numerous; and many of them are of considerable value.

The forests abound with an immense variety of trees, of the different kinds of which even the names are not yet known. Of oak there are various sorts; the black, white, red, yellow, grey, according to the colour of the wood, when cut by the saw; the swamp oak, which grows only in a moist gravelly soil; has a smaller leaf and smoother bark, than the other kinds, and is so remarkably tough, as to be frequently used in place of whale bone; and the chestnut oak, the leaf of which resembles that of the chestnut, and which is neither so tough as the last mentioned, nor so strong as the other sorts, but is peculiarly suited for being split, and for enduring a long time, in palisades and fences: all the oaks in this country grow so straight, that, in ship-building, the knee-timbers are generally made of the roots of pine. Of pines, there are the white and red in great abundance, the former of which, chiefly, grows to an amazing height, and yields excellent turpentine.—The fir are perhaps the most numerous class, one of which called
the white prickly fir, yields a kind of turpentine called Canadian balsam, which holds a place in the materia medica of most countries. — The cedars are distinguished into white and red, the former of which has its fragrance in the leaf instead of the wood, but is a different tree from the white cedar of the United States, the *cypres sus* *di istich a.*— Of maples, the harder-kind, which grows on hilly grounds, yields a richer juice, but in smaller quantity, than the soft, and its wood, which is finely veined and clouded, is peculiarly valuable for making tables, gun-stocks, &c. — Of ash, the most remarkable sort is the yellow, found only in the south-west districts, and growing to an amazing height; the outer bark of which is eight inches thick, indented with furrows, six inches deep, while the inner is of a fine yellow colour, which leaves a lasting stain upon the fingers, and is supposed useful in dyeing. Besides beech, birch, elm, poplar, and other kinds of timber, resembling the European, there are the hemlock tree, an evergreen of very large growth, with leaves like the yew; but is of no use whatever; the bass, or white wood, remarkably white and soft, light as cork, and much used in making bowls, trenchers, &c.; *valliconic* or *suckivick,* a species of wood, the bark of which when pounded, and moistened with a little water, becomes a kind of oil and adhesive glue, with which the Indians cover the seams of their canoes. In addition to the *suckivick,* *chasnut,* *hazel,* *hickory,* &c. the forests of Canada produce the buttern, or *oil-wood* tree, which grows in rich meadow grounds, bears a large and well flavoured nut, capable of yielding a very pure oil.

Fruit trees.

In a natural state are found the *crab apple tree,* bearing a fruit of better size and flavour than that of Europe; the *plum tree,* green, and purple, both greatly relished by the natives; the *cherry tree,* black, red, and sandy-coloured, but the first, only, bears a fruit pleasant to the taste; the *mulberry,* red and white, resembling those of France and Italy; *sweet gum-tree,* yielding a kind of balsam, which the Indians highly value as a salve and febrifuge; *vines,* which are very common, and some of which bear excellent grapes; besides *gooseberries,* *currants,* *raspberries,* *strawberries,* *Juniperberries,* *cranberries,* *bearberries,* &c. in the utmost abundance.

Among the more remarkable shrubs, may be noticed *sassafras* (found only in Upper Canada), which yields indeed to the size of an apple-tree, and the berry of which is sometimes used as a spice; a kind of *willow,* the roots of which are of a fine scarlet colour, and are used by the Indians to tile the ornamental parts of their dress; *moose wood,* the bark of which makes nearly as good cordage as hemp; and the *willow* tree, the nut of which yields an excellent wax of a green colour.

The most valuable roots are, *spikenard,* *sarsaparilla,* and particularly *ginseng,* which last was first discovered in the woods of Canada in the year 1718, and, being exported to Canton, was pronounced to be equal in quality to any that could be procured in Corea or Tartary. Its price immediately rose in Quebec from £1. 6d. per lb. to L1. 0:10 sterling; and the value of its export amounted, in 1752, to £20,000. But the Canadian traders, too anxious to enrich themselves on a sudden, began to reap the plant too early, and to dry it hastily in ovens, instead of gradually evaporating its moisture in the shade; by which means they destroyed its quality, and completely ruined its sale among the Chinese, by whom chiefly it is used as a stomachic.

Besides the flowers usually found in the more flowers northern countries of Europe, the woods of Canada are universally adorned by the fragrant blossoms of the *Syrian *axilepis*; and, amid a variety of curious and useful herbs, we can only notice the *rattle snake plainain,* the leaves of which are considered as the most effectual cure for the bite of the reptile from which it takes its name, and which is said to be most luxuriant in its growth during those months of the year, when the bite of that creature is most venomous. Canada abounds in natural grass; and cattle fatten easily upon the wild growth during summer. A particular species, very long and rank, called *Herbe au lien,* grows upon some of the islands, and forms a most durable covering for stable barns, &c. There is also a graminaceous vegetable, nearly allied to the rice, *zizania aquatica,* which grows abundantly in all the shallow streams, is found in situations that refuse all other culture, is a principal support of the wandering Indians, and is entitled to particular attention from the European settlers, as a plant evidently intended by nature to be the general bread-corn of North America.

Domestic animals.

Among the domestic animals of Canada, which are much the same as those of Europe, there are scarce-ly any peculiarities worthy to be mentioned. The Canadian horse is a hardly, active animal. His best pace is a trot; and, in a light cariole, upon smooth, hard roads, a single horse has been known to draw two persons ninety miles in twelve hours. It is af-

Canada. 341

mitted, that he will eat dried fish in the winter sea-

son; but he is most of all remarkable for the extra-

ordinary operation, which he frequently undergoes,

when travelling on the frozen lakes and rivers. In

these excursions, it is not uncommon for the sledge

and horses to sink suddenly in the weaker parts of

the ice, when the traveller springs from his seat up

on the ice, which is generally strong enough to sup-

port his weight, and instantly proceeds to save his

cattle. As their struggles in the water would only

tend to sink them the sooner, he pulls with all his

strength a rope, with a running noose, which is pre-

iously fixed around the neck of each, in case of such

accidents, till he succeeds in strangling the animals.

As soon as this happens, they float upon one side,

and are easily drawn out upon the ice. It is some-

times necessary to draw blood from them before they

recover; but, in general, whenever the noose is loo-

sened, respiration recommences in a few minutes, the

creatures start to their feet, proceed with their usual

vigour, and perhaps go through the same process

two or three times in one day. This singular fact is

solemnly avouched to be strictly true, both by Chat-

elaux, vol. i. p. 408, and Gray, p. 277. The native
dogs of Canada are all of the same species, with

erect ears, and a head very much resembling that of

an wolf. They are very useful to the Indians in the

chace; and the colonists frequently employ them in
the draught. They are yoked to sledges in winter, proportioned to their size and strength; and in this way one of an ordinary size will frequently draw more than 200 lbs. weight, with his driver, in addition, standing behind the sledge. They are thus employed in a variety of domestic services, in dragging children in small carriages, in bringing water from the river, and particularly by the butchers in transporting meat to their customers in different parts of the towns.

Wild animals. Among the wild animals which frequent the immense forests of this country, the principal beasts of prey are, a small lyger or panther, though it is supposed by some to be altogether a different species of animal; bears, wolves, foxes, dogs, cats of the mountain, pole-cat, caracou, lynx, racoon; but they are all inferior to those in the other quarters of the globe, both in size and ferocity; and are scarcely daring enough to attack a man, unless when they are wounded. The grizzled bear is the only dangerous animal. Those which are chiefly pursued for the sake of their peltry and fur, are, the buffallo, elk, moose deer, or rein-deer, corrubus, bear, fox, wolf, cat, beaver, otter, marten, minks, woodcreeon, racoon, ermin, fisher, squirrel, hare, rabbit, musk-cat; of which the beaver, otter, bear, fire-marten, cat, elk, and wolf, are by far the most valuable. But, for an account of these animals, our readers are referred to Pennant's Arctic Zoology, and to the articles Mammalia, &c.

Birds. Of the feathered tribe, may be mentioned, the eagle, vulture, and owl; the night-hawk, which is seen chiefly at twilight and before thunderstorms; the fish-hawks, which skims along the rivers and lakes, and is supposed to attract the fish to the surface by a peculiar oil which it emits, and one drop of which up on any bait is said to render it irresistible to every kind of fish; cranes, with bills 12 inches in length; geese, particularly the outarde or Canada goose; wild ducks, of more than twenty different kinds, of which the principal is the wood-duck, which perches upon trees, has a brilliant plumage, and flesh of superior flavour; partridges, brown, red, and black, which are all larger than the European, and which, in winter, perch upon such trees as yield them food; the white or snow bird, a kind of ortolan, which is the principal bird of melody in Canada, and announces the return of spring; teal of excellent quality; wood-pigeons in immense numbers; wood-peckers, humming-birds, black-birds, thrushes, larks, gold-finchies, &c. resembling those of other countries.

Fishes. In the numberles bakes and rivers of Canada are various kinds of fish, especially salmon, chub, and carp, like those of England; eut-fish, the flesh of which is fat and luscious like that of the eel; black bass, pickerells, and maskinonges, particularly the sturgeon, of large size and delicate flavour.

Insects. Among the insects common in this country, may be mentioned, bees, which prepare their honey under ground; silk worms, which produce much less silk than those of Europe; fire-fly, or lightning-bug, which has a very effulgent appearance at night, and two or three of which upon the hand will yield a light equal to that of a candle; horned bugs, or stag-beetle, which fly about in the evening, and whose bite is very troublesome; musquitoes, which abound in the forests and river-banks in the more southern districts; locusts, which are said to visit the more central regions every six or seven years; and in many of the islands in the St Lawrence, myriads of ticks, larger than those of Europe, which spread themselves in summer over the surface of the ground, completely cover the herbage and plants, frequently prove fatal to the cattle which graze in these places, and are exceedingly troublesome to human beings, especially if they reach the head, where, without occasioning much pain, they gradually insinuate themselves beneath the skin, and are not easily dislodged.

Canada, before its discovery by Europeans, was inhabited by an immense variety of Indian tribes, whose general character and manners have been already described in this work, under the article America; but whose particular designations, history, and territories, it is impossible to delineate. The smaller tribes, if we may judge from the number of names, amount to several hundreds; but, as they are perpetually changing their place of residence—as many of them have been exterminated by war or disease—as each of them almost is mentioned by different writers under separate appellations—as the French traders were accustomed to distinguish them by various nicknames, partly with the view of preventing them from being known to other adventurers, and partly for the purpose of concealing their subject of conversation, when they spoke of the natives in their own presence—it has thus become altogether impracticable to trace their progress, or to arrange their nations with any degree of certainty. The following sketch, however, formed from a careful comparison of different authors, may be sufficient to point out the principal Indian nations, by which the immense regions of Canada are still occupied, or at least occasionally visited; and may also help to guide the reader amidst the perplexities, which he will experience in the perusal of North American histories and travels, from the confusion of Indian names.

The Hurons, whose proper name is said to be the Tsonmontestex, who are called also Aïronducks, and who seem to be the same people with the Uttawas, dwelt originally on the east confines of Lake Huron, but were driven from their country by the Iroquois. They fled towards that quarter, where the French afterwards built Quebec; and were the first, who formed an alliance with the new settlers. They are more prudent, sober, artful, and able than most of the other natives; speak the same language and have much the same appearance and manners as their inveterate enemies the Iroquois, by whose ravages they have been almost completely exterminated.

The Iroquois, a name given by the French to the Iroquois, what are generally called the five nations, composed of—the Mohawks, or Maquis, or Agniers,—the Senekas, or Tsmonnthuans,—the Onondagues, or Ornonagues—the Oneidoes, or Onnelyouths,—the
Cayugas, or Goyogans.—These, however, are now properly the six nations, as they were joined by the Tuscororas, from the south, who dwell with the Oneidas and Onondagoes. These nations, united in long and firm alliance, claim all the country south of the river St Lawrence to the Ohio, near to the borders of Virginia; and extend 300 miles west from Lake Champlain, round Lakes Ontario and Erie. They are superior to the other tribes in stature and courage; but inferior to many of them in swiftness of foot and skill in war. They are more civilized and ingenious, than most of the other Canadian Indians, and more addicted to agricultural occupations, than to the chase. They have in general been friendly to the English; and much depends upon the continuance of their attachment.

The Algonquins, or Algonkins, appear to have originally possessed the whole tract of country along the north shore of the St Lawrence, from Tadoussac to lake Nipissing, and had no rivals in North America, as warriors and hunters; but having afforded refuge and assistance to the Hurons, a deadly war arose between them and the conquering Iroquois, who at length succeeded in driving them from their country. They seem then to have taken a westerly progress, and may be said to have peopled the country from the Atlantic, in a direct line along the St. Lawrence, and the Utawas, along the high lands which divide the waters that fall into lake Superior, from those that fall into Hudson's Bay, or to lake Winnipeg, along the Saskatchewan and Elk rivers to the lake of the Hills. The great proportion of the Indian tribes which are scattered over the cultivated parts of Canada, are of this nation; and the others, especially those in the neighbourhood of the lakes and the St Lawrence, are chiefly branches of the Iroquois, and the wretched remains of the Hurons. But the main body of the Algonkin nation is found far to the north west, and they are considered as the same people with those called Knisteneaux, Christianeaux, or Killistines. They reduced the natives as they passed along, with most of whom they are now in alliance; but they are daily losing their superiority by their fondness for spiritous liquors, which are rapidly diminishing their strength and numbers. They are of a middle stature, well-formed, swift footed, and chiefly employed in hunting. They are just in their dealings, and affable in their address. They possess an open and agreeable countenance, and a generous and hospitable disposition.

The Chepewyans or Chipawas, called also Sarcees, and rocky mountain Indians, are a numerous people, who consider as their territories all the land between 60° and 65° north latitude, and 100° and 110° longitude. Their progress is easterly; and, according to their own tradition, they came originally from Siberia; which is partly confirmed by the strong resemblance, which they are said to bear to the people now found on the nearest coast of Asia. Their country is very barren, and they are frequently obliged to subsist upon a kind of rock moss, which is the principal vegetable substance that their soil produces. They are submissive to the Knisteneaux, but hostile to the Esquimaux, to whom they give no quarter, and never indeed make prisoners in any of their wars. They are sober, timorous, vagrant, selfish, considerate, querulous, and superstitious in the extreme; more attentive to the comfort than to the appearance of their dress; not active hunters, but dexterous in snaring deer and spearing fish; uniform in their temper; not at all addicted to spiritous liquors, and by far the most peaceful of the North American Indians.

The Nadowessies, or Nadowasis, called by the French the Sioux, inhabit the western side of the Mississippi, and the lower part of the Missouri, are a powerful nation, and consist of a number of bands, who carry their excursions a great way to the north, and are the constant enemies of the Knisteneaux, or Algonquins, in those regions. The Assiniboins, or Assinipois, or Stone Indians, are of the Nadowasis nation; but they separated from the other tribes, and formed an alliance with the Knisteneaux.

The principal languages spoken among the various tribes of North American Indians are the Chepewyan, which is copious, but difficult to be attained; and which furnishes dialects to the various tribes from Churchill fort up the Mississippi; through Buffalo Lake to the Lake of the Hills; along the Peace river to the source of the Columbia, and thence due west to the sea coast.—The Nadowasis, which is a kind of hissing rather than articulate speech, and is chiefly used on the western banks of the Mississippi,—the Mohawk, Iroquois, or Huron, which is said to excel in energy and pathos, and in these respects to bear a comparison with the Greek. But the most celebrated and prevailing of all the native languages, is what Long calls the Chipewain, Carver the Chipeway or Algonquin, and M'Kenzie the Algonquin or Knisteneaux; but which, as their several vocabularies shew, are only different names for one and the same tongue. This is said to surpass all the rest in smoothness, elegance, and copiousness; is spoken by all the other tribes in their councils, negotiations, and trading interviews, though they use a distinct dialect of their own in ordinary cases, and extends from the Gulf of St Lawrence over a space of 3000 miles.

These different Indian nations are divided into an immense number of tribes and bands, which are all distinguished by particular marks on their bodies, by their mode of pitching their tents, &c.; but they are scattered over a great extent of territory, and are daily decreasing in their numbers. About the year 1780, the small-pox was introduced among them by a war party, as has been conjectured, from the Mississippi. This malignant disorder destroyed, with its pestilential breath, whole families and tribes; and the horrid scene presented to those, who had the melancholy and afflicting opportunity of beholding it, a combination of the dead and the dying; and such, as to avoid the horrid fate of their friends around them, prepared to disappoint the plague of its prey by terminating their own existence.1—" It was not uncommon for the father of a family, whom the infection had not reached, to call them around him; to represent the cruel sufferings and horrid fate of their relations, from the influence of some evil spirit, who was preparing to extirpate their race; and to
The more immediate and stationary population of Canada, when it came into the possession of the British in 1760, amounted, by General Murray's report, to 75,600 souls; but, at that period, the extensive country, now denominated Upper Canada, was not inhabited by any Europeans. At present, the lower province contains about 200,000 inhabitants; of whom the descendants of the old Canadians, who profess the Roman Catholic religion, and are allowed the use of the old French laws, constitute at least nine tenths. In Upper Canada the population amounts to nearly 100,000, who are chiefly British or Americans, speak the English language, and are governed entirely by the laws of England, both in civil and criminal cases. Thus the inhabitants of Lower Canada have nearly tripled within the last 50 years; while in the upper province, the increase has been still more rapid. Several years elapsed, after the conquest, before the latter was settled and cultivated; and so late as the year 1780, it was almost one continued forest. Much of its immense population, within 30 years, has been formed by emigrants from Great Britain and the United States, who generally preferred a settlement in the upper province, because the soil and climate are superior, the lands cheaper and easier procured, while the laws, languages, and habits, are all purely British.

Any peculiarities in the modes of life among the inhabitants of Canada are most observable during the season of winter, which in that country presents a view of nature perfectly new to the natives of Great Britain. In this season the appearance and dress of the Canadians are completely changed; and instead of the hat and red bonnet, nothing is to be seen but fur caps, fur cloaks, fur gloves, and worsted stockings, both over and under the boots. Unless protected in this manner, they could not venture, with impunity, into the severity of the frosty atmosphere; but, even under such a load of clothing, they are able to walk with the greatest agility, and to take abundant exercise, without being fatigued. When travelling in the cold of winter, they are still more completely covered with a double cloak, muff, and tippet, all of fur; and when they intend to deviate from the ordinary tract, and go into the woods, they make use of snow shoes, which are made of a kind of net-work, fixed upon a frame, above 2 feet in length, 18 inches broad, and shaped like a paper kite. This simple instrument of walking takes in so much surface of snow, that the feet sink but a few inches, and the progress is rendered inconceivably easy. On account of the depth of the snow, it would be impossible to travel with wheel carriages; and a kind of sledge, which passes over the surface without sinking deep, and which is called a cariole, is substituted in their place. The body of this conveyance is shaped like a phaeton, a vis-a-vis, a family coach, or a market cart, according to the fancy of the owner, and the particular use to which it is applied. It is fixed upon runners as they are called, which resemble in form the iron of skis, rising up in front after a similar manner; and it is generally 9 or 12, though sometimes 15 inches above the snow. These vehicles are, for the most part, light open carriages, drawn by one horse; but, though the snow under their tracts soon becomes firm and smooth, yet from the improper construction, of the carioles in common use, it is so full of inequalities, called cachots, that their motion is described by travellers as greatly resembling the rowing of a boat against a head sea, and as requiring long custom to reconcile a stranger to bear it easily. The small rivers, ditches, and fences, are so filled with snow, as to be upon a level with the fields on every side; and the country people, when they first form their tracts, direct their carioles by the nearest course, or where the snow is most level, without regarding the summer
roads. These winter tracts they mark out by fixing in the snow small fir trees at short and regular distances, which retaining their verdure till the spring, appear like walks crossing the country in various directions, and have a very curious and striking effect. They generally prefer the bed of a river for this purpose, as there is commonly less snow, and less inequality of surface in that direction; and the principal road between Quebec and Montreal is the frozen channel of the St Lawrence. The river is seldom frozen opposite Quebec, where the current, being greatly increased by the narrowing of the channel, keeps the masses of floating ice in constant motion; but sometimes, perhaps once in the space of every ten years, when there happens to be a concurrence of favourable circumstances, such as a collection of floating ice, calm weather, near tides, and severe frost, the St Lawrence is completely frozen at the place above mentioned; and, as the ice then serves the purpose of a bridge to the inhabitants, it is called by them a pont. Such a circumstance is viewed as a kind of jubilee, and is celebrated with every token of rejoicing. The solid surface of the river is then covered with booths for the entertainment and amusement of the vast multitudes, who crowd upon the ice, on their skates and carioles. But the inhabitants of the Canadian metropolis have much more solid grounds, than merely a love of amusement, for the joyful welcome, which they give to the formation of a pont, as it greatly facilitates the conveyance of wood, provisions, &c. to the town; and as these necessary articles never fail, upon the occurrence of such an event, to be brought in great abundance, and to be very much reduced in price. When the river is not frozen, these and other necessaries are chiefly conveyed in canoes, which are formed of one solid piece of wood, generally the trunk of a large tree, hollowed properly in the inside, and formed outwardly into the shape of a boat. The navigation of these vessels, however, at that season of the year, is exceedingly hazardous, and requires a dexterity of management and coolness of mind, which are very remarkably displayed by the Canadians. For the time of their excursion, they choose the period of high water, when the masses of ice are nearly stationary; provide themselves with ropes, boat hooks, and paddles; and launch the canoe into the water, when they perceive an opening amidst the moving sheets. When they encounter one of these in their progress, they instantly jump out upon it, pull the canoe after them, push it across the ice, launch it on the other side, and paddle along till they meet with a similar obstruction, which they surmount in the same manner, and so on till they cross the river.

The severity of winter in this country is attended with various advantages, especially to the inhabitants of the towns. As the lakes and rivers are then frozen, the conveyance of many articles is thus greatly facilitated; and as the people in the country have no other occupation, to which they can apply, they employ themselves in carrying to town all kinds of provisions. The markets are thus supplied from a great extent of country; fish, for instance, is brought from the United States from a distance of 420 miles; and every article of subsistence is both more plentiful and also much cheaper than during summer. By the aid of winter, also, all kinds of animal food are preserved for the use of the colony, without much trouble or expense. As soon as the frost has become sufficiently intense, the cattle, sheep, poultry, &c. before they have lost any of the flesh and fat, which they have acquired by summer feeding, are killed, and exposed for a short time to the frost; upon which they become as hard as ice, and, after being packed in casks with snow, will continue, without any other preparation, perfectly sound and good for the space of four or five months. When meat, in this state, is about to be used, it is thawed in cold water; and would be rendered putrid in an instant, by any warm application. In this way, considerable quantities of fresh fish, especially of what the Canadians call petite morue, and the English tommy cod, are preserved for the market. They are caught by the country people, during the stagnation of their usual work, by nets or lines, let down through openings made in the ice. Sometimes huts of boards, or even of ice, are constructed over these openings, with a stove within to keep the fishers warm; a strong light is then placed near the mouth of the opening, by which the fish are attracted to the surface, and are taken as fast as they can be pulled out of the water. They are quickly frozen by a few minutes exposure to the air; are thus sufficiently preserved without any salting or drying; and, upon being thawed in cold water, are found to be thoroughly fresh and wholesome. Fuel, however, is both a scarce and expensive article in Canada, and counterbalances the abundance and cheapness of provisions in the winter season. Firewood is generally provided during summer, and is brought to Quebec and Montreal in immense rafts upon the river St Lawrence; in winter, it is frequently carried on sledges. Its proportion as the grounds are cleared, the distance of carriage is increased, and the price, of consequence, augmented. No coal has yet been discovered in the country, though it is supposed to exist in the neighbourhood of Quebec; but it abounds in Cape Breton, from which it would be easy for Canada to be supplied. Indeed there is plenty of English coal in Quebec, even a cheaper rate than in London, which is frequently brought out as ballast in British vessels; but it is in no great demand in Canada, because the natives dislike its smell, and prefer wood for their stoves, as long as it can possibly be procured.

During the severity of a Canadian winter, especially when a sharp wind prevails, instances frequently occur of those parts of the body which are most exposed to the air, being frost-bitten; when a mortification immediately ensues, unless a remedy be instantly applied, by rubbing the affected place with snow. The hazard arises chiefly from this circumstance, that the feelings of the sufferer do not acquaint him with his own calamity; and that the effect is known only by the appearance of the injured spot, which acquires a white colour, while the surrounding parts continue red. In the event of such a spot being perceived, humanity dispenses with ceremony; and no one hesitates to apply a handful of snow to the cheek or nose of a perfect stranger, whom the frost has attacked. 'Sentinels, and persons

Vol. V. Part I.
who travel during night, are most apt to suffer serious injuries from this occurrence.

To guard against the intensity of the wintry atmosphere, the Canadians keep their houses extremely warm by means of stoves, generally at the heat of 73 degrees; and when they go out of doors, they thus not only carry out much warmth along with them, but so cover themselves with clothing, as to restrain the escape of the heat, and prevent the influence of the cold from being soon felt.

In order to preserve the stones of the houses from the accumulation of moisture in their fissures, and from the injurious effects which would be produced by the expansion of the watery particles in time of frost, the walls are well plastered on the outside; and that the plaster may better withstand the severity of the weather, two pounds of Muscovada sugar are frequently mixed with each bushel of lime, which renders the casting much more durable.

When the snow begins to disappear, and the lakes and rivers to break up, the ice, which is floated down the St Lawrence, is carried up and down by the tide, till it accumulates in immense quantities, and frequently chokes up the channel from bank to bank for the space of twelve or fifteen miles. Many of the individual masses, which compose this collected heap, are 400 or 500 yards in diameter; and these, dashing against each other by the tide or stream, breaking up into a multitude of smaller pieces, shelving up in a thousand forms and directions, present a spectacle of extraordinary sublimity, and of perpetual variety.

A great proportion of the people, especially those in towns, are destitute of employment during the six months of winter; but their wages during summer are seldom less than four, five, or even six shillings a day. Hence they dress as well and live as comfortably, as the lower classes in any other country; but their long idleness during the winter season seems to generate an indolent habit; and they do not perform so much work, even when they are employed, as those who are regularly engaged in labour throughout the whole year. In the country they sometimes employ themselves in cutting and carrying home firewood, or in any kind of work, that may help to keep them warm, and occasionally in making a journey to the nearest towns for the purpose of selling their surplus provisions, or of purchasing some little comforts to themselves, such as snuff, tobacco, spirits, &c. In towns, the whole six months of winter may be said to be devoted to amusements, of which the most prevalent is dancing; and besides the regular assemblies for this purpose, they have occasional country parties, which may be considered as a kind of picnic feasts.

The company ride out in the forenoon in their carriages, to some proper place, at a little distance from town, every one carrying a dish ready dressed; and after having dined, danced, and supped, they return home at midnight amidst the wind and snow; or, should the storm be unusually boisterous, contentedly remain where they are, and continue the dance till day-light appears, to guide them through the drifting blast.

The descendants of the ancient Canadian colonists retain all the politeness, sprightliness, and easy manners of the old French, from whom they are sprung.

They are healthy and robust in early life, and, when urged by necessity, capable of enduring patiently the greatest fatigues; but they soon lose their strength, and begin to have an aged appearance. Every man in the country is his own tradesman, sufficiently intelligent in his own affairs, and not liable to be easily overreached. They are naturally lively and thoughtless; and hence perhaps rather chargeable with inconstancy and ingratitude. The landlords are described, as honest, hospitable, religious, inoffensive, modest and civil; but extremely indolent, and strongly attached to ancient prejudices.

Contentment of mind and mildness of disposition are said to constitute the leading features of their character. The country people still retain much of their ancient simplicity, in point of domestic accommodation, and mode of living. The furniture of their habitations is generally of their own workmanship, and of consequence is seldom very ornamental. Their principal article of food consists of pease soup, with a small quantity of pork boiled in it, and a dish of thick sour milk. They sometimes indulge themselves with a little tea or coffee; but, in these cases, the frying pan is generally made to perform the office of a tea-kettle. The women and children seldom use any other drink, than milk and water, but the men are all passionately fond of rum; and few of them, when they go to market with their commodities, return home perfectly sober. Their address to strangers is more polite and unembarrassed, than that of any peasantry in the world. "It adds greatly," says a recent and intelligent writer on this country, "to the comfort of travelling in Canada, that you are every where treated with the greatest politeness and attention." — "A Canadian landlord, the moment you stop, receives you at the door with a degree of politeness and urbanity, which is as unexpected, as it is pleasing; Vousz vous bien, Monsieur, avoir la complaisance d'entrer; voila une chaise, Monsieur, asseyez vous s'il vous plaît. If they have got any thing you want, it is given at once with a good grace. If they have not, they tell you so in such a tone and manner, as to show that they are sorry for it. Je n'en ai point, Monsieur; j'en suis mortifiée." — "Indeed you need never be at a loss for a house to stop at. There is not a farmer, shopkeeper, nay, nor even seigneur, or country gentleman, who, on being civilly applied to for accommodation, will not give you the best bed in the house, and every accommodation in his power." — Grey's Letters from Canada, p. 126.

The following character of the French settlers contrasted with that of the British or American, and from a pen, which must be considered as sufficiently impartial, may prove interesting and even instructive to our readers. That the description may have its full effect, we shall adhere very closely to the words of its ingenious and lively author. "The American settler, of English or German descent, naturally cold and phlegmatic, sedately forms a plan of managing a farm. He turns his mind, not ardently, but without ceasing, to every thing conducive to its formation or improvement. If, as some travellers have
laid to his charge, he becomes idle, it is not till he
has obtained the object of his pursuit, what he con-
siders as a competency. The Frenchman, on the
contrary, with his troublesome and restless activity,
is led by enthusiasm, or some sudden fit, to under-
take a project, of which he has calculated neither
the expense nor the difficulties. More ingenious,
perhaps, he rallies the slowness of his German or
English rival, which he compares to that of an ox;
but the German or the Englishman will answer with
his cool good sense, that the patience of the ox is
better adapted to the plough, than the fire of the
mettlesome racer. And in fact: it often happens,
that the Frenchman, after having undone, corrected,
and altered what he had begun, and harassed his
mind with desires and fears, is at length disgusted,
and relinquishes the whole. The American settler,
slow and silent, does not rise very early; but when
he has once risen, he spends the whole of the day in an
uninterrupted series of useful labours. At breakfast,
he coldly gives orders to his wife, who receives them
with calmness and timidity, and obeys them without
contradiction. If the weather be fair, he goes out,
ploughs, falls trees, makes fences, or the like: if it be
wet, he takes an inventory of the contents of his
house, barn, and stables; repairs the doors, windows,
or locks; drives nails, makes chairs or tables; and is
constantly employed in rendering his habitation se-
cure, convenient, and neat. With these dispositions,
sufficient to himself, he will sell his farm if an op-
portunity offer, and retire into the woods, thirty or
forty miles to form a new settlement. There he will
spend years in felling trees, making for himself first
a hut, then a stable, then a barn; clearing the ground
and sowing it, &c. His wife, patient and serious as
himself, will second his endeavours on her part, and
they will remain sometimes six months without see-
ing the face of a stranger. But, at the expiration of
four or five years, they will have acquired an estate,
that ensures a subsistence to their family. The
French settler, on the contrary, rises early in the
morning, if it be only to talk of it. He consults
his wife on what he shall do, and listens to her ad-
vice. It would be a miracle if they were always of
the same opinion; the wife argues, opposes, dis-
putes; the husband insists upon or yields the point,
is irritated, or disheartened. Sometimes his house is
irksome to him, and he takes his gun, goes a shoot-
ing or a journey, or to chat with his neighbours.
At other times, he stays at home, and spends
the time in talking with good humour, or in quarelling
and scolding.1—" This alone is one of the most dis-
guishing and characteristic features of the two na-
tions; accordingly, the more I reflected on the sub-
ject, the more I am persuaded that the domestic si-
lence of the Americans is one of the most radical
causes of their industry, activity, and success in agri-
culture, commerce, and the arts; and the same ap-
pplies to the English, Dutch, and other people of the
north, from whom they are descended. In silence
they concentrate their ideas, and have leisure to com-
bine them, and make accurate calculations of their
expenses and returns. They acquire more clearness
in their thoughts, and consequently in their expres-
sions. Hence there is more decision in their conduct,
Canada.

The provinces of Upper and Lower Canada were erected by his Majesty into a bishop's see, in the year 1798; but the clergy of the established church in both provinces amount only to eleven or twelve, including the lord bishop of Quebec. Within these few years, a Metropolitan church has been erected at Quebec, which is an extremely neat and commodious building, and in which there is a very fine organ. There is also a minister of the church of Scotland, both at Quebec and Montreal, who have chapels appropriated to their use, with very respectable congregations. But the great majority of the inhabitants of Lower Canada profess the Roman Catholic religion, the free exercise of which was secured to them by the act of the British parliament of the 14th year of his present Majesty, c. 83; subject, however, "to the King's supremacy, declared and established by an act made in the first year of the reign of Queen Elizabeth." By the same act of the 14th of the King, the clergy of the said church may "hold, receive, and enjoy, their accustomed dues and rights, with respect to such persons only as shall profess the said religion."

By the above act, the Roman Catholic clergy in Lower Canada have obtained rights and privileges far superior to those of the same religion in any other part of the British dominions. It is nevertheless to be observed, that these advantages are held subject to the King's supremacy, which, consequently, gives to the crown the right of presentation to Roman Catholic church livings in Lower Canada, where there is no other legal authority to make such presentations. This very important right has hitherto, through connivance, been suffered to be exercised by the Roman Catholic bishop, who is always nominated by the governor or person administering the government of the province for the time being, as the representative of his Majesty. But, for want of proper authority from the crown, the parochial clergy of Lower Canada labour under very serious difficulties; and, from some suits which have of late years been brought into the provincial courts, but which have not been carried to a final issue, there is great reason to doubt whether, by legal process, they can enforce payment of tithes from their parishes, should the latter be inclined to dispute the point. We have only to remark farther, on this subject, that the Roman Catholic clergy of this colony are more distinguished by their devout, inoffensive, and humane dispositions, than by their learning or talents; and that they are regular and rigid in the observance of their religious ceremonies; but have much less bigotry and party-spirit, than the ecclesiastics of the same church in any other country. They live on the most friendly terms with their Protestant neighbours; attend each other's baptisms, marriages, and burials, without scruple; and have even been known to make use alternately of the same place of worship. They certainly afford a proof, as adduced by Mr Burke, that the full and complete toleration of Catholics is not necessarily followed by revolt and independence on their part; since, when all our Protestant colonies revolted and joined themselves to France, "Popish Canada was the only place which preserved its fidelity; the only place in which France got no footing." The great mass of the people are affirmed, by recent travellers and residents in the colony, to be still quiet and inoffensive, and as ready to obey any order of government as the people of Great Britain. Various measures have been proposed with a view to encourage and confirm them in their allegiance; upon the probable efficacy of which it is not our province to pronounce an opinion, and which could not with propriety be discussed in the present work; but we have been desirous, in devoting so considerable a space to the subject, to contribute our aid to attract a greater degree of the public attention to so valuable, interesting, and extensive a portion of the British dominions; and we submit the present sketch to our readers with greater confidence, as it has been honoured with a revisal, and many important additions, from gentlemen of character and ability who have resided in the colony, and who are thoroughly acquainted with the subject. See Modern Univ. Hist. vol. xxix. & xli.; McKenzie's Voyages in North America; Carver's Travels in North America; Long's Travels in North America; Heriot's Travels through the Canadas; Grey's Letters from Canada; Weld's Travels in America; Boulton's Sketch of Upper Canada; Lambert's Travels in Canada; and particularly Sir James Marriott's Plan of a Code of Laws for the Province of Quebec, printed in the year 1774, and now to be had of Mr Bickerstaff, bookseller, London.* (q)

* The writer of this article has been indebted to William Ellis, Esq. M. P. for much valuable and original information respecting Canada.

Canal.

Canal. See Inland Navigation.

Cananore, Canura, or Colanada, a town and principality of Hindostan, lies at the bottom of a small bay on the coast of Malabar. It was very early possessed by the Portuguese, who, about the year 1505, obtained leave of the king of the country to build a fort, which they secured with a strong garrison. Having thus become a point of communication with Europe, and being well supplied by the adjoining country, with abundance of rice, pepper, sugar, cardamoms, ginger, tamarinds, and other valuable commodities, it soon rose to be a populous and commercial city; and, about the middle of the 18th century, when it was under the power of the Dutch, who had established a considerable factory at this place, nearly 200 vessels arrived annually in its harbour. In 1770, Cananore was sold by the Dutch to the ancestors of the present reigning family, for
Canaree, 160,000 rupees. It was afterwards seized by Tip- 
poor Salib; but is now subject to the British, who, 
under General Abercrombie, took possession of the 
fort on the 17th of December 1790. The Bipy, or 
lady of Canaree, however, who at present manages 
the affairs of the royal family, during the minority 
of her son, is still allowed to retain the nominal sove-
reignty of the district. She pays an annual land-tax 
of 14,000 rupees to the Company, and is allowed to 
collect all the revenues, except the customs. Her 
territories on the continent are very small, extending 
no where above two miles from the town. The sur-
face is, in general, high and uneven; but it is all 
capable of cultivation, though a small part of it only 
is fitted for rice ground. She possesses also most of 
the Lacadive islands, which, however, are so 
wretchedly poor, that the tribute which she derives 
from them is altogether trifling. Her principal 
resources arise from trade, which she carries on to a 
considerable extent in vessels of her own, armed with 
Arabia, Bengal, and Sumatra; and "her commercial af-
airs are so well managed," says Dr. Buchanan, "that 
she will soon, it is said, recover the losses she is 
allotted to have suffered from the rapacity of some 
British officers, during the wars of Malabar." The 
town of Canaree stretches about half a mile along 
the shore, and is defended by a strong fortress, which 
was formerly considered impregnable, and several 
_ditched forts situated on every side. It is very nar-
row, except near the centre, where it runs a little 
way up into the land, and is terminated by a battery, 
called Spice Fort. It contains several very good hou-
ses, which are possessed by Mahometan merchants; 
but its eastern extremity is chiefly inhabited by fish-
ermen, and consists only of a group of miserable 
huts. The fortress stands a little south-west of the 
town, upon a promontory, which projects about a quar-
ter of a mile into the sea. It has the complete 
command of the bay; and, since the province was ceded 
to the Company, has been considerably strengthened 
with works after the European fashion. The sea 
surrounds it on all sides, except on the north-west, 
where it is separated from the land by a deep ditch 
and strong fortifications. It contains the wharf, 
where vessels may lie with great safety during summer, 
but, in winter, it affords very little security; a hospi-
tal, the chief's house, the warehouses, and lodgings 
for the different officers of the Company. The house 
of the present Bipy is very large, and is one of the 
best sultan's palaces in India. Canaree still poss-
esses a flourishing trade, though its exports have 
been considerably diminished by the disturbances of 
_Cotive_; and it employs from 25 to 30 vessels. It 
is about 15 miles north-west of Tellicherry; and 
lies in N. Lat. 11° 55', E. Long. 75° 14'. See Bu-
chanan's _Journey through Musore, &c._ vol. ii. p. 553; 
Bartolomeo's _Voyage_, p. 144; and a plan of the town 
and fort, in the _Oriental Repository_, vol. i. (1)

CANA, a province of Hindostan, extends along the Malabar coast between the 12th and 15th 
degree of N. Lat., and is from 30 to 90 miles in 
breadth. It is separated from the _Musore_ by the 
Western Ghauts, and comprehends the countries of 
Tulava and Haiga, with a small portion of Malayala, 
on the south, and of Kankan on the north. Its 
name is supposed to be an European corruption of 
Karnata, a people residing above the Ghauts, and 
was bestowed upon it, because it belonged to the 
princes of that nation; and we may observe, that, on 
the other side of the peninsula, the Carnatic received 
its name from the same origin, and the same cause, 
when first conquered by the Moslems. Though the 
air in this country is, in general, pure and pleasant, 
and the climate salubrious, yet, in some places, it is 
extremely unhealthy, particularly in the northern 
part of the province. In Tulava heavy rains and 
strong westerly winds prevail, between the middle of 
May and the middle of August. The rain which 
they have during the other seasons of the year comes 
from the east, and commonly falls in gentle showers; 
and, in the winter months, from November to March, 
the weather is dry, but the air is reckoned cold by 
the natives. The soil throughout this province is in 
general good; and produces abundance of rice, of 
which great quantities are exported to Europe and 
various parts of India. The best in quality is in the 
neighbourhood of the coast. In many places, it 
grows gradually worse as you approach the moun-
tains, where the rains are sometimes so excessive, as 
greatly to injure the crops; but in the inland part 
of the country, it is very favourable to plantations. 

Some of the mountains are covered with stately fo-
rests of various kinds of wood, among which the 
_Teak_ is the most valuable; indeed, the Western 
Ghauts, in general, present a very different appear-
ance from those in the east. Instead of the naked 
sun-burnt peaks of the latter, the hills here, though 
steep and stony, are by no means rugged, but are 
covered with a rich mould; and, in many places, the 
rocks cannot be observed without digging. "The 
strata on the Western Ghauts," says Dr. Buchanan, 
"are much covered with the soil; so that it is in 
few places only that they are to be seen. Having 
no compass, I could not ascertain their course; but 
so far as I could judge from the sun in a country so 
hilly, they appeared to run north and south, with a 
dip to the east of about 30 degrees. Wherever it 
appears on the surface, the rock, although extreme-
ly hard or tough, is in a state of decay; and, owing 
to this decay, its stratified nature is very evident. 

The plates, indeed, of which the strata consist, are 
in general under a foot in thickness, and are subdivi-
ded into rhomboidal fragments by fissures, which 
have a smooth surface. It is properly an aggregate 
stone, composed of quartz, impregnated with horn-
bленде. From this last it acquires its great tough-
ness. In decay, the hornblende in some plates seems 
to waste faster than in others, and thus leaves the 
stone divided into zones, which are alternately po-
rus and white. This rock contains many small 
crystallized particles apparently of iron. Below 
the Ghauts, the country consists of _laterite_ or 
brick-stone; but it is much intermixed with gra-
mites and talcose argilite, which seems to be no-
thing more than a potstone, impregnated with 
more argil than usual, and assuming a slaty form.

"The strata of Tulava, near the sea coast," says 
the same author, "semble entirely those of Ma-
layala, and consist of _laterite_ or _brick-stone_, with a 
very few rocks of grauizie interspersed. This gra-
MORAYS* of rice for every
morays of the first quality; one and a half
for middling land; and one for the worst land. The
most wealthy cultivators keep from 20 to 25 ploughs;
those in moderate circumstances have from four
to six; but the greatest proportion of farmers have only
one. All agricultural labour is performed by hired
servants and slaves. Of the farmer, a man is al-
lowed 2½ *hainies* of clean rice per day, or 21½
bushels in the year, with 1½ rupees worth of cloth, a
pagoda in cash, and a house; and a woman the same
quantity of cloth, and three-fourths of her husband's al-
lowance of grain. A male slave has 1½ hainies of
rice a-day, with an annual allowance of 2½ rupees
worth of cloth, and is permitted to build a hut in
the coca-nut garden; a female has only 1 hany per
day, with the same quantity of cloth.

Most of the cultivated lands of this country are
grown with rice. Of this plant they have a great va-
riety of kinds, each of which requires a particular
soil, and a particular method of culture. Some of
them produce three crops in the year, others only
one; and they differ greatly from each other, both
in the quantity of the produce, and in the quality of
the grain. As much of the rice ground is equally
adapted for the rearing of sugar canes, the cultiva-
tion of this article might be increased to a consider-
able extent; but the farmers consider rice a more
profitable crop, particularly since the late reduction
of the duties upon its exportation; and consequent-
ly the sugar is comparatively neglected. Cocoa nuts,
betel nuts, mangoes, pepper, cardamoms, turmeric,
ginger, &c. are produced in great abundance; and
several cucurbitaceous plants, with a variety of kit-
chen stuffs, are cultivated in almost every garden.
Black pepper grows spontaneously in the woods,
and wild nutmeg and cinnamon are very common.
The forestis abound with sandal, teak, and sissa trees,
which furnish a considerable revenue to government.

In the southern division of the province there were,
in 1800, 247,218 morays of rice land in a state of
cultivation, which employed 71,716 ploughs; and,
besides forests, it contained 111,956 morays capable
of culture, of which 24,181 morays were cleared for
grass, 7043 were capable of being converted into rice

* The moray or mudi, a dry measure of Canara, is equal to 13\frac{1}{2} bushel; and the moray, or land measure, is equal to
49,003 square feet, or nearly 1\frac{1}{10} acre.

† Cabob China are the buds of the cinnamon tree.
The principal articles of commerce during the last of these years, is contained in the following table, which is selected and abridged from the revenue accounts given by Dr Buchanan in his Journey from Madras through Mysore, &c.

A STATEMENT OF THE EXPORTS AND IMPORTS BY SEA, IN THE SOUTHERN DIVISION OF CANARA FOR 1795

* As many of the weights and measures of the Hindoos, though called by the same denomination, vary in quantity according to the different purposes to which they are applied, it is difficult to ascertain the exact value of each. In order, however, to give our readers some idea of them as they are used in the foregoing Table, we observe, that the standard Seer weight, or Indian pound, should weigh 24 Bombay rupees, making nearly nine ounces avoidapuus, but these pieces being rather a scarce article in Canara, the merchants commonly use Dube or Dadas, which are somewhat heavier, and consequently raise the Seer to about 9.75 ounces. Of these Seers, 44 is supposed equal to one Mound or Manna; and 20 Mанны make one Candy, or nearly 540 lb.

† The value of the Pagoda is about 8s. sterling. It is divided into 10 Fans or Hunas; which are again subdivided into Aund, or fractions of 16 parts.

</table>
The exports of this division by land consist chiefly of salt, salt-fish, betel-nut, ginger, cocoa-nuts, cocoa-nut-oil, and raw silk to the annual amount of 20,388 pagodas; and its principal imports are cloths, cotton, thread, blankets, tobacco, black cattle, and sandal-wood, to the value of 37,455 pagodas.

The commerce of the northern division of the province is equally flourishing, as will be seen from the annexed tables; the first of which contains the average annual exports and imports by sea of the northern districts below the Ghauts, in the years 1800-1, and the other is a statement of the land commerce of the whole division for the same years.

### THE AVERAGE ANNUAL EXPORTS AND IMPORTS BY SEA IN THE NORTHERN DIVISION OF CANARA BELOW THE GHAUTS, FOR 1800-1.

* The Seer measure, in the two last tables, is 73.683 cubic inches, of which 514 make a Moray, and 1470 a Corge. The Candy, Mauud, and Seer weight, are the same as before stated; the Tula is equal to 40 cubits; the Lead is the common burden of a man; and the Rupee is valued at about 2s. sterling.

Balance in favour of the province: £142,633

The revenue which the Company derives from this country, arises chiefly from the duties upon commerce and the land-tax; and the produce of these, we may conclude, is very considerable, as the sea customs of the southern division alone amounted, in 1795, to 23,760 pagodas, 5 fuams, and 14 anas, being about L. 9564 sterling. In Tulava, the land-tax, or shista, as it is called by the inhabitants, was formerly demanded in rice, and other articles of consumption, for the troops, at a low rate; but since the conquest of the country by the British, it has been paid in money, and the part of Malayala, which is contained in Canara, yielded, in the first year of the Company's government, 6000 pagodas. We are unable, however, to give the full amount of this tax; but we may with safety state it at about one-fourth of the gross produce of the land.

Canara, before its subjugation by the Sultans of Mysore, was possessed by several independent rajats. Many of these, upon its first conquest by Hyder Ali, were permitted to retain the entire management of the country, on paying an annual tribute, which they raised by a land-tax; and even when this permission was withdrawn, they still enjoyed some valuable privileges. Considerable allowances were granted to the temples and Brahmanas; and the Christians, of whom great numbers of Kankana descent, had settled in Tulava, possessed, in quiet, many valuable estates in that place. Upon the accession of Tippoo, however, to the throne of his father, these allowances were reduced, and the estates of the Christians confiscated; their priests were also thrown into dungeons, their churches destroyed, and the laity forcibly converted to Islamism. But the native chiefs were never so entirely subdued by the Mahometans as the greater part of the Hindoos, and have always been able successfully to resist the pretensions of their governors to be proprietors of the soil. Upon the fall of Seringapatam, and the death of Tippoo, when this country came into the possession of the British, they were even disposed to try how far they could assert their independence, and refused for a time to settle with the British collector of the revenue, until some decisive measures were adopted to punish the most obstinate and troublesome. The country is now governed by the servants of the Company.

The inhabitants of Canara are chiefly Hindoos, and are divided into casts as in other parts of India, each of which has its peculiar manners and customs. But such is the state of society in this country, that the chastity of their women cannot be depended upon; and in order to secure the succession of property in the family, it is a common law in Tulava, that a man's own children cannot be his heirs. He may give them money during his life-time, but all that he dies possessed of goes to his sisters and to their children. Polygamy is admitted, and is generally practised. A man, however, may turn away any of his wives whenever he pleases, though a woman cannot leave her husband's house without his consent. She then retires to her brother's, and may marry again. In some cases, if a man's sister be living in his house, she assumes the active management of it, and his wives have no authority. Their language is rather peculiar, and is called Canarese. It differs considerably from the Tamil, or what is called, the Malay language by the Europeans at Madras, though they are evidently branches of one dialect. Their written characters are nearly the same, but in the Canarese there is a great admixture of words from different languages.

In the southern division of Canara, there are 79,856 houses, of which 25,695 are inhabited by Christians, 3223 by Mahometans, and the rest by Hindoos and Pagans. The total population of this district is 396,672, of whom 206,633 are males, 190,039 females, and 7924 slaves. The houses in the northern division amount to 41,380, of which the Christians possess 476, the Mahometans 2300; and the Hindoos and Pagans the remainder. The number of slaves is about 1544. The principal towns in Canara are Mangalore and Carwar. See Buchanan's Journey from Madras through Mysore, Canara, and Malabar, vol. iii.; Dellon Voyage aux Indes Orientales, p. 195; &c.; and Bartolomé's Voyage to the East Indies, p. 103.

**CANARINA,** a genus of plants of the class Florae, and order Monogynia. See Botany, p. 184.

**CANARIUM,** a genus of plants of the class Dicocae, and order Pentandria. See Botany, p. 396.

**CANARY ISLES,** a group of islands in the Atlantic Ocean, which are supposed to be the same with the Insulae Bedetes, or Fortunate Isles, of the ancients. They lie about 150 miles west from the coast of Africa, between 27° and 30 degrees N. Lat. and are seven in number, viz. Lancerota, Forte Ventura, Grand Canary, Teneriffe; Gomera, Hierro or Ferro, and Palmra, besides the small islands of Allegranza, Santa Clara, Graciosas, Roca, and Lobos.

These islands, though particularly described by Ptolemy and the Elder Pliny, and though their situation was accurately pointed out by Strabo, remained unknown in Europe after the decline of the Roman empire until near the middle of the 14th century; and the first account which we have of the Canaries, is from the grant of Pope Clement VI. who bestowed them upon Don Louis de la Cerda, with the title of king, upon condition that he should cause the gospel to be preached to the natives. This grant, however, was never acted upon, owing to the death of Don Louis; and nothing farther was done to-
wards the reduction of these islands till the beginning of the following century. During this interval, the island of Lancerota had been several times visited and plundered by private adventurers, who, in one of these expeditions, carried off a large booty of goatskins, tallow, and sheep, with about 170 of the inhabitants, among whom were the king and queen of the island. In 1400, a fleet was equipped at the private expence of John de Betancour, a Norman baron, and Gadifer de la Sala, an inhabitant of Rochelle, for the sole purpose of visiting the Fortunate Isles. When they landed at Lancerota, the natives, dreading that they were come with the same hostile intentions as their former visitors, retired into the country; but observing that the French remained in the same situation for several days without attempting to molest them, they took courage, and even ventured within the camp, where they were so kindly treated by the chiefs of the expedition, that, laying aside all apprehensions, they cheerfully assisted the French in erecting a fort, which was built at the port of Rubicon. Pleased with the ready obedience and quiet demeanour of the inhabitants, John de Betancour determined to pass over to the neighbouring island; but here he met with a different reception from what he had experienced at Lancerota. The inhabitants were much stronger, and of a more warlike disposition; and gathering in great numbers, compelled him to re-embark. Finding that it would be impossible to accomplish the conquest of these islands with such a handful of men, he set sail for Spain, in order to procure fresh supplies; and to render more unquestionable his right of conquest, he obtained a grant of the Canaries from Don Henry III. then King of Castile. During his absence, the friendly intercourse between the French and the inhabitants of Lancerota had been broken by the cruel and licentious behaviour of the garrison which he had left behind; and such was the consequence of the rupture, that the Europeans shut up in the fort were reduced by famine to such an extremity, that they must soon either have surrendered or perished, had they not been relieved from their perilous situation by the arrival of their commander, who soon restored tranquillity to the island, and established anew a good understanding with the natives, who were left in the full enjoyment of their houses, cattle, and liberty. A church was built at Rubicon, named the Invocation of St. Marcial; and Guadarfa, the King of Lancerota, with many of his subjects, were converted to the Roman faith, and received the ordinance of baptism.

Betancour so won upon the affections of these islanders, by his kindness and attention, that they looked upon him as a father rather than as a conqueror, and he found in them some of his most faithful followers. By the same courteous behaviour he gained the confidence and friendship of the inhabitants of Forte Ventura, who also embraced the religion of their conquerors; but in his attack upon Gran Canary, he was received with such open hostility, and opposed with such determined courage, that he was compelled to retire with considerable loss. His attempt upon Palma was equally unsuccessful. These failures, however, were compensated by the friendly and joyful reception which he experienced from the inhabitants of Gomera and Ferro, who, without the least opposition, but rather with cheerfulness, gently submitted to his government. Perceiving that with his slender means it would be impossible to extend his authority, in their present state of watchful hostility, over the other islands, he again embarked for Spain in 1405, to solicit assistance from the King of Castile, by whom he had formerly been so liberally supported. But wishing, before his departure, to settle the government of those which had already submitted, he made a partition of the lands among his followers, reserving to himself a fifth part of the produce, and appointed his nephew, Mason de Betancour, governor of the islands in his absence. Death, however, prevented his return; and with him fled for a time the prosperity and tranquillity of the Canaries. His successors had neither his abilities nor dispositions. All their measures were marked with severity, deception, or injustice; and the only enterprises undertaken against the unconquered islands were merely for the purpose of making prisoners, which were sent to Spain and sold for slaves. By his arbitrary conduct, Mason de Betancour became daily more unpopular among the natives; and he found himself at last so unpleasantly situated, that he disposed of all his possessions in the Canaries to the Count of Niebla, in 1418, and retiring to Madeira, he infamously sold them over again to the Infant of Portugal in exchange for some lands in that island, which transaction was afterwards productive of considerable contention between the courts of Portugal and Castile. Repeated attempts were now made for the reduction of Grand Canary, but all without effect. The Canarians wanted neither conduct nor courage. They defended themselves with such resolution, that the conquest was in a manner deemed impracticable: and the only advantage that was gained by the Europeans after nearly 60 years of almost incessant hostilities, was the building of the fort of Gando, and even this was obtained by intrigue more than by force. The difficulty of this conquest had excited the attention of the court of Spain, who viewing the unconquered islands with rather a censorious eye, and wishing to add them to the Spanish crown, pretended that the present governor Diego de Herrera was unable to subdue them by his own power, and consequently that he should cede them to their Catholic Majesties, in order that their reduction might be speedily completed, and the natives brought to the Christian faith. This cession was made in the year 1476, when Diego de Herrera received in lieu of his right five millions of maravedis, (about 3000l.)

The honour of Spain was now staked in the enterprise; and an armament, consisting of 900 foot, and 30 horse, under the command of Don Juan Rejon, was dispatched for the reduction of Grand Canary. This expedition was well equipped, and provided with every necessary, and accompanied by Don Juan Bermudas, dean of Rubicon, a person well versed in the affairs of the Canary Isles. The troops were landed, without opposition, on the 22d of June 1477, and their tents were pitched in a commodious plain, where now stands the city of Palmas. To secure themselves from any sudden attack of the natives,
they immediately proceeded to build a castle, and to throw up a fortification around their camp. The Spaniards, among whom considerable differences had existed, respecting the usurpation of some of their chiefs; seeing the determination of the Spaniards to settle in the island, laid aside all private animosities, and, uniting their forces, advanced to the expulsion of the enemy. They encountered the Spaniards with the fury of men whose liberty and religion were at stake; and displayed, in every attack, the most heroic and obstinate resistance. For three hours the battle continued without any apparent advantage on either side: but the Canarians were unable to withstand the fire-arms of the Spaniards, and were compelled to retreat, which they did in good order, with the loss of 300 men killed, and their bravest chief Adargona, who was wounded and taken prisoner. After this battle, which was called the battle of Guiniguada, the natives, in some measure terrified by the sight of the horses, which had appeared for the first time in the island, did not attempt to engage the Spaniards again on level ground, but retiring to the mountainous parts of the country, contented themselves with continually harassing the enemy, in their marches, and foraging excursions. This species of warfare continued for nearly six years, during which time the Spaniards had received frequent reinforcements. The Canarians were determined to persist rather than submit. In many of their conflicts they had come off victorious; and their courage had been roused, and their hatred inflamed, by the bad faith of the enemy, who had trepanned about 200 of their subjected countrymen out of the island, under pretence of sending them to the reduction of Tenerife, and carried them to fight against the Moors in Barbary, where they all perished. Jealousies and contentions had also existed among the Spanish officers, and before the object of the expedition was accomplished, three different governors had been sent out to Grand Canary. Their progress, however, though slow, promised them a successful conclusion; the greatest part of the island was in their possession; and the natives were reduced to their last strong hold. Six hundred Canarian warriors with about a thousand women and children, had assembled at the mountain of Ansite, a place deemed impregnable, with the resolution of losing their liberty only with their lives. But by the persuasion of one of their converted chiefs, who had been taken prisoner, and had embraced the Christian faith, they were induced to lay aside all thoughts of resistance, and to submit to the Spaniards, upon condition of their being protected in the possession of their liberties and effects, and that especial regard should be paid to the rank and dignity of their nobles. This event happened on the 29th of April 1483, which day is now annually held as a great festival throughout the island of Grand Canary, where the standard which was then in the Spanish camp, and which is deposited in the church of St Anna, is carried in solemn procession. On the 20th of February 1487, this island was incorporated into the crown of Castile, with the title of kingdom, and declared free from certain duties. In the same year it was erected into a bishopric by Pope Innocent VIII.; and its patronage was given to the king of Spain, and his successors for ever. In 1499, a body of laws and charters was sent over to Grand Canary for the government of its inhabitants; and, in 1515, the Emperor Charles V. bestowed on Palmas, the capital of the island, the title of noble and royal city of Palmas.

After the reduction of Grand Canary, many of the Spaniards preferring an active military life to one of ease and retirement, which they might have quietly enjoyed in that island, looked to Palma and Teneriffe as the scenes of farther conquest. Among these was Captain Alonzo de Lugo, who had served with much reputation in the Canarian war, and who, by his interest at court, procured a grant of the conquest of the two islands from their Catholic Majesties. With a fleet properly equipped, and well supplied with men, ammunition, &c., necessary for the undertaking, he sailed for Palma, and on the 29th of September 1490, landed at the port of Tassacorta, on the west side of the island. Having fixed and strongly fortified his camp, and also built a chapel, which he dedicated to St Michael, he proceeded to the subjugation of the inhabitants. This, in part, he easily effected, especially with those of the south west quarter of the island, whom he reduced, not by force of arms, but by promises and presents. The natives, however, in the north-east side, refused all his offers. They had formerly suffered very injurious treatment from the Spaniards of Ferro, and, suspecting their present intruders of the like intentions, no promises could induce them to submit. They retired to one of their strong holds among the mountains, which the Spaniards called the cauldron, from its resemblance to that vessel, and here they defied all the skill and valour of their adversaries. But finding that the Spaniards had come to settle in the island, and were determined upon their reduction, they at last agreed, that if the Spaniards would retire to the foot of the mountain, they would come next day and make their submission. Alonzo de Lugo complied, but at the same time suspecting that it was merely a stratagem to dislodge him from his present position, he left an ambush to cut off their retreat, in case they should follow him, and afterwards wish to return to the cauldron. When the natives appeared, according to the agreement, they found the Spaniards armed, and in order of battle, and, apprehensive of some treacherous design, they refused to proceed. But Tanause, their chief, assured them, that as he had Alonzo's promise, they had nothing to fear. The faith of the Spaniard, however, was of too accommodating a nature to allow the present opportunity to escape, and not being yet assured of their real intentions, fell upon them with all his forces, when a very bloody skirmish ensued, which ended with the death or captivity of all the natives. Tanause, who was among the prisoners, was sent over, with several of the other chiefs, to Spain, along with the agreeable tidings of the conquest. He bitterly complained against Alonzo for his breach of promise, and took it so much to heart, together with his being sent out of the island, that he obstinately refused all manner of nourishment, and starved himself to death.

The conquest of Teneriffe was not so easily accomplished, and the reverse which Alonzo met with in
that island, were justly merited by his perfidy at Palma. He landed at the port of Santa Cruz, on the 3d May 1493, and no sooner had he encamped in the plain of Laguna, than he was invited in a friendly manner by several of the petty kings of the island, who then happened to be at war with Ventomo king of Taoro. Ventomo was the most powerful and independent prince of Tenerife, and when invited to a conference, and requested by Alonzo to embrace Christianity, and become a vassal of the king of Spain, he replied: that as to embracing Christianity, he knew not what he meant; and as to his becoming a vassal of the king of Spain, he never would, for as he was born free, and had all his lifetime continued so, so he intended to die. Alonzo, relying upon the strength and valour of his forces, and the friendship of the other chiefs, who seem to have remained quiet spectators of the contest, advanced fearlessly into the country.

Having made a great booty of cattle, he was returning back, but was intercepted in a narrow defile by the brother of Ventomo, at the head of 800 Guanches, who fell upon the Spaniards, with such fury, that these being unable, from the nature of the place, to avail themselves of their cavalry and superiority of numbers, were completely routed, and pursued with dreadful slaughter. When Ventomo came up with fresh troops, he found his brother resting himself upon a stone by the wayside, being much fatigued, and reproaching him severely for not joining in the pursuit, the other coolly replied: "I have done my part in vanquishing the enemy, now the butchers are doing theirs in killing them." In this battle the greatest part of the Spanish army perished, and Alonzo himself narrowly escaped. This was the severest defeat the Spaniards had ever experienced in these islands, and the place where the action was fought is, to this day, called La Mantansa de Centejo, "the slaughter of Centejo." Alonzo, quite dispirited by this disaster, reembarked the remains of his troops, and returned to Grand Canary. But having received considerable reinforcements from Spain and La Gompta, and, after recruiting his own forces, he found himself at the head of 1000 foot and 70 horse completely armed. Not discouraged by his late failure, he again proceeded to Tenerife, but found the whole island now united against him. He, however, advanced to the plain of Laguna, avoiding in his march all ambuscades and difficult passes. The natives, astonished at his speedy return, after such a defeat, with so large an army, and finding, from the good order and precautions with which he advanced, that, in their several encounters, they could make no impression upon the Spaniards, thought seriously of coming to some agreement. Having requested a conference, they demanded of the general, why he invaded their island in that hostile manner, without any provocation, disturbing the repose of the inhabitants, plundering them of their cattle, and carrying the people into captivity? To this Alonzo replied, that he had no other design than to make them become Christians, which if they consented to do, they should remain in quiet possession of their land and effects. To this proposal the Guanches, after some deliberation, agreed; and all who were then present were immediately bap-

tised. Having thus peaceably secured the submission of the island, Alonzo founded a hermitage on the spot where the treaty was concluded, which he called Nuestra Senora de la Victoria, our Lady of Victory; and after settling the government on a regular plan, he laid the foundation of the city of Laguna, on the 25th of July 1493. This conquest completed the reduction of the Canaries, which were immediately annexed to the crown of Spain, and they still constitute a part of the dominions of that kingdom.

The Canary Islands, before they were subdued by Europeans, were divided into several small states, each governed by its respective Guanarteme or prince, and separated from one another by a wall of loose stones, frequently crossing from sea to sea. A whole island was sometimes under the dominion of one prince, as was the case with Ferro, and also with Tenerife, a few years before its conquest; though at that time it was divided into nine different kingdoms. The royal dignity in this island was elective; and the king was always obliged to marry a person of his own rank. If such a one, however, could not be found, he took his own sister, not being permitted to debase his family by a mixture of plebeian blood. Besides these chiefs, they had also in Grand Canary a race of nobility, who were distinguished from the vulgar by the peculiar cut of their hair and beards. This rank, however, was not altogether hereditary; for, before the son of a nobleman could be considered as noble, he must have been formally, declared so by the Fayog, an officer of great rank, and next in dignity to the Guanarteme, whose business it was to regulate the ceremonies of religion, and to act as judge in civil affairs. The ceremony of conferring this dignity was performed with great solemnity. The young man claiming the honour of nobility was presented before the assembled nobles; and inhabitants of the town or district to which he belonged. These were required to declare upon oath whether they had ever seen the youth demean himself by submitting to any mean occupation; whether he had ever forcibly, or by stealth, taken away any of his neighbours' cattle; and whether he was in any way discourteous, ill-tongued, or guilty of any indecent behaviour. If even one of these charges were brought against him by any of the assembly, and sufficiently substantiated, the Fayog shaved his head, and dismissed him with disgrace, by which he was rendered incapable of nobility, and remained ever after a plebeian. If, on the contrary, however, he was declared free from every such imputation, the Fayog cut his hair in a round form, and so short as not to hang beneath his ears; then putting into his hand a staff or pole, called magodey declared him noble. In Tenerife, the inhabitants were divided into three classes, the nobles, the yeomen, and the peasants. From the variety of interests in these islands, frequent disputes arose concerning their flocks and pastures, and the boundaries of their respective districts. These disputes often ended in wars which overspread the face of the country with blood and carnage. Their principal weapons were wooden spears and darts, sharpened at the point, and hardened in the fire. They also threw stones with great force and dexterity, either...
from the hand or a sling; and sometimes used huge clubs, which, in Grand Canary, they called modogas. In Teneriff, when an enemy approached, they alarmed the country by kindling a fire, or by whistling, which was repeated from one to another, and was heard at a most incredible distance. The women often attended their husbands to the field of battle, and were employed in taking care of the wounded, and carrying off the dead, which they interred in caves. By these wars, whole districts were depopulated, and some of the states, in a short time, experienced many changes of masters. Duels were very common in these islands; and it was upon such occasions, in particular, that they were most anxious to display their strength and valour. Public places were set apart for this purpose; and the combatants were surrounded by their friends and relations, not to assist them, but to be quiet spectators of their gallantry and behaviour. These disputes were generally decided on public festivals or rejoicings, in the midst of a great concourse of people. The battle was begun by each of them throwing three round stones, which they in general dexterously avoided, by the writhing of their bodies; then, arming themselves with cudgels in their right hand, and sharp flints in their left, they cut and beat one another until the Gayres or nobles cried out “gama!” enough! when they immediately retired, and ever after remained good friends. Though much addicted to war, this people were of a humane, cheerful, and friendly disposition, of which the Spaniards sometimes took advantage; and, during their reduction, often gained more by conciliatory measures than by force. They were faithful in all their dealings; and it was owing to the failure of the Europeans in this respect, that the Canarians resisted so long every offer of accommodation.

Excepting the inhabitants of Lancerota and Forteventura, who were more gigantic and better made than those of the other islands, the natives were in general of a middle stature, but extremely athletic, and particularly skilful in the exercise of wrestling. A remarkable feat of this kind is related of Aargoma, the Canarian chief, who was taken prisoner by the Spaniards at the battle of Guimiquada. When at Seville, a peasant of La Mancha, famous for his strength, having heard of the Canarian as an extraordinary wrestler, challenged him to a trial of skill. Aargoma accepted the challenge, but proposed that they should first drink together; and, taking a glass of wine, he said to the Spaniard; “Brother, if you can, with both your hands, prevent my carrying this wine to my mouth, or cause me to spill one drop, then I will wrestle with you; but if you are unable to do this, I would advise you to return home.” He then drank off the wine, in spite of all the other’s efforts to prevent him, which so astonished the peasant, that he prudently took his advice and retired. The common dress throughout the Canaries was a cloak made of sheep or goat skins, to which the women added a petticoat, reaching down to the knees, and a cap or bonnet of the same materials, which they sometimes adorned with feathers. Their shoes were formed of raw hides, with the hairy side out. The Canarians had also a light coat, the stuff of which was manufactured from a sort of rush, which being beat, became soft like flax. Some of their garments were curiously sewed with thin thongs of leather, as fine as common thread, and painted with various kinds of dyes, which they extracted from the roots of trees and herbs. Their houses were all built of stone, but without cement or mortar of any kind, and sometimes so neat and regular, that many of the villages made a very good appearance. In Grand Canary they laid wooden rafters or beams along the top, which they covered with earth; but in Terro, where the houses were of a circular form, and so large that they sometimes contained twenty families, the roof was formed of branches of trees and fern. Their furniture consisted of goat skins, which were their only beds; and baskets and mats very ingeniously wrought. They had also earthen vessels dried in the sun, which they used in cooking, and for holding their victuals. Goat’s flesh and mutton, either roasted or boiled, constituted their principal food. These, however, they ate alone, without any addition of bread or roots. They used also barley meal roasted and dressed with butter, which they called gofio; and in some of the islands, they had a kind of bread made of fern roots, which, with milk and butter, composed the chief part of their diet.

In Grand Canary, no person was allowed to kill his own cattle. This office was confined entirely to the butchers, who, from their employment, were held in general abhorrence; and this trade was accounted so ignominious, that it was unlawful for a butcher to keep company with any but those of his own profession. He was not even permitted to enter the house, or to touch any thing that belonged to the rest of the inhabitants, who were in their turn prohibited from visiting any of the public shambles. The only compensation for this degraded trade was, that the natives were obliged to supply the butchers with every thing they had occasion for. This aversion for an employment, which, from its very nature, must deaden in some measure the feelings of kindness and humanity of those who exercise it, shew a degree of refinement in this people which is seldom to be found even among the most civilized nations. Their delicacy with regard to the female sex is equally worthy of admiration. The least indecent word or action was severely punished, and it was a prevailing custom at Teneriff, that if a man by chance met a woman alone on the road, or in a solitary place, he was not to speak to, or even to look at her, but to turn out of the way until she was past. Contrary to what some authors have affirmed, these islanders never had more than one wife at a time, though in their marriages, they paid no regard to consanguinity, except that of a mother or sister. In Grand Canary, when parents were inclined to marry their daughter, they confined her for thirty days; and fed her with large quantities of milk and gofio, in order to fatten her; for they imagined that lean women were incapable of conceiving children. They could, however, put away their wives when they pleased; but, in such cases, their children were, by this means, rendered illegitimate, and incapable of inheriting their father’s effects. In all diseases, their prevailing cures were bleeding, burning, and anointing. When any one fell sick, they rubbed his body with sheep’s
marrow and butter, and then covered him well up, to keep him warm, and promote perspiration; but, when troubled with acute pains, they drew blood, by scarifying the affected part with sharp stones. When they received any cut or wound, they burned it with fire, and then anointed it with goat's butter. They also employed herbs; and, in Teneriffe, they had a kind of medicine prepared from *mocanes,* which they used in fluxes and pleurisies, the most common diseases of the island. When any of the nobles died, they embalmed the body, and shut it up in the cave set apart for the family burying-place. Some of them were put into chests, and afterwards deposited in stone sepulchres. The office of embalming belonged only to particular persons; and each sex performed it for their own dead. In Teneriffe, the king could only be buried in the cave of his ancestors; and the corpses were so arranged as to be known again. About the middle of last century, two of these embalmed bodies, which were taken out of a cave, were found perfectly entire, and as light as cork. The hair, teeth, and garments, were quite sound and fresh, and without any disagreeable smell.

Some of these islands were remarkable for their good government and strict administration of justice. In Grand Canary, the punishment immediately followed conviction. If the delinquent was charged with a capital crime, his head was placed upon a flat stone, when the executioner, with another, dashed out his brains. In all other cases, they used the *lex talkonis.* In Ferro, no crimes were punished but murder and theft. The murderer was put to death in the same way as he had killed the deceased; and the thief, for the first offence, lost one eye, and for the second the other, that he might not see to steal any more. In Lancerota and Forte Ventura, they had a law, that, in cases of quarrel, if a man entered openly by the door into his enemy's house, and killed him, or did him harm, it was not little to be punished; but if he climbed over the wall, or came upon him unawares, he was condemned to suffer death; and the method of execution was the same as in Grand Canary. In Palma, as in Sparta, theft was considered as a virtue; for he was esteemed the cleverest fellow who could steal with such address as not to be discovered; and, if detected in the act, he was merely obliged to restore the plunder. The common punishment in Teneriffe was cudgelling, which was generally executed in the presence of the king and elders. In cases of murder, the criminal was punished with banishment and the confiscation of property, which was bestowed upon the relations of the deceased; but death was never inflicted for any crime, as they had a belief that it belonged to God alone to take away that life which he gave.

Some authors, following the account of the Nubian geographer, have represented the inhabitants of the Canaries as gross idolaters. This geographer relates, "that in each of the Fortunate islands is to be seen a pillar raised of stone, of an hundred cubits length, each pillar supporting a brazen image, with its hand lifted up and pointing backwards." Pyramids of this description, though without the image, were found in the island of Palma; and in one district, there is a long narrow rock upwards of a hundred fathoms high, where the natives used to worship their god Idafe, whose name the rock itself still retains. It would appear, however, that the religion of many of these islands was pure theism. They adored only one god, whom they denominated by various titles, as the Great, * the Sublime, † the Possessor of the World, ‡ the Sustainer of Heaven and Earth; § and the only worship which they offered, was the lifting up of their hand towards heaven in silent adoration. In Grand Canary and Lancerota they had houses of worship, but no images, or any representation of the Deity; and their sacrifices consisted in the pouring out offerings of goats' milk. The Canarians had also several convents, inhabited by religious women called Magadas, which were held sacred; and all criminals who fled thither, were protected from the officers of justice. In Ferro, however, they had two deities; one of them male, named Eraranzan, who was worshipped by the men; the other female, called Moneyba, worshipped by the women. In seasons of great distress, occasioned by a long drought, or any other public calamity, it was an universal custom in these islands, for the natives to assemble in certain places, set apart for the purpose, with their children and flocks, and, sitting in a circle on the ground, began to lament and make a mournful noise; their flocks belling also for want of food; for both men and beasts, on these occasions, were debared all kind of sustenance. These fasts sometimes lasted three days and three nights. The wealth of these islanders consisted chiefly in their flocks and herds. Agriculture was little known among them; and practised only in its rudest form. They broke the ground with a wooden hoe, which had sometimes a goat's horn fixed to the end of it, and then threw in the seeds. Barley was their principal grain; but they had also wheat, beans, and peas on the same. In harvest, they reaped only the ears, which they threshed with sticks, or beat them with their feet, and then winnowed the corn with their hands. Their only fruits were *vicacerras,* mocanes, and wild dates.

Various opinions have been entertained concerning the first inhabitants of the Canary islands; but the most probable account is, that they were originally Lybians, who, upon the conquest of Barbary by the Arabs, fled thither, to avoid falling into the hands of their victorious enemies. The truth of this Mr Glas has attempted to prove, by a comparison between the language of South Barbary and that of the natives of the Canaries. The languages of all the islands, except Teneriffe though different, had some affinity to each other; and were evidently branches of one original language; and their resemblance to the Shilleh, and other dialects of the Lybian tongue, is a strong presumption, that they derived their origin from the same stock. The probability is also considerably strengthened by the similitude of customs. The principal dish of the Lybians, called *consoucou,* was much the same with the goffio of the Canarians. They both poured hot butter into their

* Achubuiaian. † Ashubucana. ‡ Guararari. § Acheran.
wounds; and they both fattened their daughters with milk before they gave them in marriage. The language of Teneriffe, however, was perfectly different from that of the other islands; and, according to Mr. Glasse, it seemed to have some resemblance to the Peruvian, or some other of the American tongues.

Since the conquest of these islands, the language and customs of their inhabitants have been almost entirely lost in those of their conquerors. The natives have been so incorporated with the Spaniards and other Europeans, that they have become one people. They all use the Castilian language; and, in their dress, manners, and appearance, resemble their fellow subjects in the peninsula. Their complexions, however, are rather more swarth; but they have good features, and fine large sparkling black eyes, which give a vivacity and dazzling lustre to the countenance. The higher classes are in general poor, yet extremely polite and well bred. They boast much of their birth, and claim their descent from some of the best families of Spain. The peasantry have also a considerable share of good manners; but still retain their aversion to certain professions, as butchers, tailors, millers, and porters. The poorest fisherman would think himself degraded, by exercising any of these employments, and would even refuse to sit at the same table with any one belonging to these trades. People of all ranks are rather of a romantic disposition, particularly in love affairs. All intercourse between the sexes is restrained within the strictest bounds of decency and decorum; and what even English women would consider as innocent freedoms, no virtuous woman in the Canaries would bear. Love-engagements are declared binding by law; and if a woman can prove, that a man has in the least instance endeavoured to win her affections, she can oblige him to marry her. It must be allowed, however, that unhappy marriages are more common here, than in those countries where innocent freedoms subsist between the sexes previous to their union, and where the lover has an opportunity of perceiving that his mistress is mortal, and partial of human frailty. The diversions among the vulgar are, wrestling, cards, quoits, and throwing a ball through a ring; also, music and dancing, of which they are very fond. Each of the islands, and even every town and village, has some particular saint for its patron, whose day is celebrated as a festival, by a particular service in the church, and by a fair and rejoicings in the evenings. Every family of eminence, also, has its saint or patron, to whose honour an annual festival is held at great expense; and on such occasions, the gentry vie with one another in costly entertainments and splendour. All the inhabitants of these islands are rigid Catholics, and it is impossible for a person of a different persuasion to live among them. There is a house in every island belonging to the Inquisition, with its proper officers, whose duty it is to prevent all appearance of heresy or disrespect to the clergy. The bishop of the Canaries resides in the city of Palmas, in Grand Canary. He is a suffragan to the archbishop of Seville in Spain, and is treated with all the respect and homage due to a sovereign prince. The superiors of the different orders of friars and nuns live in the city of Laguna, in Teneriffe, and are accountable only to generals of their respective orders. The civil government is vested in the royal audience of Grand Canary, which is composed of three judges, a regent, and fiscal, who are generally natives of Spain, and always appointed by the king. Of this tribunal, the governor-general is president, though his usual residence is at Teneriffe. From the sentence of this court there is no appeal, except in cases of property, when appeals must be carried to Spain. The other magistrates in these islands are the corregidor, the tinent, the alcalde major, and the alcalde. The corregidor is appointed by the king, and holds his office for five years; the others are nominated by the royal audience. The office of alcalde nearly resembles that of a justice of peace in England, and every town or village of any consequence has one.

From the appearance of the different strata which compose these islands, we may reasonably conclude, that they are of volcanic origin. A very great proportion of their surface is also covered with calcined rock, pumice stones, and black dust and ashes, which are evidently the remains of several successive eruptions. The craters of several volcanoes are still discernible in many of the islands; and also the channels made by the lava which flowed from them. The climate, however, is delightful, and exceedingly salubrious.

The rainy season continues here from the beginning of December until March, which they call winter, though it very seldom freezes; and snow is only to be seen on the tops of the mountains. During the summer, the sky is always serene, and the heat is very intense, particularly during the months of July, August, and September. The climate, however, in these islands is far from being uniform; for while in the cities upon the coast the air is hot, dry, and calm, the inhabitants of the mountainous districts experience fogs, winds, and even rain. From the centre of many of these islands being exceeding high, and full of lofty mountains, which tower so far above the clouds as to intercept the current of the winds, a calm generally prevails on the lea-side of the island, or a gentle breeze from the opposite quarter. These calms, or eddy winds, are extremely dangerous to small vessels approaching the islands; for, at the extremity of the smooth water, the waves break in all directions; and when a ship comes among them, she is shaken and beaten on all sides in such a manner, that it is almost impossible to withstand it. The calms on the leeward of Grand Canary extend 20 or 25 leagues into the ocean; those of Teneriffe 15; of Gomera 10; and of Palma 30.

The soil of these islands is very fertile, and produces all kinds of grain, fruits, and pulse, in great abundance; but the method of cultivation which is practised by the inhabitants tends very little to its improvement. The lands are here let, not for money, but for the half of the produce. The proprietor furnishes the seed, and other articles of the first necessity, also the cattle, which indeed belong to him, and which he can take back at the expiry of the lease. For these, he receives the half of the crop during the term of agreement, besides a junega, or wheat for
every head of cattle. The peasants often rent the cattle without the land, merely to share the half of their increase. In these agreements the husbandman has no inducement to exertion. A moderate crop is all that he expects or desires; for a plentiful harvest can be of very little value to him, who is prevented, by the prohibitory measures of his government, from converting the surplus into wealth, or exchanging it for foreign commodities. The necessities of life are all that he requires; and his labour is confined to the production of these alone. Thus rendered indolent and improvident, he is never prepared against a season of scarcity; and is sometimes reduced, like his savage ancestors, to feed upon bread made from fern roots. It is, however, a fact, the truth of which is established by experience, that a scarcity of provisions in any country arises, not so much from the sterility of the soil, as from the measures of government; and it need scarcely be remarked, that famine is more frequent in some of the rich and fertile districts of the south, where the exertions of industry are paralysed by arbitrary regulations, than in many countries which possess an ungrateful soil, but which are ruled by a wiser and more liberal policy. Sugar was formerly made here in great abundance; and twelve sugar mills were employed in the manufacture of this article in Grand Canary alone. It has of late, however, very much fallen off; and the cotton plantations have also been greatly neglected. Besides these, olives, mulberries, and tobacco, might be cultivated here with great success. These islands produce plenty of honey, wax, and a kind of black gum or pitch called bray. All the islands furnish excellent wine, but the preference is in general given to those of Palma and Teneriffe. In good seasons, Teneriffe alone produces above 30,000 pipes, a third of which is Malmsay or Canary sack, which sells from 50 to 60 piastres a pipe. The rest is a dry hard wine, which sells for about half that price. When two or three years old, it can scarcely be distinguished from Madeira; but when allowed to stand for four years, it turns mellow and sweet, and resembles greatly the wine of Malaga in Spain. The cattle of the Canaries are, horses, oxen, goats, sheep, roebucks, and wild asses. They abound with several kinds of game, and poultry, also with singing birds, particularly the Canary bird, so well known throughout Europe; and their shores are well stocked with fish, especially sturgeons and mackerel, which are a great source of nourishment to the poor inhabitants.

Teneriffe is the great centre of European commerce in these islands. Some ships go to Grand Canary and Palma, but their number is very inconsiderable; and this branch of trade is chiefly in the hands of the English. The principal exports to Europe and the British colonies in America, are wines, brandy, fruits, orchilla weed, and commodities which they receive from the Spanish West Indies. From the British islands they receive various kinds of woollen clothes, hats, stockings, hardware, &c. also wheat when there is a scarcity in the island, and beef, pork, butter, candles, and salt herring; from the north of Europe, linens, cordage, gun-powder, bar iron, &c.; from the Mediterranean, cottons, silks, velvets, salt, oil, bass cordage, and innumerable small articles, either for home consumption, or for exportation to the Spanish West Indies; from North America, deal boards, pipe staves, laccazu or dried cod, hams, bees-wax, rice, &c. All these goods, imported into the Canaries, or exported from them, pay a duty of 7 per cent. on the rated value. The commerce which these islands carry on with the Spanish settlements in the West Indies, is under particular regulations and restrictions. No foreign bottoms are permitted to be employed in this trade, nor are vessels allowed to be fitted out from any of the islands except Grand Canary, Teneriffe, and Palma. This trade is confined to their own produce, of which they annually export nearly 2000 tons; but they also find opportunities of smuggling into the country immense quantities of European commodities. Besides this foreign commerce, the Canaries carry on a considerable trade with each other. The island of Teneriffe is the principal staple of all West India and European commodities, which it distributes among the other islands; and receives in exchange, from Grand Canary provisions of all sorts, coarse woollen blankets, raw and wrought silk, flags, filtering stones, and some salt, &c.; from Palma, almonds, sugar, sweetmeats, boards, pitch, and raw silk; from Gomera and Ferro, raw silk, brandy, and cattle; from Lancerota and Forte Ventura, a great quantity of corn, cattle, and fowls, also some salt and dried fish; and from all of them orchilla weed.

The principal manufactures of these islands are, taffeties, coarse linens, gauze, quilts, knit silk hose, and silk garters; and in order to encourage their silk manufacture, the exportation of raw silk is strictly prohibited. Coarse woollen cloths, and white blankets, are also manufactured in many of the islands from the produce of their own sheep. In all the villages, the women only are employed in weaving, or as tailors, and it is only in large towns that the men exercise those trades. The inhabitants of the Canaries employ a considerable number of vessels in the fishery on the coast of Barbary, which, if properly encouraged by the Spaniards, might be rendered a source of great convenience and profit to those islands. But the trade is clogged with foolish and unreasonable duties; and the price is impulsively regulated by the magistrates. This fishery extends along the coast about six hundred miles, from Cape Blanco on the south, to the southern extremity of Mount Atlas on the north. The vessels employed in this trade are from fifteen to fifty tons burthen, the smallest carrying fifteen men, and the largest thirty; and the general place of rendezvous is at Porto de Luz, in the island of Grand Canary. They make from eight to ten voyages in the year. The bulk of their cargo consists of sambes or breem; but they also catch a great quantity of tassarte, cod, anchous, carbinio, and other kinds of fish. The tassarte tastes like a very large and fat mackerel, and when dried cannot be distinguished from dried salmon; and the cod that is caught on this coast are considered as preferable to those of Newfoundland. "Although this fishery," says Mr Glas, "is capable of the greatest improvement, yet the English have no reason to be apprehensive of the Spaniards ever being able to bring it to any degree of perfection, so as to rival them in the Spanish or Italian markets: the power of the clergy
in Spain is a better security to the English against such an event, than if a fleet of a hundred sail of the line were stationed on the coast of Barbary, to obstruct the Spanish fishery."

The situation of the Canary islands, the salubrity of their climate, the fertility of the soil, and the quality of their productions, all conspire to render them the most valuable of the Spanish colonies; and even preferable to these boasted possessions of America, which fill their galleons with treasure. If they were inhabited by an active and industrious people, and placed under a government where agriculture and commerce were encouraged and protected, they would soon rise to deserve the distinguished appellation of the Fortunate Isles. According to M. Humboldt, the population of these islands is estimated at 160,000 persons, and their revenue at 240,000 piastres; but the expenses of their administration are such, that they require an annual remittance from Spain. See Histoire de la premiere de couverture, et conquête des Canaries, par F. Pierre Bouthier Religieux de S. François, et Jean le Verrier Prestre, Paris 1836, 8vo.; Gla's Description of the Canary Islands; Viera's History of the Canaries; Bory de St Vincent Essai sur les îles Fortunées; and Memoires de l'Institut National à Paris, tom. i. p. 280. (P.)

**CANARY, GRAND.** One of the Canary islands, which gives the general appellation to the group, lies between the islands of Teneriffe and Forte Ventura, and about 100 miles north west from Cape Bojador on the African coast. It received the epithet of Grand from John de Betancourt, not on account of its size, but because of the strength, courage, and number of its inhabitants, who baffled all his attempts to subdue them. But from whence it derived the name of Canary has never yet been determined. According to Pliny, it was on account of its abounding with dogs of a very large size, two of which were presented to Juba, king of Mauritania. But if such animals ever did exist in this island, they were completely extinct when it was first visited by Europeans. Some modern authors derive it from a species of fruit very abundant here, called: by the Latins, *Uva canina*, dog grapes; or from a herb named *canaria*, which dogs eat in the spring to cause them to vomit. Others suppose, and with more reason, that it received its name from its first inhabitants, who were probably a tribe of Africans, as Pliny mentions a people called Canarii, who dwelt beyond Mount Atlas, a part of Africa which lies adjacent to the Canary islands. But however that may be, it is rather strange, that we have never been informed under what name it went among the natives.

At a distance, this island has the appearance of a single mountain rising gradually from the circumference to the centre. It is about fourteen leagues in length, nine in breadth, and thirty-five in circumference. Though Grand Canary is high and mountainous, yet near the sea coast there are many plains, and more level ground than in any of the neighbouring islands. On the north-east end is a small peninsula about two leagues in circumference, which is joined to the main land by a narrow isthmus two miles long, and about a quarter broad. On the south side of this isthmus is a spacious bay called Porto de Luz, which is a capital road for shipping of any burthen, and where the water at the landing place is generally so smooth, that a boat may lie broadside to the shore without danger. About a league to the west is the city of Palmas the capital, and residence of the royal audience or sovereign council of the Canaries. It is a place of no strength, but of considerable extent, and contains several fine buildings, particularly the cathedral of St Anne. The houses, though only story high, are in general elegantly built and flat at the top. It has four convents; and its population is estimated at about 12,000. The other ports are Gando and Gaete, and, excepting at these places, the whole coast is inaccessible to boats or vessels, on account of the high surf which is continually breaking upon it. Its other towns are Galdar, Telde, Tírachana, and Luz.

This island possesses one of the finest climates in the world. The heavens are seldom overcast, but are almost continually serene, and free from storms and thunder. No where in the same latitude are the heats of summer so temperate, and no where do the natives enjoy such health and longevity. The only disagreeable weather which they experience, is when they are visited by a south east wind from the great desert of Africa. It is hot, dry, and stifling, and does great damage to the fruits of the earth by its pernicious quality, and is generally attended with immense clouds of locusts, which devour every green herb upon which they alight. This wind, however, blows very rarely, and never lasts long.

The soil of this island, though light and sandy, is covered with a rich mould, and yields two harvests in the year. It is well watered, and suited for every species of agriculture, and is very productive in all kinds of trees, fruits, and herbs. The pine, palm, wild olive, laurel, poplar, elder, bressos, dragee tree, terra nua, or *Lignum Rhodium*, aloe, Indian fig, tubayba, euphorbium, tarabala, and many others, grow spontaneously and without cultivation. It also abounds with almonds, walnuts, chestnuts, apples, pears, peaches, apricots, cherries, plums, mulberries, figs, bananas, dates, oranges, lemons, citrons, limes, pomegranates, and all the American and European fruits, except the anana, or pine-apple, which is not to be found in any of the Canaries. The fertile districts of this island, however, bear no proportion to the stony, rocky, and barren ground, which covers almost six-sevenths of its surface. Yet they have plenty of excellent wheat, barley, and maize, melons of different sorts, potatoes, yams, pumpons, the best onions in the world, and many other kinds of roots all good of their kind; and the husbandman is amply repaid for the labour of cultivation. But the spirit of industry is completely checked by the imprudent conduct of the government, which prohibits the exportation of provisions in a plentiful season, and fixes a price upon them in the island. Many lands are, on this account, allowed to lie waste, which, had the inhabitants more liberty and security for their property, would, by a little labour and expense, be soon rendered abundantly fruitful, as they have the utmost facility of watering them, by turning the course of the many rivulets
The sugar plantations, which were formerly numerous and extensive in this island, and which employed fourteen large manufactories, have now, in a great measure, given place to the cultivation of the vine. The wines and brandies of Grand Canary have always been in great demand in the Spanish West Indies, and the inhabitants find it more profitable to exchange these for sugar than to raise it in their own country. The wine of Grand Canary, however, though good, has not such a body as that of Teneriffe, and is consequently not so fit for exportation. The animals of Grand Canary are camels, horses, asses, mules, bullocks, a few sheep, &c. also turkeys, geese, fowls, ducks, partridges, and Canary birds. Population 40,000. See CANARY ISLES, and the references subjoined to that article. (p)

CANCER. See SURGERY.
CANCER. See CRUSTACEA.

CANCER, or the Crab, in astronomy, is the name of one of the twelve signs of the zodiac. The particular arrangement of the stars in this constellation is supposed by some to have been the origin of the name, from their fancied resemblance to a crab; while others ascribe it to the analogy between the retrograde motion of this animal, and the motion of the sun which begins to recede from the earth when it enters the sign Cancer. In Ptolemy's catalogue this constellation contains 29 stars, in Tycho's 15, in Bayer's and Hevelius's 29, in Flamsteed's 83, and in the catalogue which we have given in the article ASTRONOMY, at p. 762, it contains 87 stars. (m)

CANDAHAR, or KANDAHAR, the capital of a country of Asia of the same name, situated between Persia and Hindostan, and supposed to be a part of the Paropamisus of the ancients. The city of Candahar, which is both populous and flourishing, is built of a square form, and is comprehended within an ordinary fortification of about three miles in circumference. From its favourable situation on the great road which connects India with Persia and Tartary, this city has long been a distinguished mart of trade. Many Hindu families, principally of the Moultan and the Rajpoot districts, have established themselves here. By their industry and mercantile knowledge, they have greatly increased the trade and opulence of Candahar; and the extensive range of shops which they occupy, and the ease and contentment expressed in their deportment, is a sufficient testimony of the liberty and protection which they enjoy. This city is likewise frequented by the Turcoman merchants of Bucharia and Samarkand, who carry away into their own country a great quantity of the indigo with which Candahar is annually supplied from the various parts of upper India. Provisions are here much cheaper than in most places on the west side of the Indus, and the supply is also more abundant. Candahar stands in an extensive plain, intersected with numerous streams, and covered with fruit gardens and cultivated ground, which produces grapes and melons of the finest flavour. This plain is interspersed with hills near the site of the old fortress, but they are moderately high, and do not form a barrier of difficult access. This fortress, which is about two or three miles north of Candahar, stands on the summit of a rocky hill of moderate height, but abrupt elevation. It was destroyed by Nadir Shah, who founded a new city called Nadirabad. This city was completed by Ahmed, who gave it the name of New Candahar, and intended it for the capital of Afghanistan. The road is here carried over a stony ascent of easy access, and is sheltered on each side with scattered hills and wide intervals of level land. On the road from Ghizni to Candahar, the general aspect of the country is barren, and the supply of wood and water is scanty. From this scarcity of water, the buildings are constructed, as in Cabul, of bricks burnt in the sun, and are covered in with a flat arched roof of the same materials. The climate of Candahar is considerably temperate, and neither equals the heat of India nor the cold of Ghizni.

A son of Timur Shah governs this city and a tract of the adjacent country, which is said to bring in an annual revenue of eighteen lacs of rupees. East Long: 65° 33', North Lat. 33°. See Forster's Journey from Bengal to England, vol. ii. Lett. xiv. p. 115; and Decouverte de l'Empire du Candahar, Paris 1750, 12mo. (o)

CANDIA, the ancient Creta, a rich and extensive island in the Mediterranean Sea, lies between 23½ and 26½ degrees E. Long., and forms as it were a base to the Grecian Archipelago. Its length from its most western coast to Cape Samonium on the east is about 60 leagues; and it is nearly 15 at its greatest breadth, from Cape Sasso on the north to Cape Matala on the south. A chain of mountains, called the White Mountains, or the mountains of Phelachia, traverses the greatest part of the island. During half the year it is covered with snow, great quantities of which are piled up by the inhabitants in deep vales, exposed to the north, where it condenses and hardens, and is then used for cooling their liquors in summer. From these mountains flow numberless streams, which, during winter, are swollen into torrents by the rains, and, in the spring, by the melting of the snow, and rushing with dreadful impetuosity down the steep declivities, do not stop till they lose themselves in the ocean. Many of them, however, are completely dried up during the summer; and the water with which the inhabitants then refresh their lands is drawn from the springs that issue from the bottom of the hills. The coast of Candia is indented with numerous harbours and roadsteads, which afford excellent and safe anchorages. The principal of these are, Grabusa on the west; the bay of Suda on the north; and Palevo Castro on the east. On the south, however, there are few places where a ship can ride in safety.
This island enjoys a most delightful climate, equally removed from excessive heat and violent cold. In summer, the rays of the sun are constantly tempered by refreshing winds from the sea; and during the short period of winter, which begins with December, and ends with January, snow never falls on the low grounds, nor is the temperature ever so low as to require artificial warmth. During this season the rains are frequent, but of short duration; and though the sky is sometimes obscured with clouds, and the north wind blows violently, yet the sun appears almost immediately after the rain, and the atmosphere is often clear and serene. Rain never falls in summer, either in Candia, or in the islands of the Aegean Sea. Vegetation is supported by the copious dews which fall during the night, and which sufficiently refresh such plants as are indigenous to the climate; but all others must be watered, in order to be successfully cultivated. Though Candia is situated under the 35th degree of latitude, yet, in the course of a year's observations, Mr Savary found, that from the month of March to the beginning of November, the thermometer never varied more than from twenty to twenty-seven degrees above the freezing point. But what conduces chiefly to the salubrity of Candia, is the complete absence of those noxious vapours which rise from marshy grounds, and the abundance of salutary plants. The waters never stand here in a state of stagnation; and scarcely is a morass to be found in the island. "The mountains and hills," says M. Savary, "are overspread with various kinds of thyme, and with a multitude of odorous and balsamic plants. The rivulets which flow down the valleys are overhung with myrtles and laurel roses. Clumps of orange, citron, and almond trees are plentifully scattered over the fields. The gardens are adorned with tufts of Arabian jasmine. In spring, they are bestrewed with beds of violets. Some extensive plains are arrayed in saffron. The cavities of the rocks are fringed with sweet smelling dittany. In a word, from the hills, the vales, and the plains, on all hands, there arise clouds of exquisite perfumes, which embalm the air, and render it a luxury to breathe it." This climate has been famous from the remotest antiquity; and Hippocrates, the father of physic, considered it the best restorer of health to his debilitated patients, whom he sent hither to breathe an atmosphere impregnated with such delightful emanations. Under this genial sky the Turks have acquired a taller stature, a more robust make, and a more majestic step, than their countrymen on the continent; and it has been matter of surprise, that the natives, who enjoy the same blessings of nature, should have degenerated both in form and beauty. But the cause may be found in the yoke of that cruel slavery with which they are oppressed, and which has a tendency to degrade the body as well as the mind. They drag out their days in fear and anxiety, and are sometimes hurried by despair to put a violent end to their existence. Their countenances are disfigured with the marks of servility and meanness; and the high-spirited Cretans, once the jealous guardians of liberty and the arts, are now converted into cowardly, abject, and indolent Cretians.

With the exception of the leprosy, diseases in this country are very rare. The victims of this loathsome disorder are driven from society, and prohibited from all communication with healthy persons. They are generally confined to small cottages by the high-way, where they live upon the produce of a little garden, and the alms of passengers.

The salubrity of the climate is equalled by the fertility of the soil, which is capable of producing, in the richest profusion, whatever can delight the senses, or gratify the appetite. Among its spontaneous productions, besides innumerable fragrant flowers and shrubs of the most brilliant colours and dazzling variety, are myrtles, oleanders, walnuts, figs, pomegranates, apricots, almonds, lemons, citrons, oranges, olives, grapes, melons, and cucumbers. The grapes grow here to a very large size, and afford excellent wine, which still preserves its ancient reputation, though it is not made in such quantities as formerly;—the inhabitants of many of the districts preferring to carry their grapes to town, or to dry them for trade. Homer praises the wine of Crete as the best in the world; and Jupiter drank no other nectar during his stay in this island. All Candian wines, however, are of a fiery quality, and apt to fly quickly to the head, and to injure the nervous system. At the foot of Mount Ida, and on the hills in the vicinity of Canea, grows a species of rock-rose, which yields ladanum, or, according to the ancient Greeks, ledon, a resinous substance used for perfumes, and the preparation of certain drugs. It is gathered from the leaves of the plant in the hottest time of the year, and during the greatest heat of the day. Great quantities of it are consumed in the East; and it is a considerable source of employment and profit to the peasants of Candia. Forests of pines, cedars, and fir crown the summits, and cover the declivities of the mountains; and afford an inexhaustible source of materials for ship-building. The coasts abound with fish. The plains are well stocked with plenty of game, particularly red partridges and golden plovers; and the groves and gardens are filled with a variety of singing birds, among which are the laniat, the nightingale, the petty-chap, the gold-finch, the bull-finch, the lark, and the thrush. This last mentioned bird is taken in immense quantities, by the peasants, in the winter season, and carried to market. But the most melodious and valuable is the solitary black-bird, which inhabits the summits of the mountains, and fills the desert with its music. It is called by the Greeks, petro-cockise, "bird of the rocks," and by the Turks, karabou-bowel, "nightingale of the rock." It is in great request throughout Turkey, for its charming melody, and is seldom bought for less than a hundred dollars. But in this rich and delightful country, where the soil requires very little labour from the hand of the husbandman, to produce in profusion the necessaries, and even luxuries of life, the Candian

* Cistus ladaniferus, Linn.

† Le merle solitaire, Buff.—Turdus cyanus, Linn.
Canada, or dare not, appreciate the blessings and
advantages which nature has so liberally scattered
around him. Oppressed by his tyrannical masters—
exposed to insult, to outrage, and even to robbery
from every janizary, he feels no inclination to in-
crease, by labour, a produce which he would soon
have the mortification of seeing pass into the hands
of those whom he has so much reason to hate. In-
dustry, of consequence, is almost extinct in the Greek
villages subject to the Turkish agas. The fields
which their forefathers cultivated and adorned, when
under the mild government of the Venetians, are now
running to waste. The soil is washed away by the
rains; the olive-tree is allowed to perish, and the
vine to disappear; and this unfortunate and degraded
people do not think of repairing the damages which
time has already occasioned, or of preventing future
desolations. It is only the calls of hunger, or the
payment of their taxes, that can incite them to the
least exertion; and they sow their lands, and gather
their olives, with the cheerless prospect, that a part
of the produce must be devoted to their oppressors.
The least appearance of wealth, or even of comfort,
will immediately draw upon them new exactions; and
they are compelled carefully to conceal whatever is
not absolutely necessary for their daily subsistence.
Their very clothes must have the appearance of po-
verty; and when those are renewed, they must be of
the coarsest stuff, and plainest colours, otherwise
they would run the risk of being deprived of them
by the Turks. In the Turkish villages, agriculture
and industry are equally neglected, though from very
different causes. Most of the Turks in this island
are enrolled among the janizaries; and though they
may improve their property, without the dread of
being despoiled of its produce, yet they prefer rather
to depend upon their pay, and the extortions
which, upon every opportunity, they wring from the
industry of the Greeks. The only spot where cul-
tivation is practised with any success, is on the moun-
tains of Sphachia, which are inhabited by a hardy
race, who, though oppressed with the same yoke as
their brethren in the plains, have still preserved the
energy of independence. Habituated to a simple
and industrious life, the Sphachiots is a shepherd, a
farmer, and an artisan. He requires no foreign sup-
plies. He manufactures with his own hands the uten-
sils and implements which he employs, and subsists
upon the produce of his land, and of his flocks, en-
joying, without molestation, the fruits of his labour.
This people, from the first subjugation of the islands
by the Romans, have declined to mix with the na-
tions that have successively occupied their country.
Bred to the use of the bow from their youth, they
are excellent soldiers; but bearing a mortal hatred
to their present masters, several of them disgrace
their courage and their skill, by robbing and murder-
ing such Turkish travellers as they can waylay upon
their mountains.

Were the least encouragement given to agriculture
in this island, and were its advantages of soil and climate
in any degree appreciated by the Turks, it would
soon become the granary of the surrounding nations.
But every species of improvement is here so disgra-
ced and persecuted, and indolence and effeminacy
have so destroyed all spirit of emulation and exer-
tion, that the inhabitants of this fertile region are
compelled to draw from other lands the means of
their subsistence. Public granaries are erected near
some of the principal towns, for containing the corn
which is annually imported from Volo, Salonica, the
Morea, Syria, and Egypt. The few places that are
under cultivation, notwithstanding the deficiency of
proper culture, produce most luxuriant crops. Wheat
is sown after a single ploughing, and they content
themselves with scattering the barley on the stubble,
and then going over it with the plough. Whole
fields are sown with lupins, which is a very common
food with the Candians; but many useful plants,
for which no soil or climate is more propitious than
that of Candia, are almost completely neglected.
The mulberry tree, which thrives wonderfully in this
island, is very scarce; and most of their silk is
brought from Syria. Flax is tolerably plentiful, but
not sufficient for the wants of the inhabitants; and
they draw their cotton from Smyrna, and the envi-
rons of Ephesus. Sesamum occupies some spots in
the plains; but instead of extracting oil from its
seeds, the inhabitants use it only for mixing with their
bread, to give it more flavour. Olive trees, how-
ever, grow here in great plenty; and their fruit is
the chief article, both of the industry and commerce
of the Candians. The annual produce of oil in this
island, in a good season, is estimated at 200,000
milleroles, or 13,200,000 pints, Paris measure.

The ancients asserted, that this happy region, the
birth place of Jupiter, was freed, by the indulgence
of the gods, from every noxious animal. It is true,
no quadrupeds of a ferocious temper belong to the
island. Lions, tigers, bears, wolves, and foxes, are
here unknown. The wild goat is the only inhabi-
tant of the forest and the lofty mountains, and have
nothing to fear but the ball of the hunter. Sheep
overspread the hills and the plains, and graze in se-
curity, undisturbed by their ravenous enemies. Birds
of prey, however, are to be found here, and also
some venomous reptiles. Pliny *, indeed, mentions
the tarantula as an inhabitant of Crete; and Belon
enumerates three species of serpents which were
known here,—the ophis, the ochendra, and the ephlo-
ti †. The tarantula is a kind of spider, about eight
or ten inches in length, with a scaly skin. Its sting
is mortal, and it generally lodges, during winter, in a
deep hole, formed in the declivity of small hillocks;
but, in the summer, it keeps in the air, and spins its
web. M. Sonnini mentions another species of spider,
equally dangerous with the tarantula, which is of the
same size, but lives constantly in subterraneous re-
tracts.

Among their domestic animals are, the horse,
which is of the Barbary breed, but is much neglect-
ed, and ill-used; and has greatly degenerated, both in
form and beauty, from the original stock. They are,
however, strong and nice footed, and traverse, with

* Nat. Hist. lib. viii. cap. 58.
† Belon Observation de plusieurs singulieres et choses memorables trouvées en Grèce, &c.
great facility and safety, the roughest descents over steep and rocky mountains. The dog of Candia is a species of large grey-hound, which, for fleetness and agility, was formerly reckoned the best in Greece, after those of Sparta; but, since the Turks have made themselves masters of the country, this faithful friend of man is repulsed, beaten, and almost starved. Oxen are little used here, except in rural labour, and beef is scarce; hogs are also not very common, but lambs and kids are excellent and cheap, and turkeys and poulterers are in great plenty, and sold at a moderate price. Notwithstanding, however, the abundance of every article of subsistence in this favoured country, the Greeks are obliged to live, through the whole year, on barley bread, salted olives, lupins, and wild plants;*—the most valuable produce of their labour being reserved to discharge their taxes, and to pay the frequent and exorbitant extortions of their Agas.

This island is divided into three pachalkis, or government; viz. Candia, Canea, and Retimo. In the first resides a pacha of three tails, who is seraskier, or commander-in-chief of all the forces in the island. He nominates all military employments, and is entrusted with the inspection of the forts and arsenals. In Canea and Retimo are pachas of two tails, who, except in military concerns, are entirely independent of the pacha seraskier. The power of these officers is absolute within the bounds of their respective provinces. The justice of their decisions are never called in question; and their sentences are instantly carried into execution. As their chief object is to get rich as speedily as possible, they practise all the arts and cruelties of oppression to squeeze money from the unfortunate Greeks, who have become so habituated to misfortune, that they seem to have lost all desire of deliverance. Under these governors are the agas and soubachis, who are appointed over a certain number of villages, and are equally rapacious with their superiors, but still more troublesome inquisitors, being incessantly occupied in setting the inhabitants at variance, and then seizing the property of both. The Greeks have a capitam, or primate, chosen by themselves from their own nation, who acts as a justice of peace, in deciding all private disputes, and in watching over the interests of his countrymen. His opinion is generally submitted to without hesitation, in order to save themselves from the severe and more formidable decisions of the Turkish cadis, to whose tribunal all litigious affairs are carried as a last resort. They have, also, a dascalos, or writer, who keeps a register of all the names of the Greek inhabitants, and of the sums which every one must pay for their carach, and to the aga, after each harvest. Besides these, and other exactions, which are altogether arbitrary, and the amount of which depends upon the population and circumstances of the inhabitants; the Greeks, in common with the Turkish land-owners, are taxed with a seventh of the produce of their lands and of their olives. But what renders their situation most degrading, is the power which the agas assume over their personal liberty and domestic connections. — No married man is allowed to quit the island, unless a mariner or a merchant; and every bachelor, before he is permitted to go and work in the Morea, must pay a tax of sixty paras, or two piaster. No Greek can marry without permission from the aga, and this must be purchased by a present, which, however, is not always successful. Should the young woman please this petty tyrant, he keeps her for himself. The disappointed lover must bear his misfortune in silence. Complaints are unavailing, for the cudgel is always ready to strike the reluctant slave; and should he presume to apply for redress to the pacha or the porte, he would pay for his presumption with his fortune or his life. But so destitute are these unhappy people of every generous feeling or moral sentiment, and so seductive is vanity to the female sex, that it is uncommon for a Greek woman not to be flattered with such an exaltation, which, however, is but of short continuance, for, in a few years, she is turned off to make way for some more fortunate rival, and married to some Greek who dares not refuse her. Such is the shameful slavery in which this country is immersed; and Candia, once famed for the happiness of its inhabitants, and the equity of its laws, and where liberty in a manner took its birth, is now a prey to lawless oppression, and bent under the yoke of a most insulting bondage.

The native Candians are of the Greek church, and are allowed the free exercise of their religion; but are prohibited from repairing their religious houses or places of worship. By costly bribes, however, they obtain permission from the pachas, so far as to prevent them falling entirely to ruin. The island is divided into twelve bishoprics, viz. Gortynia, Cnosso, Mirabella, Hyera, Girapetra, Arcadia, Chersonese, Lambs, Milopotamo, Retimo, Canea, and Cisamo. The bishop of Gortynia is appointed by the Patriarch of Constantinople, and assumes the title of archbishop. He wears a triple tiara, writes his signature in red ink, answers for all the debts of the clergy, and nominates to all vacant bishoprics in the island. He resides at Candia, and is the only Greek who enjoys the privilege of entering the city on horseback.

The situation of this island, as an emporium for commerce, can scarcely be surpassed. Placed at almost an equal distance from Europe, Asia, and Africa, it bears an equal relation to these three quarters of the world, and might be rendered the emporium of their various productions and manufactures; but, like its other advantages, this favourable position for trade is entirely neglected by the Turks, who are utter strangers to industry and the arts; and the Greeks dare not take measures to promote either the public welfare, or their private advantage. The commerce of Candia is, consequently, very insignificant, considering the extent of the island. The principal article of exportation is oil, which, according to Savary, in 1779, employed 24 vessels, of from 100 to 200 tons each, and the value of whose cargoes amounted annually to 2,169,000 livres, or 90,000l. sterling. Nineteen of these ships belonged to Marseilles, and besides oil,

* A list of these plants will be found in Olivier's Travels in the Ottoman Empire, vol. ii. p. 350.
† The carach is a tribute which the Grand Signior levies from all his grown-up subjects who are not Mahometans.
the French merchants, settled at Candia, purchased wax and other articles, to the amount of nearly 80,000 livres. The whole exports of the island he valued at 2,886,666 livres. The oil trade, however, since that time, has been considerably reduced, great quantities of it being now consumed in the soap houses, of which there are 25 at the town of Candia, 20 at Canea, and 8 at Retimo. Though the soap made here is not so good as the French soap, yet it is preferred by the Turks for its cheapness, and now constitutes a most important branch of exportation. It passes to Tunis, Constantinople, and all the towns of the Levant, and also to Venice and Trieste. The other exports of Candia are, wax, honey, cheese, raisins, almonds, walnuts, chestnuts, St John's bread, lintseed, and liquorice-root. The wax is chiefly purchased by the French, and consumed in Europe. A small quantity of honey, and Spahiancheese, to the value of 30,000 livres, pass to Constantinople; raisins, and other fruits, and a small quantity of laudanum, to Egypt, Syria, and the Levant; and lintseed is purchased by the Italians; also some hones, which are likewise sent to Marseilles.

The most considerable of the imports were formerly from France; but the trade with that country has, within the last 20 years, greatly decreased. In 1779, M. Savary says, that the French imported goods into Candia to the value of 550,000 livres, which, according to M. Olivier, who visited the island in 1795, is now reduced to 150,000 livres, consisting of Carcassonne woollen cloths, gilding, lace, and stuffs of Lyons, imperial serges manufactured at Nismes, small shot, tin, iron, steel, coffee, sugar, nutmegs, cloves, indigo, cochineal, paper, and various articles of hardware. From Venice and Trieste they receive glass-ware and hard-ware, but particularly planks for making soap-cases. Their other wood is procured in Caramania or Greece. From Salonica, they draw corn, cotton, tobacco, and iron; from Constantinople, Bursa stuffs, Angora bedsteads, shoes, handkerchiefs, and copper utensils; from Smyrna, hides, Turkish leather, cotton, English shalloons, and some French goods; from Gaza, ashes; and from Syria, corn and silk. Egypt supplies them with linen cloths, flax, rice, and corn. Derna and Bengazi, on the coast of Africa, with butter; and Tunis and Tripoli with caps. In Candia, Europeans pay three per cent. in value of merchandise; the Turks only two and a half; and the Greeks, Jews, and Armanians, five per cent. Their principal manufactures are soap, some cloths in silk and cotton, and in silk and flax, also a few silk strings and ribbands, which are exported to Constantinople.

Among the people who inhabit this island, we may remark the Abadiots and Schachiots. The Abadiots are the remains of the Saracens, who held the dominion of Candia for nearly a century and a half. They are of a middle stature, meagre and swarthly, suspicious and vindictive, and are always armed. Among themselves they speak the Arabic language, and occupy twenty little villages to the south of Mount Ida, forming a population of nearly 4000. The Schachiots, whom we have already mentioned, are the real descendants of the ancient Cretans, and are distinguished from the other Cretians by a majestic stature, a handsome countenance, and a love of liberty. They inhabit the mountains on the south of Canea and Retimo; and, amidst the many revolutions in the government of their country, have preserved their ancient language, their customs, and their laws. The other inhabitants are Turks and Greeks, amounting in all, according to Olivier, to nearly 250,000 souls,—a number very disproportionate to the extent and fertility, or even the ancient population of the island. Crete, celebrated in antiquity for its hundred populous cities, must, upon the lowest calculation, have contained above a million of inhabitants; but, since that time, it has been subjected to the tyranny of the Romans, the ravages of the Saracens, and the depopulation of the Turks; and its depopulation has been gradually decreasing until now. Even in 1779, M. Savary reckons the inhabitants of Candia at 550,200, of whom 65,000 Greeks paid the carach, while M. Olivier, about 14 years afterwards, reduces the number of Greeks subject to this tax to 20,000! Such is the effect of the impudent and oppressive measures of a despotic government.

We are to attempt a circumstantial detail of the various revolutions which this island has undergone since its first subjugation by the Romans, we should far exceed the bounds prescribed for such articles in this work; we intend, therefore, to confine ourselves to the more prominent events, which have brought it to its present degradation. For the ancient history of Candia, we refer our readers to the article CRETE. Before this island was conquered by the Romans, its inhabitants had greatly degenerated from their ancient simplicity and virtue. Elated by power, and enervated by prosperity, they had become turbulent, covetous, and ambitious. The Archipelago was infested with their piratical fleets, which disturbed the tranquillity, and molested the commerce of the neighbouring states; and they continued their depredations, till the Rhodians armed themselves for the general defence, and succeeded in sinking, burning, and dispersing their squadrons. When attacked by the Romans, a spark of their ancient valour still guided them in battle, and it was not till after a long, obstinate, and vigorous resistance, that the Cretans were obliged to yield to the talents and fortune of Quintus Metellus, in the year 66 B. C.; when the laws of Minos were abolished, and those of Numia established in their stead. This island, in conjunction with the small kingdom of Cyrene, on the Lybian coast, was then converted into a Roman province, and governed by a proconsul. It continued under the dominion of the Roman emperors till the beginning of the 9th century, when the Saracens, invited by the beauty and fertility of the island, landed without opposition, and built the strong fortress of Chandak, which afterwards, under the Venetians, assumed the name of Candia. From this citadel, they carried havoc and devastation into the interior of the country; and, notwithstanding the efforts of the emperor Michael Balbus, they soon made themselves masters of the whole island. Repeated attempts were made, both by Michael and his successors, to expel the Saracens from Crete, but without success; and it was reserved for the Emperor Nicephorus Phocas to deliver
this fine island from the yoke of the infidels. After various encounters in the field, he drove them to their fortresses, which he successively reduced, and in 912 took Chandak, their last resources, with their king Curup, and his lieutenant Aremas, prisoners. The island was again united to the empire, of which it continued to form a part till the taking of Constantinople by the Crusaders, when Baldwin, count of Flanders, being raised to the throne, bestowed it, with several other islands in the Archipelago, upon the Venetians in 1204, as a recompense for their important services during the war. Under the wise and liberal government of the Venetians, the commerce and agriculture of Candia soon began to revive; and in a short time it became a most flourishing conquest. The Genoese, jealous of the growing prosperity of their sister republic, excited the Candians to revolt; and promised them powerful succours. Some of their chief men, accordingly, appeared in arms; but, though powerfully supported by the Genoese, they were unable to withstand the bravery of the Venetians, who soon reduced them to obedience, and divided the whole island among the nobility, upon condition that they should maintain it at their own expense, pay an yearly tribute, and acknowledge the sovereignty of the mother country. The peace of the island being re-established, it continued with little interruption till the middle of the 17th century; when the Turks, who had made several attempts upon Candia, obtained by perfidy, what they could not accomplish by open force. During the preparations of a mighty armament which was to be employed against this island, the emperor of Constantinople deceived the Venetian ambassadors with the most solemn assurances, that Malta was the object of attack, and that the republic might be under no apprehensions for the safety of her possessions. He even loaded them with presents, and directed his fleet to bear for Cape Matapan, as if they were bound far west of the Archipelago. But in the midst of his protestations of amity, the Turkish fleet, consisting of 400 sail, with 60,000 troops on board, entered the bay of Canea, in 1645. The Venetian governor, Corarno, who had made no preparations for their reception, was awakened from his seeming security only by the intelligence of their descent upon the island. A body of 3300 infantry, and a small number of cavalry, were the only force he had to oppose to this powerful armament; and his distance from Venice deprived him of all hope of a speedy reinforcement. The Turks having seized the forts upon the island of St Theodore, invested the city of Canea, whose garrison consisted only of 1000 regular troops. These, however, being strengthened by 250 more, which Cornaro found means to throw into the city, made a most desperate resistance. Monks and women appeared upon the walls among the defenders; and for two months they held out against the mighty power of the Turks. Despairing at last of relief from Venice, with three breaches in their walls, and reduced to 500 men, exhausted with fatigue and covered with wounds, they made an honourable capitulation, and marched out of the city with the honours of war. Twenty thousand Ottomans was the sacrifice which the Caneans had exacted for the loss of their city.

The fall of Retimo soon succeeded, with the death of Cornaro, who fell in the ranks of his soldiers, with boldly opposing the approach of the Turks to that city; and the victors sat down before Candia in 1646. Many heroic deeds of valour were performed before this city, and its siege is one of the most memorable recorded in history. For two years, the Turks made little or no progress. They were routed in many desperate and bloody encounters, and sometimes compelled to retire to Retimo, in order to recruit their shattered forces. In the mean time, the plague had been introduced into the island by some Turkish reinforcements, and had spread with such rapidity, that many of the inhabitants fell before its fury, and others, to escape its ravages, had fled into the Venetian territories on the continent. Candia was thus in a manner depopulated; scarcely a Greek was to be seen in the open country, for such as had escaped from the pestilence took refuge in the different fortresses; and the Turks themselves had suffered so much, both by disease and the sword, that they were compelled to raise the siege in 1649, and retire to Canea. But in the following year, they were enabled, by the arrival of fresh troops, to renew the siege, which they prosecuted with such vigour, that they soon made themselves masters of one of the advanced forts. This being turned against the city, proved so troublesome to the besieged, that they were obliged to blow it up. The Venetians, however, had now got possession of the sea. The Ottoman fleets had been defeated in several engagements, and their supplies were every year intercepted in the Straits of the Dardanelles. Depressed by some severe losses, and the want of succours, the Turks had converted the siege of Candia into a blockade; while the Venetians, on the other hand, elated by success, attempted the recapture of Canea in 1660, which, however, when about to surrender, was snatched from their grasp by the appearance of the Pacha of Rhodes, who having escaped the Venetian galleys which were stationed to intercept him, but which were becalmed off Cape Spada, reinforced the defenders with two thousand men. The Turks were now commanded to appear again before Candia, and to make every possible effort for its reduction. For six years, however, their efforts were unavailing, and it was not until they had been reinforced by a formidable army under the Grand Vizier, and supported by a numerous artillery, that they made any impression upon the Venetian works. A rapid demolition now commenced. All the exterior forts were destroyed; and the walls battered by incessant discharges of cannon, gave way on all quarters. The Turkish troops, encouraged by the presents and promises of their chiefs, performed prodigies of valour; and during one year (1667) it is recorded, that 500 mines were blown up; 18 combats were fought in the underground works; 17 sallies were made by the besieged; 32 times the city was assaulted; and 20,000 Turks and 3000 Venetians fell in the contest. The Caneians, however, though reduced to the most dreadful extremities, were still undismayed, and held out for three years more against all the forces of the Ottoman empire. Succours from France, under the Duke of Noailles, had animated their hopes. But
the first sally of their new allies was discouraging and disastrous, and soon led to the surrender of their city. The command of the former hope had been entrusted to the Duke of Beaufort, admiral of France. He advanced furiously against the enemy, and attacked him within his trenches; but in the midst of the engagement, a magazine of powder was set on fire, when Beaufort and the flower of the French leaders disappeared for ever. The soldiers fled in disorder, and the Duke of Noyelles with difficulty effected a safe retreat within the city. The French accused the Venetians of treachery, and prepared to reimburse. Their departure determined the fate of Candia, which, after a siege of 24 years, surrendered to the Turks. Of more than 50,000 Christians that had entered this city since the beginning of the siege, 500 only remained; and above 100,000 Ottomans perished at the foot of its walls. The Grand Vizier entered Candia on the 4th of October 1670, and the whole island submitted to his dominion, except the forts of Sude, Grabasa, and Spina Longa. These continued in the possession of the Venetians until 1715, when they were reduced by the Turks, who have remained masters of the island ever since.

Besides the division of this island into governments, these are subdivided into provinces, which we shall content ourselves at present with merely enumerating. In the government of Canea are Kissamos, Selino, Cydonia, and Apocorona; in the pachalic of Retimo are Retimo, Aion-Vassali, and Amari; and in that of Candia are Sphachia, Candia, Nilo-Potamo, the island of Stan-Dia, Messara, Mirabel, Hera-Petra, and Settia. (See Savary's Letters on Greece, p. 203, &c.; Olivier's Travels in the Ottoman Empire, vol. ii. p. 266, &c.; and Somnitt's Travels in Greece and Turkey, p. 209, &c. (p))

CANDIA, the capital of the island of Candia, and from which the island derives its name, is situated on a beautiful plain, watered by the river Ceresa. It is supposed, both by Savary and Sonnini, to occupy the site of the ancient Heraclea; but Olivier rather refers it to port Panormus, which, according to Ptolemy, lay between Cyzicus and Hermiaca. It received its present name from the Saracens, who, on their first arrival upon the island, built the fortress of Chandak, which, in the Arabic language, signifies "entrenchment," and which was converted by the Venetians into Candia.

This city, which is of a semicircular form, and about four miles in circumference, is strongly fortified by walls, ditches, and advanced works; and its approaches by sea are defended by a strong wall, built on rocks, and mounted with several pieces of cannon. Its streets and squares are regular and well built, and are evidently the work of the Venetians; but several divisions of the city are void of inhabitants, many of whom, together with the foreign merchants, have removed to Canea. It is, however, still the residence of the Pacha Seraskier and his military council, which consists of a kyama or lieutenant, an aga of the janissaries, two commanders of the artillery, a treasurer-general of the imperial revenues, a keeper of the imperial treasury, and the chief officers of the army. Of the many beautiful churches built by the Venetians, three only are now possessed by the Christians, the handsomest having been converted into mosques. The Jews have a synagogue here, and the Capuchins a small convent. The harbour of Candia is naturally a fine basin, securely sheltered from every storm; and, if properly cleared, would contain from thirty to forty sail of merchant vessels. But the Turks, by their general improvidence, have allowed it to be so choked up with mud and sand, that boats and the small banks of the country only can enter it; and the docks and arsenals, which were constructed by the Venetians for building galleys, and putting them under cover when laid up, are also allowed to fall fast into decay. Ships that load at this port must take in their cargoes at Stan-Dia, a small island about four leagues off, and opposite to Candia, where the goods are conveyed in boats, and where there are three capital road-steads in its south quarter. From this inconvenience, the trade of Candia, which was so extensive and flourishing under the Venetians, is now almost annihilated; and with its trade have also fled the majority of its inhabitants. Its population scarcely amounts to 14,000, of whom 2000 or 3000 only are Greeks, and 60 Jews. Candia is chiefly famous for its sieges; for which, see the preceding article, and the references subjoined to it. N. Lat. 32° 19', E. Long. 25° 18'. (p)

CANDLE is an article so well known in domestic economy, as to render any description of it entirely superfluous. The term is obviously derived from the Latin candela, and that from candere, to burn. Candles are by no means a modern invention, though lamps seem to have been chiefly used by the ancients for domestic purposes. Mention is made of something like candles, both of tallow and wax, and not unfrequently of pitch. The wicks were originally small cords; afterwards the papyrus and the pith of rushes were used. But the ancients seem at no time to have been able to produce an article in any degree to be compared with the candles of modern times.

Candles, as we shall notice afterwards, may be manufactured from a great variety of substances, but those chiefly employed are tallow and wax.

1. Tallow Candles. Candles made from tallow are either dipped or moulded. The first kind are the candles in common use, and have been long known in commerce; the second sort is a more recent invention, and claimed by a Parisian. We propose to give our readers a short account of the mode of manufacturing both kinds.

The tallow employed by the candlemaker consists chiefly of ox and sheep tallow. That obtained from the hog is rarely used, on account of the bad smell which it has in burning, as well as a thick black smoke; but chiefly on account of its being easily melted, a quality of the very worst kind, as will be shown afterwards.

The first part of the process of candle-making is to sort the tallow. Sheep-tallow, with a portion of the best ox-tallow, is set aside for the moulded candles. Candles made principally from sheep-tallow have a better gloss and firmer texture than those which are manufactured wholly from ox-tallow. This last kind, with the inferior pieces of sheep-tallow, are used for making dipped candles. The quality of the candles depends as much upon the care and clean-
Candle.

Candle.

ness with which the tallow is collected by the butcher, as upon the species of animal from which it is derived; but, even where the greatest care is employed, parts of the tallow must necessarily be mixed with impurities, which cannot afterwards be completely separated from it. The extensive manufacturer will therefore select not only the tallow for the finer candles, and for those of common use, but will separate from his stock the inferior pieces of tallow, and such as are mixed with impurities, in order to dispose of them to the inferior dealer. After the tallow is properly sorted, it is then put into a wooden vessel and cut into small pieces preparatory to the first melting, which, in the technical language of the workmen, is called rendering. Much depends upon this operation being performed as soon as possible after the tallow comes from the hands of the butcher. If the tallow is allowed to remain for several days exposed to the action of the air, which must often happen to the inferior dealer, who receives his tallow in small quantities, and at considerable intervals, part of it will corrupt and infallibly injure the whole mass; but if the tallow is rendered soon after it comes from the slaughter-house, it may be kept for months or years, and even improved by keeping, provided the temperature is moderate. The object of this operation, is to separate from the tallow the skin and fleshy parts which always adhere to it, and expel, by evaporation, the aqueous particles or other liquids which are combined with it. With this view, the tallow, after being cut into small pieces, is thrown into a large boiler, and heat gradually applied. As the tallow melts, new portions are added; and particular care is taken to stir it frequently, in order to prevent the more solid parts from adhering to the bottom of the vessel. After boiling a considerable time, the more solid parts collect at the surface in the form of a cake, which is called the crackling; part of the liquids have been driven off by the boiling, and the remainder subsides to the bottom after the boiling ceases. The cake is then put into a strong press, and a great pressure applied, in order to extract from it every particle of tallow; it is afterwards set aside to be sold for food to dogs and other animals. The liquid tallow is now taken from the boiler and put into an adjoining vessel, by making it pass through an iron sieve, by which means any of the solid parts which have not united with the cake are separated from the liquid mass. Still, however, many foreign substances will remain blended with it. In order to purify it still more, the tallow is now put into another vessel, and a certain quantity of water mixed with it. The water being specifically heavier than the tallow, sinks to the bottom, and carries along with it any impurities which may have escaped the operation of the sieve. After standing a sufficient time for the impurities to settle, this tallow is transferred, by means of tinued iron buckets, into tubs of a moderate size, and allowed to congeal. It is then taken out of the tub in a solid state, and piled up for future use. In transferring the tallow from the large vessel into the tubs, great care must be taken not to agitate it too much, lest the slidy matter collected at the bottom rise and mix with it again. To prevent this inconvenience, the workmen usually cease emptying the vessel when they come within an inch or more of the slindy matter, which they readily discover by its muddy white colour. The residue of the tallow is allowed to remain in the vessel during the night, and in the morning it is taken out in a solid state, and set apart to be re-melted with new tallow.

From this statement, it appears, that in the preparatory process of rendering, water is an indispensable requisite; and that in one stage or other of the process, it must be mixed with every portion of the tallow. We are at a loss, therefore, to understand the meaning of that caution uniformly given to candlemakers by our fellow Encyclopedists, not to mix water with the tallow intended for the three first dips. To those who have seen the gross impurities which are disengaged by the water, it must appear obvious that water, or some other agent of a similar nature, must be employed to remove those foreign substances, which, if allowed to remain blended with the tallow, would produce consequences far more destructive to the candle than the spitting, of which they seem so much alarmed. But, in this case, there is certainly no occasion for a balancing of evils; for, if the water, after being mixed with the tallow, be allowed to subside, and if the tallow be taken off in the manner above described, scarcely any moisture will adhere to it; and whatever may happen to remain, will infallibly be driven off by the new boiling, preparatory to its being used for making either dipped or moulded candles. This caution seems to have been suggested by a practice not unusual with the small manufacturer, of putting water into the dipping mould in order to supply the want of tallow. In this case, the caution is certainly well-timed, and highly deserving of attention, but quite inapplicable to the trade in general, who, it is to be supposed, have no necessity for having recourse to such expedients.

After having sorted and purified the tallow in the manner above described, the candlemaker now proceeds to cut and arrange the wicks, which, with the exception of such as are intended for the coarser dipped candles, are made of fine spun cotton. The cotton usually employed is chiefly obtained from Turkey, and comes into the hands of the candlemaker in the form of skeins. Four or more of these skeins, according to the intended thickness of the wick, are wound off at once into bottoms or cluses, and afterwards cut by means of a very simple machine, into pieces of a particular length, corresponding to the size of the intended candle. Before putting the wicks into the moulds, or placing them on the sticks for dipping, it is usual to dress them, by slipping them between the fingers and thumb, with the view of laying the threads smooth, and removing knots and such foreign substances as might injure the candles. Even after "this dressing," it is difficult, in consequence of the shrinking of the cotton, to keep the wicks, when placed upon the broaches, completely separate from each other. To obviate this inconvenience, it is usual to take a great number of wicks into the hand, and dip them into melted tallow. After rubbing them between the palms of the hand, and allowing the tallow which adheres to harden, they may be arranged with perfect ease upon the broaches.
We shall now describe the process of dipping and moulding. The dipping-room is furnished with three important pieces of apparatus, viz.: a boiler for melting the tallow, the dipping-mould, and a large wheel for supporting the broaches. The first part of the process must obviously consist in remelting the tallow, which had been previously rendered and set aside in a solid state. The expense and trouble of remelting is sometimes saved by commencing the operation of dipping immediately after the rendering, or before the tallow cools; but the saving thus effected is not to be compared with the advantage gained by employing tallow of different ages. We are told, that a mixture of tallow recently rendered, with some of ten or twelve months standing, is the best for making either dipped or moulded candles. The melted tallow, after being carefully skimmed, is transferred into the dipping mould by means of ladles or small buckets, in such quantities as may be required. The dipping-mould is nothing else than a box of an oblong form, lined with lead, of about three feet in length, two in breadth, and two feet in depth, erected on a frame at such a height as to suit the convenience of the workman, who sits on a chair beside it. To the extremities of the box are sometimes attached two leaves or boards, to receive the droppings of the candles as they rise successively from the dipping-mould. This additional piece of apparatus may, however, be dispensed with, provided the workman is careful to raise the tallow in the liquid mass; or, what is to the same purpose, to allow the suspended drops again to touch the surface of the tallow. To prevent the tallow in the dipping-mould from freezing, or becoming less liquid than the process requires, it is usual, in some manufactories, to place a chaffing-dish below the dipping-mould, for the purpose of keeping the tallow at the proper temperature. When the tallow is kept very hot in the adjoining boiler, and when the process of dipping proceeds with such rapidity as to occasion a constant renewal of the tallow in the dipping-mould, it will be found that a chaffing-dish is quite unnecessary, except in very cold weather. At each supply, however, of new tallow, the workman ought to be careful to remove from the sides of the vessel whatever may have hardened in the interval. Things being thus arranged, the workman, according to the first plan of dipping, takes into his hands three sticks or broaches, on which has previously been suspended a certain number of wicks, corresponding to the size of the candles intended to be made, and keeping them at an equal distance from each other by means of his second and third fingers, he immerses the wicks two or three times in the liquid tallow, and then hangs the rods upon a rack to cool. The same operation is repeated several times, till the candles acquire the proper thickness. With the view of facilitating the process of dipping, and in order to diminish the fatigue of the workmen, the following improvement, we are told, has for more than fifteen years been practised by the London manufacturers. From the ceiling of the workshop is suspended a long beam in the shape of a balance, to one extremity of which is attached a wooden frame for holding the broaches with the wicks arranged at proper distances: the opposite arm is loaded with a weight to counterbalance the wooden frame, and to enable the workmen to ascertain the proper size of the candles. The end of the lever which supports the frame (it is almost unnecessary to observe) is placed immediately above the dipping-mould; and the whole machine is so adjusted, that, by a gentle pressure of the hand, the wicks are let down into the melted tallow as often as may be required. After the first dipping, the frame is removed and hung up to allow the candles to cool, and the same operation is repeated till the candles acquire the proper size. It is obvious, that the only advantage gained by this improved method, is a small increase in the number of broaches, and a partial diminution of the labour of the workman. Much delay is still occasioned by the tardy system of cooling; and the necessity of removing the frame after each dipping is certainly a great inconvenience. Many of these disadvantages, we think, are completely removed by the following method, which has been practised for several years in Edinburgh:

In the centre of the dipping-room is erected a large upright shaft AA, which turns easily on its two extremities. See Plate CVIII. Fig. 8. Near the middle of the shaft are cut, at small distances from one another, six mortises, into each of which is inserted a long bar of wood BB, which moves vertically upon an iron pin also passing through the middle of the shaft. The whole presents the appearance of a large horizontal wheel with twelve arms. A complete view of two of them only is given in the figure. From the extremity of each arm is suspended a frame, or port as the workmen call it, containing 6 rods, on each of which are hung 18 wicks, making the whole number of wicks upon the wheel 1296. The machine, though apparently heavy, turns round by the smallest effort of the workman; and each port, as it comes in succession over the dipping-mould, is gently pressed downwards, by which means the wicks are regularly immersed in the melted tallow. As the arms of the levers are all of the same length, and as each is loaded with nearly the same weight, it is obvious that they will all naturally assume a horizontal position. In order, however, to prevent any oscillation of the machine in turning round, the levers are kept in a horizontal position, by means of small chains aa, one end of which is fixed to the top of the upright shaft, and the other terminates in a small square piece of wood b, which exactly fills the notch c in the lever. As one end of the levers must be depressed at each dip, the square piece of wood is thrown out of the notch, by the workman pressing down the handle D, which communicates with the small lever e, inserted into a groove in the bar B. In order that the square piece of wood fixed in one extremity of the chain may recover its position upon the workman's raising the port, a small cord is attached to it, which passes over a pulley inserted in a grove near c, and communicates with another pulley and weight, which draws it forward to the notch. In this way, the operation of dipping may be conducted by a single workman with perfect ease and regularity, and even dispatch. No time is lost, and no unnecessary labour expended in
Candle.

Candle.

removing the ports after each dip; and, besides, the process of cooling is much accelerated by the candles being kept in constant motion through the air. The number of revolutions which the wheel must make in order to complete one operation, must obviously depend upon the state of the weather and the size of the candles: but we are told, that, in moderately cold weather, not more than two hours are necessary for a single person to finish one wheel of candles of a common size. Upon the supposition, therefore, that six wheels are completed in one day, no less a number than 7776 candles will be manufactured in that space of time by one workman.

It is of the greatest consequence, both for the purposes of commerce, and with a view to levying the duty, that a certain number of candles should regularly amount to a definite weight, and consequently that the operation of dipping cease at the precise time when the candles have attained this weight. In order to ascertain this important point, the workman, when he thinks the candles have nearly acquired the proper size, lifts one of the broaches from the end of its lever, and hangs it upon the arm of a balance placed beside him, whose opposite scale has been previously loaded with the proper weights.

We shall next describe the process of moulding, which, if possible, is even less complicated in its details than that of dipping. The moulds are made of some metallic substance, usually pewter, and consist of two parts. The shaft, or great body of the mould, is a hollow cylinder, finely polished in the inside, and open at both extremities. The top of the mould is a small metallic cup, having a moulding within side, and a hole to admit the wick. The two parts are soldered together; and, when united, as will readily be imagined, have the shape of a moulded candle. A third piece, called the foot, is sometimes added: it is a kind of small funnel, through which the liquid tallow runs into the mould, and being screwed to the opposite extremity of the shaft, is removable at pleasure. This additional piece may certainly be useful in very mild weather; since, by removing it, the candles may be drawn more easily from the moulds; but, in general, it may be dispensed with. It is seldom used, and indeed is scarcely known in any of the large manufactories of Scotland.

Twelve or sixteen of these moulds, according to their size, are fixed in a frame, which bears a great resemblance to a wooden stool, the upper surface of which forms a kind of trough. The top of the moulds points downwards; and the other extremity, which is open, is inserted into the bottom of the trough or top of the stool, and made quite level with its upper surface. In order to introduce the wicks into the mould, the workman lays the frame upon its side on an adjoining table, and holding in his left hand a quantity of wicks, previously cut to the proper length, he introduces into the mould a long wire with a hooked point. As soon as the hook of the wire appears through the hole in the top of the mould, he attaches to it the looped end of the wick, and immediately drawing back the wire, carries the wick along with it. In this manner each mould in succession is furnished with a wick. Another workman now follows, and passes a small wire through the loop of each wick. This wire is obviously intended to keep the wick stretched, and to prevent it from falling back into the mould upon the frame being placed in the proper position for filling. The frame is now handed to the person that fills the moulds, who previously arranges the small wires in such a manner that each wick may be exactly in the middle of the mould.

The moulds are filled by running tallow into the trough from a cistern furnished with a cock, and which is regularly supplied with tallow of the proper temperature from an adjoining boiler. When the workman observes that the moulds are nearly half filled, he turns the cock, and laying hold of that portion of the wick which hangs out of the mould, pulls it tight, and thus prevents any curling of the wick, which might injure the candles. He then opens the cock, and completes the process of filling. The frame is now set aside to cool; and when the tallow has acquired a proper consistence, which the workman easily discovers by a snapping noise emitted by the candles upon pressing his thumb against the bottom of the moulds, he first withdraws the small wires which kept the wicks tense, and then scraping off the loose tallow from the top of the frame with a small wooden spade, he introduces a bodkin into the loop of the wick, and thus draws each candle in succession from its mould. The candles are now laid upon a table for the inspection of the exciseman, and afterwards removed to the storehouse. Previous to storing them up, some candle-makers bleach their candles, by exposing them to the air and dews for several days. This additional labour can be necessary only when the dealer is obliged to have early sales; for if the candles are kept for some months, as they ought to be, before they are brought to market, they become sufficiently whitened by age.

Besides the common dipped and moulded candles, a kind of candle intended to burn during the night without being snuffed, is also made of tallow. These candles are usually called rush-lights, from the wick being made of split rushes.

II. Wax candles. Next to tallow, the substance most employed in the manufacture of candles is wax. Wax candles are made either by the hand or with a ladle. In the former case, the wax being kept soft in hot water, is applied bit by bit to the wick, which is hung from a hook in the wall; in the latter, the wicks are hung round an iron circle, placed immediately over a large copper tinned basin full of melted wax, which is poured upon their tops, one after another, by means of a large ladle. When the candles have, by either process, acquired the proper size, they are taken from the hooks and rolled upon a table, usually of walnut-tree, with a long square instrument of box smooth at the bottom. As the candles must be rolled one by one, in order to preserve their warmth, and keep the wax soft, those made with the ladle are laid, previous to the rolling, in a feather-bed folded in two, at convenient distances from one another. The same precaution is not so necessary with the candles made by the hand, as they may be rolled just as they are formed. Besides the common cylindrical
form, wax candles are sometimes made of a conical figure, and are intended chiefly to illuminate churches, and to be used in processions and funeral ceremonies. The pyramidal form is given them, by pouring the wax upon the wicks at different heights; the three first ladles are poured on at the top of the wick; the fourth ladle at the height of three-fourths; the fifth at one-half; and the sixth at one-fourth. Candles of this shape, after being rolled and smoothed, have their big end cut off, and a conical hole made in it to receive the point in the candlestick. There is still another kind of wax candle, or taper, said to be the invention of Pierre Blossimere de Paris, and brought by him from Venice about the middle of the 17th century. The process consists in making a wick, of some yards in length, pass several times through a brass bason of melted wax, and at the same time through the holes of an instrument like that used for drawing wire, by means of two rollers of wood turned by a handle.

We shall now give an account of the different improvements which have been suggested upon the manufacture of the common candles, and mention some of those substances which have been proposed as substitutes for tallow and wax. It will be necessary, however, previously to explain the process of burning in candles, and to state the comparative advantages of the two substances usually employed.

The wick of the candle being always a combustible substance, readily catches fire upon the application of a flame. The heat thus produced fuses a portion of the tallow, or wax, which immediately rises through the fibres of the wick by a kind of capillary attraction. The melted matter, as it approaches the flame, is gradually volatilized and set on fire; a new portion of melted tallow, or wax, ascends in the same manner, and is, in its turn, heated and burned: and in this way a constant combustion is maintained. A candle differs from a lamp, chiefly in the circumstance, that the tallow, or wax, is melted gradually, and in small quantities, and is retained in a cup formed by the solid part of the candle. As this cup must obviously be of very small dimensions, it is of the last consequence that the quantity of matter melted never exceed the power of the wick to absorb it, otherwise the candles will gutter. The size of the wick, therefore, must always be proportioned to the fusibility of the substance employed; the more fusible substance obviously requiring the larger wick. Of the two substances commonly used, wax is the least fusible. Tallow melts at 92° of Fahrenheit, spermaceti at 139°, and bleached wax at 155°. The flame of wax is less brilliant than that of tallow, which is supposed to be owing to the wax being already combined with a portion of oxygen. This disadvantage, however, is more than compensated by its being less fusible; by which means a smaller wick may be used, which not only affords the advantage of a clear perfect flame, but, in consequence of its flexibility, it naturally falls to one side, and, by thus coming in contact with the air, is burnt to ashes. The wick of the tallow candle being much larger, preserves its position in the centre of the flame, which is less perfect, from its internal part not being completely exposed to the action of the air. As the burning proceeds, the wick lengthens, and, consequently, the distance between its top and the point of the flame diminishes; from which it follows, that the oil which issues from the extremity of the wick, having a smaller portion of flame to pass through, will be less perfectly burnt, and will pass off partly in smoke. The wick soon rises above the top of the flame; but, owing to its size, and the quantity of oil which it contains, it is not converted into ashes, and dissipated, as in the case of the wax candle. On the contrary, the half decomposed oil is converted into a kind of coal, or soot, which gradually accumulates upon the top of the wick, and assumes the appearance of a fungus. In order, therefore, that a tallow candle may burn with any degree of clearness, constant snuffing is requisite.

From the above statement, it appears, that the chief difficulty in improving the burning of the tallow candles, arises from the great fusibility of the tallow. Several attempts have been made to remove, or at least to lessen, the evil, but none of them have completely succeeded. If it were possible, by means of some chemical agent, to produce such a change upon tallow, as to raise its melting point several degrees, and there is reason to believe, that some such change is produced in wax by the absorption of oxygen; this, certainly, would be the most direct method of removing the evil. Several chemists, and, among others, Mr Nicholson, have engaged in experiments with this view; but we are not aware that their success has been in any degree equal to the importance of the object sought after. As a substitute for this desideratum, it has been proposed to strengthen the cup by covering the tallow with a thin coating of wax. A candle of this kind, called lobcock, is known at Canton in China. Mr Nicholson informs us, that he attempted to imitate this Chinese candle, by pouring a quantity of wax into a mould, and immediately pouring it out again before running in the tallow. In this way he covered the tallow with a thin film of wax; but owing, perhaps, to the wax naturally contracting more than the tallow in cooling, or to the sudden cooling of the wax before the tallow was poured in, he found, upon drawing the candle, that it was cracked longitudinally on its surface. At any rate, it is not at all likely, when we consider the additional labour and expence connected with the manufacture of this species of candle, that it will ever become an article of general use.

The next expedient employed, was to make an artificial cup; which, in fact, is nothing else than burning the tallow in a lamp. With this view, a hollow brass tube is attached to the top of a cylindrical piece of tallow, or a candle without a wick. The upper aperture of the tube is partly closed with a ring, in the centre of which is inserted a small metallic piece, nearly resembling that part of the common lamp which carries the wick, with which it is also provided. The tube rests upon the upper extremity of the candle, and is so nicely adapted to its size, that it slides gently down as the tallow consumes. The flame produced in this way is brighter, and more uniformly intense, than that of a candle of
the same size, and is, at the same time, free from all disagreeable smell; but it was found, that the heat acquired by the metallic piece, during the combustion, fused more tallow than the wick could take up; and, consequently, that part of the melted tallow flowed down between the candle and the brass tube, and, upon cooling, fastened them together in such a manner, that the gradual progression of the tube, and the necessary supply of tallow, was obstructed.

An invention, upon a similar principle, was proposed, about twelve years ago, by Mr William Bolts of London, for which he obtained a patent. The great object of this invention, is to get rid of the trouble of constant snuffing, and to prevent the running of the candles. To accomplish this, he employed a solid candle, or cylindrical piece of tallow, to the top of which he applied a small wick, by means of a projecting spring. The wick was kept in contact with the upper surface of the candle, either by making the wickstand pass round the candle like a collar, and slide down by the pressure of a spring, or, by making the wick immovable, and putting a spring at the bottom of the candlestick, which presses the candle upwards as the tallow is consumed. Instead of a solid candle, he sometimes used one having a perforation longitudinally; on the top of which he placed, for a wick, a small tuft of cotton; to the lower end of which was attached a thread, which passed down through the perforation to the bottom of the candle, and was wound round a key, or pivot. By turning this pivot, the wick is brought down as the candle consumes. In this way, the wick being kept constantly soaked in the melted tallow, consumes very slowly, and, consequently, supersedes the necessity of snuffing. The size of the wick may also, by this contrivance, be proportioned to that of the candle, and the fusibility of the material employed; while, by the action of the spring, or pivot, the flame may be made to approach or recede, as circumstances require. This contrivance, however, requires too much attention for common use, and is obviously too complicated. The only other attempt at improving the wick, which deserves notice, is that of the candlemakers of Munich, who use a thin slip of wood bound round with unspun cotton to the thickness of a small quill. These slips are made of pine, willow, and other kinds of wood, but most commonly of fir. They are prepared by first scraping off the bark, and reducing them to the size of a small straw. They are then rubbed over with wax or tallow, and afterwards rolled on a smooth table, on very fine carded cotton. When they have acquired the proper size, they are introduced into the moulds, or hung on the dipping frame, as formerly described. These candles, we are told, besides burning longer than the common ones, do not blaze, and are less prejudicial to the eyes of those who are accustomed to read or write at night. They must be snuffed with a pair of sharp scissors, and great care must be taken not to break or derange the wick.

Various methods of purifying the tallow, and rendering it more firm and compact, are described in the Dictionnaire de l'Industrie, under the article Chandelle. In all these processes, alum seems to be the chief agent, to which is sometimes added nitre and sal ammoniac. In order to give tallow the appearance of wax, quicklime is used in purifying it, and sometimes vinegar. The tallow thus prepared, when mixed with an equal portion of wax, makes very beautiful candles. Several attempts have been made to deprive tallow of the bad smell, but none of them have completely succeeded. A decoction of rosemary, sage, laurel, and wild mint, has been used; and the powder of charcoal has been suggested: the former, however, it is likely, only conceals the odour without removing it, and, at any rate, could scarcely be employed on a great scale; the effect of the latter, as far as we know, has not yet been ascertained.

In the Archives des Découvertes, published at Paris in 1810, M. Bonnatins announces a new method of purifying tallow, by which it is deprived of all colour and humidity, and may be kept for several years without becoming either yellow or rancid. The process is kept a secret; but M. Vauquelin has examined the tallow, and his report is favourable. The candles made from it are distinguished by the purity of their light, and the absence of smoke, but chiefly by their not running, and their requiring to be seldom snuffed.

We have already mentioned, that tallow, purified with quicklime, is sometimes mixed with wax, in order to improve the candles, or, rather, to diminish the price. In the Journal de Paris for 1787, is announced the discovery of a new species of wax candles, made of wax and the pulp of potatoes. The wax extracted from the fruit of the waxtree, when mixed with a portion of common wax, or, what is better, with tallow, makes excellent candles, which diffuse an agreeable odour in burning. Candles have also been made of the butter of the cocoa-nut, and of an oil extracted from the brain of the whale, which, after being exposd to the air, soon acquires a considerable degree of consistence. Candles made of the latter material are covered with a slight varnish; and those made from the cocoa bean with a clear steady flame, and last much longer than tallow candles.

We shall conclude our remarks with a short abstract of the excise laws respecting candles.

These laws relate chiefly to four points, viz. the license for making and selling candles; the additional duty levied by the weight; the checks upon smuggling; and the penalties to be exacted for neglecting or opposing the provisions of the act. The license to make wax candles is L. 6, and L. 1 for tallow candles. The license to sell is 10s. 6d., and both must be renewed annually; but those who take the license for making, are not obliged to take the license for selling also during the same year. The additional duty upon wax candles is 3½d. per lb. and that on tallow candles 1d. The checks upon smuggling consist in allowing the excise-officers to lock up and seal all furnaces, moulds, &c. made use of in the manufacture of candle, and to open them only upon notices from the manufacturer: these notices to be given in at the head office six hours, in a city or market-town twelve hours; and elsewhere within twenty-four hours before they are to be used. The penalties in general are L. 20, L. 50, and L. 100; but never exceed the last sum.
CANDY. See Ceylon.
CANE. See Sugar.

CANA, a seaport town of Candia, lies on the north side of the island, at the eastern extremity of a large bay, and is supposed to occupy the site of the ancient Cydonia. Canea is of an oblong figure, about two miles in circumference, and defended by a strong wall, and a broad and deep ditch cut through a bed of rock. It has four bastions on the land side, and a raveline at the north-east corner. Towards the sea, on the left of the harbour, are four batteries mounted with heavy cannon, and, on the right, is a strong wall extending along a chain of pointed rocks, at the extremity of which is an old castle now falling into ruins. The streets are straight and spacious, the squares are adorned with fountains, but there are no buildings in it worthy of notice. The houses are mostly of one story, with flat roofs forming a terrace; and some of them, which are contiguous to the harbour, are adorned with balconies, which command an extensive prospect of the bay. The town is intersected by many groves, on which are planted the native vines, the most famous of which is the <i>Crétes</i>, one of the varieties of <i>Canedon</i>.

In the neighbourhood of Canea are some fine forests of olive trees, intersected with cultivated fields, orange groves, vineyards, and gardens. The rocks are covered with the famous dittany of Crete, so celebrated by the ancients, which is gathered by the peasants into small bundles, and brought to market. Near this town are huts erected for the accommodation of lepers, who subsist upon the produce of a small garden, and the alms of passengers; and on the side of the highway are exposed the bodies of criminals, who have undergone the dreadful punishment of emplacement. "They are ranged," says M. Sonnini, "on each side of the road; and in this dreadful rank are seen men, whose body is longitudinally transfigured by a stake, some dead, others expiring, some smoking their pipe with as much sang-froid as if they were sitting on cushions, railing at the Europeans, and living, as long as twenty four hours, in the most excruciating torments." North

CANNABIS, a genus of plants of the class Dicocoe, and order Peuceandria. See Botany, p. 335.

CANNÆ, in ancient geography, a small town of Italy, situated on the river Ausidus in Apulia, not far from the sea. The traces of Cannæ are at present very faint, consisting of a few fragments of walls, gates, and altars, with some excavations. Even the river seems to have degenerated from its ancient grandeur,—its sounding stream, so much celebrated by the poets, being, when visited by Swinburne, but a tame muddy rivulet. The embankments, however, by which its embankments are restrained, sufficiently attest its force in winter, when it is swelled by the mountain torrents. Cannæ is chiefly remarkable for the battle fought in its vicinity, between Hannibal and the Romans in the second Punic war. This great engagement, which nearly annihilated the power of Rome, and which, in that case, would have totally altered the destinies of the world, was fought in the year of Rome 536, before the Christian era 216.

After the battles of Trebia and Trasimenus, in which the flower of the Romans perished, nothing short of madness could have prompted the senate and people to oppose to the victorious veterans of Hannibal their raw tumultuary levies, however numerous and brave. Fabius Maximus accordingly adopted the wise policy of procrastinating the war; and contenting himself with a moderate number of troops, took care never to lose sight of the enemy, but at the same time not to come to a regular engagement. By this mode of warfare, the only one that has ever been successful in similar circumstances, the Carthaginians, in an enemy's country, were speedily thinned by the sword, famine, and disease. In proportion as the Romans increased in numbers and experience, the invading army was diminished and disheartened; and so nearly was Hannibal worn out by this plan, that his
mercenarys were on the point of deserting, and he himself entertained the project of escaping into Gaul with his cavalry alone. But his affairs were destined soon to be followed by the foolish impatience of the Roman populace. A few successful encounters, hazard'd contrary to the injunctions of Fabius, raised the spirits of the giddy rabble to such a pitch of frenzy, that they now began to impeach the courage and even integrity of Fabius, to demand a new system of war, and to look out for generals of a more enterprising description. Even the senate became infected with these sentiments; and though they made some opposition to the election of Varro, a headstrong fiery character, and gave him for his colleague Paulus Aemilius, a man of the same description as Fabius, they undeniably empowered these two consuls to seek the enemy, and bring the war to the issue of a general engagement. The preparations made for this event were such as Rome had never before witnessed. Each of the four veteran legions already in the field, was recruited to the strength of 5000 foot, and 300 horse. In addition to these, four entirely new legions were organised, consisting of the same number as the former; and the whole being joined by an equal number of auxiliary foot, and twice the number of horse, a magnificent armament was thus quickly formed of about 88,000 combatants, of whom 7200 were cavalry. Hannibal's army was only 50,000 strong, composed chiefly of Gauls and Spaniards; but of these, 10,000 were cavalry in the highest state of discipline. This superiority of the Romans in point of numbers, was more than counterbalanced by the inexperience of their troops, and by the opposite dispositions and unbecoming quarters of the two consuls. Varro, all eagerness for engaging, and Aemilius, attached to the Fabian system, soon found it utterly impossible to carry on a joint command. From a partition of the troops, they were impossibly deterred by the recent disastrous example of Fabius and Minucius: they therefore resolved on the equally dangerous expedient of taking the supreme command each his day alternately.

When the two consuls came up with Hannibal, whom they had followed from the north, they found him encamped near the village of Canne, but on which side of the Aufidus is uncertain. Their first care, as usual, was to fortify a camp, which they pitched not far from Hannibal's, on the same side of the river; and to secure a free communication with the opposite bank, they pushed across a strong detachment, who fortified themselves in a lesser camp on the other side. It is probable, however, that the river was at this season, which was summer, easily fordable in most places, and that it presented no other obstacles than those arising from a rugged channel and steep banks. To Hannibal, who was apprised of every transaction within the Roman camp, the consular dissensions augured well; and on the hot temper of Varro he resolved to practice some of his old artifices. With this view, he ostentatiously offered battle, insulted the enemy by every means in his power, and while he thus encouraged his own troops, who were at first terrified by the amazing numbers of the Romans, he succeeded in bringing on what was necessary to him in his present embarrassed circumstances, a general engagement. By a trivial event, he completely exhausted the patience of Varro; for after having repeatedly insulted the greater camp of the Romans, he dispatched a party of Numidian horse across the river, who falling suddenly on the watering parties of the lesser camp, drove them with great slaughter before them, and advanced to the very ramparts. Had Aemilius not happened to have the command this day, Varro would have crossed the river instantly to revenge the affront; but this measure he was compelled to put off for a few hours longer, by the authority of his colleague, who was entire averse to a general action.

Next morning's dawn discovered to the eyes of both armies the red flag, the signal for battle, flying over the tent of Varro; who immediately after conducted his forces across the Aufidus, and joined them to those from the lesser camp. Aemilius seeing now that all opposition was fruitless, accompanied Varro to the field, and, like a faithful soldier, seconded all his measures. The reasons which determined Varro to this movement with his main body, seem to have been both the desire of a position better adapted for his infantry, in which his chief strength lay, and the consideration, that on that side Hannibal had no camp to which he could retire in case of a defeat. The whole Roman army, with the exception of those left to guard the two camps, being now united, was drawn up by the consuls in the following array. In the right wing were posted the knights, the flower of the Roman cavalry, having their right flank protected by the river, and their faces turned to the south. Next came the legions, drawn up, on this occasion, in one very deep compact line, on account of the smallness of the space for such a multitude, and probably the better to resist the shock of cavalry. On the left of the legions were drawn up in similar array, the whole body of the allies, having their own numerous cavalry posted on their left, who terminated, on that hand, the general line. An advance or first line was composed of the light infantry, armed with bows, slings, and javelins. The two consuls commanded the wings, Aemilius the right, and Varro the left, and to Servilius, a consul of the preceding year, was committed the conduct of the centre.

During these proceedings among the Romans, Hannibal was not idle. As soon as he discovered their intention, he hastened to meet them beyond the Aufidus, on the ground which they themselves had chosen for the field of battle. Sending over his Balearic slingers and other light troops before him at break of day, to cover his passage, he himself soon followed at the head of his regular forces, which were conducted into the field according to their intended stations. While his men were coming up, Hannibal rode forward to an eminence with a few attendants, in order to reconnoitre the enemy, whom he found already ranged in order of battle. Gisco, a Carthaginian nobleman, observed to him, with symptoms of alarm, that the number of the enemy was very astonishing; Hannibal, with a serious countenance, told him, that there was something yet more astonishing; "for," said he, "in all that immense army, there is not one man whose name is Gisco!" This unexpected jest made all the company laugh, and soon produced a si-
The disposition of Hannibal’s army was regulated, in a great measure, by the arrangement of the enemy. On the left extremity of his line, and nearest the river, were posted the Gaulish and Spanish cavalry, as being best calculated to cope with the Roman horse; on the right extremity were the Numidian cavalry, excellent in pursuit, though not firm enough for a shock, but altogether proper antagonists to the social cavalry of the Romans. Between these two wings extended his main line of infantry, which was so arranged, that the African foot, who were heavy-armed, composed both its extremities; while the Spanish and Gaulish infantry, who were not so regularly armed, occupied the centre. The light troops were a little in advance, before the main battle. By this disposition Hannibal had two objects in view; to oppose corresponding descriptions of force to the Roman line, and to break down and intermix his various nations, so as to make them a check upon each other. Having assigned the left wing to Hasdrubal, and the right to Maharbal, he himself, with his brother Mago, commanded the centre. Livy affords us a most lively view of this various assemblage of nations, when drawn up in line, and ready for battle. The Africans, he tells us, might well have been mistaken for a Roman army, being equipped with the armour of the Romans, vanquished in the battles of Trebin and Trasimenus. The shields borne by the Gauls and the Spaniards were nearly of the same form; but the swords of these nations were dissimilar. The swords of the Gauls, like those of our own ancestors the Caledonians, were excessively long, and without point; while those of the Spaniards, who were accustomed more to thrusting than to cutting, were remarkable for their shortness and their sharp points. The general appearance of these two nations, conspicuous for the gigantic size of their bodies, and their barbarous aspect, was terrible to the view. The Gauls were naked from the waist upwards; the Spaniards were dressed in linen habits of a surprising whiteness, the effect of which was magnificently increased by a rich border of purple.

In the direction of his line, as well as in the choice of his ground, Hannibal was evidently compelled, in some degree, to conform to the arrangements of Varro, who had first taken his station in the field. This being the case, the left of the Carthaginians touched the river, their line ran parallel to that of the Romans, and their faces were turned to the north, independently of the foresight of Hannibal, who yet is mentioned by Plutarch as having drawn up his men, so as to have the wind Vulturums to their back, while that hot and suffocating wind blew clouds of dust into the eyes of the Romans. The meridian sun, and the wind Vulturums, were indeed in his favour; but the merit was not his, for Varro, who had overlooked and probably despised these advantages, had forced them unavoidably upon his antagonist. Some difficulties have been started by Chaupy, respecting what quarter the armies faced, founded on topographical considerations, and the direction taken by the fugitives after the battle. But it is abundantly obvious, that a rapid stream flowing through a sandy plain, and restrained at present from changing its course only by mole and embankments, must have occasioned, in the space of 2000 years, many alterations in the aspect of the vicinity; and also that in a tumultuary engagement, bodies of men may escape in all directions. In our opinion, the expression of Polybius is no more equivocal than that of Livy. As the Aulius runs generally in a north-easterly direction, we must suppose such a large elbow as Swingborne observed in the vicinity of Canne, in order to make the armies, while their faces are turned respectively to the north and south, to have each of them an extremity resting on the river. But the supposition of that traveller is altogether inadmissible, that Hannibal, after fording the stream, drew up his men within the bending of the river in front of the Romans, his troops forming the chord, of which the river in his rear was the arch. In this case, Hannibal would have had both his wings resting on the river, a circumstance never before heard of; and his danger, in the estimation of every military man, must have been prodigiously increased by his entangled position.

Both armies being drawn up as we have described them, the light troops on either side raising, as usual, a great shout, began the battle. Soon afterwards, Hannibal ordered his Spanish and Gaulish horse, the best in his army, and stationed as already mentioned on his left wing, to attack the Roman knights. This terrible conflict, as Livy observes, was not in the usual style of equiteman engagements; for confined on one side by the river, and on the other by the infantry, the horsemen were compelled to rush straight forward against each other, and to fight man to man; and when the horses were so crowded and intermixed that they could scarcely move, the soldiers pulled each other from their seats, and continued the action on foot. The veteran horsemen of Hannibal at last prevailed. Most of the knights were slain upon the spot, and the remainder pursued and dissipated by Hasdrubal. This general immediately wheeled round to the right wing, routed in a short time the cavalry of the Roman allies, and dispatched the Numidian horse in pursuit.

While this awful prelude was going on, the regular infantry on both sides drew near to try their strength. The Romans seem to have received the onset, and to have continued with one straight front till actually engaged. But Hannibal ordering his heavy-armed Africans, who comprised the extremities of his infantry, to stand still, moved forward in person at the head of the main body, composed of the Gaulish and Spanish infantry. The centre of this body was considerably advanced beyond its flanks, which however still rested, like the extremities of a great arch, on the heavy-armed Africans. The great superiority of the Romans, who were nearly double his numbers, had obliged Hannibal to extend, and consequently to weaken his infantry. This weakening, however, of his line, we have reason to believe, was confined exclusively to the prominent part of it in the centre, the Africans being firm and compact in their array. It was the singular glory of Hanni-
bal on this occasion, to have converted his deficiency of strength into the cause of victory. Well aware that his barbarous auxiliaries, arranged in a thin line, could not long withstand a regular shock of heavy-armed infantry, his intention was most clearly, from the beginning, to encourage the Romans to break through his centre, and thus expose themselves on their flanks. Accordingly, after the advanced Gauls and Spaniards had fought most desperately for some time, they began at last to give way; and this body, which originally presented a convex line to the enemy, was now bent in the contrary direction, and embraced the advancing Romans in the form of a half moon. These thinking to overwhelm Hannibal at once, pushed on with irresistible fury, and drove him before them with shouts of victory. Varro and Æmilius appear to have been carried along with the soldiery by the blindest presumption; for instead of securing their flanks, and overturning the Africans in their course, they seem to have concentrated their troops, for the purpose of entirely breaking through the enemy, and attacking him in the rear. This movement proved fatal to the Romans. The Africans, who had hitherto stood still, were now closing on the Roman flank, while Hasdrubal and his victorious cavalry was ready to fall upon their rear. Vigorously attacked on both sides, the consul made their men face different ways; but the contest was no longer equal, the Africans were quite fresh and in order,—the Romans, already exhausted with fatigue, were also in the utmost confusion. The return of Hannibal with his Gauls and Spaniards, whom he had soon rallied, made it no longer a battle but a carnage. Fighting hitherto with the greatest bravery, and performing all that could be expected from high spirited men, the Romans were now at length utterly broken and routed. The Carthaginian cavalry, in which arm Hannibal was stronger, acting on a plain, and in the midst of a disorderly crowd of flying enemies, allowed few to escape; while the infantry, in like manner, exasperated by their fatigue and their habitual enmity, revelled with savage eagerness in the work of destruction. Hannibal himself was at last so much touched with compassion at the fate of the Romans, that he cried out several times during the slaughter, "Hold, soldiers! spare the vanquished!"

The fate of the consul, Æneas Æmilius, as described by the ancient writers, is truly affecting. This brave captain had been severely wounded early in the day; but his zeal would not suffer him to quit the field till most of his troops were cut to pieces. At this last extremity, in the hopes of restraining the pursuit, he ordered the few cavalry who still kept by him to dismount, and engage the enemy on foot. This slender band, however, was soon overwhelmed by the impetuous enemy, and every man who was able mounted his horse, and fled. During this melancholy exigency, Cneus Lentulus, a legionario tribune, happening to ride that way in his retreat, espied the consul sitting on a stone, and covered all over with wounds and blood. The generous tribune immediately offered him his horse, observing that he could help him to mount, and protect him. But Æmilius, with an air of grandeur, declining his offer, advised him to make use of his small time for escaping, expressing, for his own part, his fixed resolution to expire on those heaps of his dead soldiers, by whom he was surrounded. He, at the same time, rejoined the tribune to advise the senate to fortify Rome with all speed, and to assure Fabius that he had lived. And was now dying, impressed with the wisdom of his counsels. Before Lentulus had gone far, he observed, with the keenest anguish, the noble consul surrounded, and still feebly fighting in the midst of the enemy, who were not then aware of his quality. The other consul, Varro, escaped to Venusia, attended only by seventy horse.

This was perhaps the greatest defeat that the Romans ever experienced, not excepting that from the Gauls. Of an army of near 90,000 men, not more than 4000 escaped directly from the battle; some thousands more of those who had guarded or reached the camps, availed themselves of the darkness and confusion of the following night, to reach Cannausim, a strong fortress in the neighbourhood. Besides the consul Æmilius, two quaestors, and one-and-twenty legionary tribunes; there fell, on this fatal day, Servius, the third in command, Minucius, consul and general of the horse under Fabius, fourscore senators, who had volunteered their services, and such a prodigious number of knights, that of the rings which they wore as the badge of their order, three bushels were sent to Carthage. Polybius makes the general loss amount to 70,000, though Livy reduces it to 50,000. The loss of Hannibal was comparatively trifling, consisting only of 4000 Gauls, 1500 Spaniards and Africans, and 200 horses.

Having allowed his troops the whole of that night for the purpose of repose, he employed the next morning in going over the field of battle, and gathering the spoils. The scene was horrible beyond description, even to the Carthaginians themselves. In the course of the day, he besieged the two camps, which were still defended by about 10,000 men, chiefly wounded, who almost immediately surrendered by capitulation. It is difficult to assign the true reason, which had deterred this matchless general from making an attempt on Rome immediately after his tremendous victory. But having consumed some days in the neighbourhood of Canna, the favourable opportunity was lost for ever. The consul Varro was already posted at Canusium, with the wreck of his army, now accumulated to 10,000 men; the senate and people of Rome, after the first transports of terror were over, now spoke more loftily than ever; the city was put in a formidable state of defence, and assistance hastening from all quarters; and with a force of less than 30,000 infantry, destitute of magazines, machines, and other necessaries of war, Hannibal could not pretend to besiege a city in form, which still contained more soldiers than he had under his command. His subsequent feeble attempts on some small towns, demonstrate incontrovertibly the insufficiency of his means for undertaking the siege of Rome at this period. The battle of Cannae, however, though not involving in its consequences the immediate destruction of Rome, was notwithstanding highly beneficial to the Carthaginian cause. He, who before that great event was a mere fugitive in an enemy’s country, having neither
CANNIBALS, is an appellation given to those savages who feed on human flesh.

Much incredulity has been displayed concerning the existence of men who could devour their own species, and the fact has been considered so abhorrent to the laws of nature, so offensive to the Deity, and so improbable in itself, that the possibility of it has been keenly denied. It has been maintained also, that loathsome diseases would be generated by feeding on human flesh, and that inevitable destruction would follow; for such were the consequences of compelling animals of the same tribe to subsist on each other, that they either became ferociously mad, or wasted away and died. Yet it must be admitted, that the opinions of those who have argued in this manner have resulted, more from their aversion to credit such an atrocity, as degrading to mankind, the chosen work of the Creator, than from philosophical considerations. Authentic history, and present experience, equally prove, that there are not only cruel and sanguinary races of cannibals, but that, even among the more civilized part of mankind, individuals repeatedly resort to banquets of human flesh, in situations of extreme necessity.

A belief in the existence of cannibals has prevailed in all ages of the world; and, in the writings of the ancients, we find whole tribes, or nations, characterised as men eaters. Herodotus, Mela, Strabo, and Pliny, speak of such, either from their own knowledge, or the report of others, and describe the particular regions in which they dwelt. Herodotus, who is entitled to the greatest credit, from the extent of his travels, the accuracy of his observations, and especially because the modern investigations of his geography have given it corroboration, alludes to a nation, apparently in India, called Callaitè, or Callantice, who regularly killed the more aged among themselves, and devoured their bodies. The ancient Scythians, also, by almost universal concurrence, seem to have been considered cannibals; and Strabo, on the authority of Ephorus, relates, that they ate human flesh, though they abstained from that of animals.

Herodotus speaks of an adjoining tribe, separate and distinct from the Scythians, using a peculiar language of their own, but wearing similar apparel, who were the rudest of mankind. They led a rural life, obeyed no laws, acknowledged no superiority, and fed on human flesh. Such national characteristics must be viewed as different from those accidental circumstances, which, from temporary revenge, or necessity, have induced mankind to devour their own species. The Jews, in the time of Trajan, for example, are stated to have exercised unheard of cruelties; they are said to have killed 40,000 men in Egypt, Cyrene, and Cyprus; to have fed on their flesh, be-

smeared their faces with their blood, and clothed themselves in their skins: yet they do not come under the denomination of cannibals.

In Europe, however, there are strong indications of their existence, long subsequent to the Christian era. St. Jerome, in his writings against Jovinian, plainly declares, that it was the custom of some of the British tribes, or those from Britain in another country, to feed on their own species. Though his description of the people is not void of obscurity, his words can admit of no doubt. "Why should I refer to other nations, when I myself, while a youth in Gaul, have seen the Atticotti, a British tribe, eating human flesh? Should they find shepherds tending their herds of swine, or cattle, and flocks of sheep in the woods, they are wont to cut off the fleshy parts of the men, and the breasts of the women, which are esteemed the most delicious food." St. Jerome lived in the fourth century. But to descend still lower, we find traces of the same barbarous custom in Scotland, at a far later period. During a war with England, the "men of Galloway" committed the most horrible atrocities. They not only slaughtered the innocent, without distinction of sex or age; but they cut out the bowels, devoured the flesh, and drank the blood of their victims mixed with water. Their ravages were carried far into the country, until the invaders were met, and defeated at the battle of the Standard in 1138.

Perhaps this is the last instance of such savage barbarity known in Europe; and here we can trace the customs of the Scythians, from whom the inhabitants of these kingdoms are by many believed to have sprung. The Scythians drank the blood of their enemies, and made drinking cups of their skulls. There was a certain festival at which none could drink who had not killed an enemy; and it at length became connected with religious rites, as well as being a token of conquest. Livy relates, that the Boii, availing themselves of a victory which they had gained, cut off the head of the Roman general Postumius, and having set his skull in gold, deposited it in a temple for consecrated libations. It can scarcely be doubted, therefore, that in former years cannibals were known in Europe, and it is probable that the tribes of Britain may be ranked among the number.

This sanguinary and repulsive custom has, for centuries, been confined to the African and American continents; for we do not know, with certainty, that it has been found in Asia strictly so denominated. Though many have been inclined to consider the narratives of the earlier European navigators to America as in this respect fabulous, cannibals were recognised there from the time of Christopher Columbus. Intelligent observers, who resorted thither, either for a permanent or temporary residence, about the middle of the sixteenth century, have detailed the whole of the barbarous ceremony, and with such intrinsic evidence, that we cannot reject their testimony. It does not appear, however, that human flesh was an ordinary means of subsistence; on the contrary, the enemies taken in open hostility, or by stratagem, were alone sacrificed by the victors. Many superstitious ceremonies were practised on the occasion; the victim was reserved until a certain time,
Cannibals.

sometimes remote from the period of his capture; and, in the mean time, he was copiously fed, and allowed sufficient exercise. As his fate approached, his face and body were painted with mystic lineaments, which were also impressed on the club that was to give the fatal blow. He was confined the night previous to execution in a hut specially built for the purpose, which, after his removal, early next morning, was thrown down. But these preparations, and others which followed, were insufficient to inspire him with the fear of death: he continued to congratulate himself on the mischiefs which he had already been enabled to inflict on his enemies, boasted of the prowess of his nation, and foretold the vengeance that they would take for his death. He beheld, without emotion, the fire, and the surrounding hordes invited to partake of the bloody repast, and stood undaunted to receive the blow which was to terminate his existence.

In the feast which followed, we find a lively picture of the descriptions contained in Homer; and if that poet had lived subsequent to the days of Herodotus, we could, under some modifications, have traced them to the historical truths which he records. The poetical fictions which are employed to embellish the adventures of Ulysses are also founded on the general belief of the times. The body of the victim being carefully washed and skinned, was cut into quarters, and the flesh was immediately devoured, roasted or half boiled, amidst savage rejoicings. Here, the women acted as conspicuous a part as the men; they were employed in the mystic ceremonies, and they witnessed the execution, and participated in the banquet with equal indifference. When it was their misfortune to suffer, they shewed the same fortitude that was exhibited by warriors. John Lery relates an instance that came under his own notice, of advising a woman, who was about to be massacred, to pray to heaven; she replied that it was unnecessary, and that she laboured under no apprehension of death.

The same custom has been practised down to the present day, though it is now greatly declining. Father Hencpin, and M. Laborde, observe, that the Caribs were cannibals when visited by them in the latter part of the seventeenth century; and that they frequently carried the hand and foot of a slaughtered enemy along with them. M. de Belleisle, a French officer, was taken prisoner, in 1719, by the Atakapas, a tribe near the Gulf of Mexico, who fed on human flesh. As he displayed the utmost repugnance to this practice, they deceived him into a participation of their repast, which was common at that time, but which is now altogether eradicated from among their descendants. That the South Sea islanders were cannibals during the voyages of discovery from this country, is attested by Captain Cook; and there is some reason to believe that the body of that celebrated navigator was devoured at Owhyhee. Such was unquestionably the fate of one of his cotemporaries, M. Marion de Fresne, who had been sent out from France with a native of Otaheite, brought over by M. Bougainville. Having reached the bay of islands in New Zealand, he entered into an amicable correspondence with the natives and their chiefs. Mutual civilities were unremittingly interchange during

the 53 days that he lay at anchor on the coast; the natives slept on board of his vessel; and the seamen, after wandering about on shore in safety, or penetrating the interior, were regularly conducted to the beach by the islanders. At length, M. de Fresne, accompanied by 17 people, embarked in his long boat, and was received on shore with the accustomed demonstrations of friendship. But while resting in perfect security, and when all his party, unsuspicous of treachery, had separated, they were suddenly attacked by the natives, and the whole, except a single seaman, were inhumanly massacred. The unhappy victims were immediately ripped up, cut into quarters, and distributed among the ferocious assailants, in sight of their comrades, who lay concealed among some brushwood during the tragic scene. The French were not slow in avenging the death of the sufferers: they landed in force, and proceeded to the principal village, from which the inhabitants fled on their approach; but there they obtained too conclusive evidence of what had passed. In the hut of the chief was found a human skull, of which some remaining flesh still bore the marks of the teeth of the cannibals; part of a human thigh was also seen on a wooden spit, about three-fourths of which had been devoured; and human entrails, which are said to be considered a delicacy, appeared ready cooked. The village of these barbarians was then reduced to ashes, and their canoes also burnt.

It was known, indeed, before this period, that the New Zealanders were cannibals. They had acknowledged to Captain Cook that they devoured their enemies, but considerable incredulity respecting it prevailed. They had also admitted to Mr Savage, who visited them in 1805, that in times of scarcity they had been obliged to eat human flesh; yet their manners were more favourably viewed than they merited, as has been recently exemplified by another catastrophe like the preceding. A British ship repaired to New Zealand in 1809, for the purpose of purchasing timber, and an amicable correspondence, as before, was entered into with a chief. He was received on board with great respect; and, on one occasion, the captain, accompanied by part of the ship's company, attended him on shore. The chief soon returned, and when those who were necessarily occupied in the vessel least suspected treachery, he gave a sudden yell, upon which his companions immediately began to massacre the unfortunate crew. Ten or twelve who had precipitately ascended the rigging on the first appearance of danger, were deluded by promises of safety to come down; yet, on reaching the deck, they also were cruelly butchered. The captain and his companions had been previously dispatched by the natives on shore; and, of the whole, no more were preserved, than a woman, two girls, and a boy, who some time afterwards were rescued. Thirty or forty men thus fell a sacrifice to the savages, and their bodies were devoured. These, among other instances, forcibly prove that savages can never be trusted; that they are all cruel and ferocious; and that they only wait for the moment when their superiority may prevail over the unsuspecting victims.

The natives of New Caledonia have been represented by some voyagers, considering them in their
most pacific state, as a race endowed with gentleness and docility. Yet experience proves that they are cannibals to as great an extent as the New Zealanders. They were seen by the navigators sent out in search of La Perouse, in 1793, devouring human flesh; and a portion roasted, which proved to have belonged to a young person of 14 or 15 years of age, was offered to one of their number. The natives acknowledged that they relished such an exquisite feast, and with their teeth greedily tore the remaining sinews and ligaments from a bone. A skeleton, bearing the marks of fire, hung from a post beside the door of a hut, which was found to be the remains of an unfortunate wretch who had been devoured. The natives explained, in an unequivocal way, how they proceeded to a repast on the bodies of their enemies; and maintained, that these were the only victims whom they devoured. After the victim fell under repeated strokes of a club or javelin, the belly was ripped up with an implement made of a hard sharp edged stone, specially adapted for the purpose; and then, with another implement of human bone, also prepared for the occasion, the entrails were drawn out. The legs and arms being next severed at the joints, were distributed among the combatants, to be carried home as food for their families. The muscular portions of these members were esteemed particularly delicate; and, indeed, the same cannibals grasped the fleshy parts of their visitors with an eagerness and avidity, clearly demonstrating the gratification which they should enjoy from making a meal of it.

It is possible that the continual wars in which petty states or inconsiderable islands are involved, may render the inhabitants more ferocious; for all human passions only lurk in concealment, and are ready to be excited into action. During a war in Tongataboo, in the year 1799, independent of devouring the dead bodies, the women were seen, after a battle, licking their hands which had been dipped in the blood of the slain. In those which have been called the Friendly Islands, the natives are as savage as in those islands where warfare is known to prevail without intermission: whence, it is to be concluded, that cannibal practices are far more widely diffused than has hitherto been supposed.

Nearly about the same period that the catastrophe above related happened to the British vessel at New Zealand, a scene as sanguinary and horrid was passing at the Fijee islands. Several Englishmen at that time being taken prisoners by a warlike chief, who aimed at conquering all the neighbouring territories, were retained to witness the progress of his arms. An immense fleet of canoes sailed from his principal residence, and was met by one brought out by his opponents to guard their island; but after a long and obstinate conflict, the latter, overpowered by numbers, forsook their vessels, and leaping into the sea, escaped by swimming ashore. Only one boy was taken, who being presented to the relentless savage, was dispatched by three blows of a club, and his body given in charge to an attendant, to be roasted for him. But this did not satisfy his vengeance; he resolved to extirpate his enemies, by massacring the helpless women and children who could not accompany their husbands and fathers in their flight. A shocking carnage ensued, wherein all were butchered on the spot by the furious assailants, without distinction of age or sex, or were dragged half dead into the canoes, where they breathed their last. When the cruel object was completed, no less than 42 corpses were extended on the platform of the canoe which the chief commanded, and delight was pictured in every countenance at the horrible banquet which was to follow. The body of a young female principally attracting his attention, he ordered it to be laid aside for himself and his second in command: a fact which coincides with what is told of some barbarous leader who, on a march, always carried young women along with him, who were occasionally sacrificed for his food. The dead bodies were accordingly conveyed home with the invaders, and deprived of the limbs, which were hung up on trees, and ready to be cooked. Twenty or thirty men afterwards appeared with baskets full of human flesh, half roasted, which is the method adopted for preserving it, and the English were urged to partake in the succeeding repast.

The ancient and modern existence of cannibals is, therefore, too satisfactorily proved, ever to be again called in question.

It is difficult to account for the origin of so barbarous a practice as that of devouring human flesh, though men may be conducted to it by imperceptible gradations. Those tribes which are of the rudest manners, and sunk lowest in the scale of civilisation, can scarcely be accused of participating in it; for the cannibals presently known are rather nations verging towards improvement, and animated by the desire of conquest.

Feeding on human flesh may have resulted either from necessity, or from some religious ceremonial; and it may gradually have been adopted as a token of personal prowess. Where the culture of the soil is neglected, and a scanty sustenance precariously obtained, mankind are exposed to long and severe privations. To quell the cravings of hunger, tight ligatures are bound around the body, and lumps of unctuous earth greedily swallowed. If an animal be killed, its blood is drank, and its flesh is devoured raw; and the meal is repeated as often as occasion will allow. Under the pressure of necessity, therefore, while the savage makes a necklace of the teeth of his fallen enemy, or ornaments himself with his bones, it is less unnatural that he should at once give an-unquestionable proof of his prowess, and satisfy the cravings of nature, in making a repast on his flesh. From some principle of religion or duty, it is well known, that certain tribes expose their aged relatives, or those labouring under incurable disease, to inevitable death. They are said, as we have already seen, to have fed on them of old; and there is still a tribe dwelling on the island of Sumatra, who, from a religious rite, devour the flesh of their kindred. Human sacrifices are yet offered up to the deities of savage nations; portions of the flesh are presented; and libations of the blood are raised to the lips of the bystanders.

It is not long since the Araucanians sacrificed a
CANNIBALS.

CANNIBALS, who, and nor it Hjcronymus, and the primary object among men, that some one of a number shall suffer death, that his body may be the means of supporting the rest. Of this, several deplorable instances have been witnessed in sieges and distresses at sea. During the former, soldiers have sustained themselves on the bodies of their fallen comrades; as in that of Sancerre, in 1572, where parents even fed on the bodies of their deceased children. Cases of the latter are more general, from unexpected circumstances, and the difficulty of providing against accidents, where no resource is to be obtained. Confining ourselves to instances of modern date, it may be observed, that the Nottingham, an English vessel, was wrecked, in 1710, on a rock called Boon Island, on the coast of America. This happened in the depth of winter; the place was utterly desert; and, in a short time, two of the crew perished of want. The body of one was committed to the waves; but the strength of the miserable survivors being inadequate to remove the other entire to a distance, whenever it was dragged without the tent which sheltered them, they began to appease their hunger on the raw flesh, for they were destitute of fire. Thus they subsisted, until they were discovered by strangers. In another vessel, which endured dreadful sufferings from famine at sea, in the year 1765, a negro on board was shot, and his flesh broiled, to supply the necessities of the seamen. But this being all exhausted, it became necessary that one of the crew should die by lot; and accordingly the victim was preparing for his latter end, when a ship came in sight. In 1797, the slaves of a ship from the coast of Africa having risen upon the crew, their only chance of escape was by leaping into the boat and cutting her adrift. Twelve in this manner were saved; who, after eating everything they could swallow, including their clothes, were obliged to resort to the dreadful expedient of devouring each other. At length having cast lots, the first victim resolutely resigned his life, only requesting to be bled to death, which the surgeon, who had his case of instruments about him on quitting the vessel, proceeded to do. But no sooner had he touched the vein, than he applied his lips to drink the blood as it flowed, and his companions quickly made a repast on the flesh. Yet, from immediate indulgence, it did not contribute to their general preservation, for only three survived when the boat drifted ashore at Barbadoes, on the thirty-eighth day after they had left the ship. A similar calamity occurred, and the same resources were employed, in 1799, by six men who had lost their course in a boat from St Helena. Being nearly a month at sea, and having suffered incredible distress from hunger and thirst, four of the number proposed to sink the boat, that an end might be put to their misery. But this being objected to, they agreed to cast lots which should be slain for the subsistence of the rest, and that the person on whom the lot fell should bleed himself to death. Accordingly one who, being sick of a scarlet fever, was exempted, formed the lots; and he by whom the fatal one was drawn, cut his veins in three different places, the wrist, foot, and hand. Praying forgiveness of heaven, he died in about a quarter of an hour. The others supported themselves on his flesh, until they reached the coast of South America. So lately as the year 1807, when the Nautius asleep of war was wrecked on a barren rock in the Mediterranean, and most of the crew dashed to pieces or drowned, the body of one was resorted to for the preservation of the survivors. Numerous other instances might be quoted, which clearly illustrate that the repugnance naturally excited amidst abundance, may be conquered under the pressure of necessity: nor has it ever been remarked that human flesh is unpalatable food.

But there is one most singular fact invariably concomitant on indulging this cannibal appetite, which is well deserving of consideration. It is uniformly attested by persons in opposite parts of the globe, under various climates, in different circumstances, and where they could have no knowledge of each other’s experience, that an uncommon degree of ferocity is speedily generated by feeding on human flesh. A more forcible picture can scarcely be drawn than in the words of the commander of a vessel cast away on a desert shore, whose crew were compelled to adopt such means to preserve their miserable lives. “In a few days I found their very natural dispositions changed, and that affectionate peaceable temper they had hitherto displayed altogether lost. Their eyes were wild and staring, their countenances fierce and barbars, and, instead of obeying my commands, as they had universally and readily done before, I found that all I could say, and even prayers and entreaties, were fruitless. Nothing was now to be heard but brutish quarrels, supplanting that quiet submissive spirit of prayer and supplication which we had hitherto enjoyed.” Yet it is not to be denied, that hunger in itself also renders men ferocious; it enfeebles their minds as well as their bodies, their nature is altogether altered, they view each other with a malignant eye, and even feel an insatiable desire to feed on their own excoriated members. But a supply of food, though scantily administered, will quickly restore them to their ordinary condition.

It is thus established, by incontestible evidence, that there are various tribes of cannibals subsisting at this moment; and that it is not unusual for mankind, in cases of extreme necessity, to preserve their life, by devouring the bodies of their fellow-creatures. See Herodotus, Mela, Strabo, Pliny, var. loc.; Hieronymus, Adversus Jovinianum, lib. ii. Opera, tom. iv. part 2.; Audret de Bello Standardii, ap. Twyden; Scriptores decrem. p. 1138; Leuay Hist. Navigationis in Brasiliam; Crozet, Nouveau Voyage de M. M. Marion, Duclosmeur, et de Survillé; Kossel Voyage d’Entrecasteaux, tom. i. p. 337; and Bosson’s Trav. in Louisiana. (c) CANNON. See GUNNERY.
CANOE, the name given to the boats and vessels of savage tribes. A particular account of the different canoes will be found in the description of the different countries where they are used. (w)

CANON-LAW is that body of law which was at different times, and in different portions, promulgated under the authority of the see of Rome, for regulating the consciences, and fixing the property, as well civil as ecclesiastical, of all the inhabitants of Christendom. It is composed partly of the justest principles of equity, and partly of absurd canons and rescripts on the subtlest points of casuistry, and the uncontrollable supremacy of the church over secular authority.

The collected form in which the canon-law now appears, under the title of Corpus juris canonici, consists, 1st, Of a selection, called the Decretum, of the opinions of the fathers, popes, and church-councils, made by Gratian, a Benedictine monk, about the middle of the twelfth century, in imitation, as it would seem, of the Roman pandects, which are a selection of the opinions of their most eminent lawyers; 2dly, Of the Decretalia, or rescripts of the popes, collected by Gregory IX. sometime after Gratian's collection, and digested into five books; 3dly, Of the other decretales collected by Boniface VIII. called the sixth book of Decretals; 4thly, Of those of Pope Clement V. Pope John XXII. and of certain other popes, called Extravagantes, because they are over and besides the six books of the Decretals. All these different collections were revised by Pope Gregory XIII., and published by him as the Corpus juris canonici, or body of the canon law.

Before the Reformation, the authority of this body of law was, of course, very great in most countries of Christendom. Some governments, however, especially those of France and England, appear to have always entertained a just spirit of jealousy against its encroaching authority, in matters of civil property, and, unless when the monarch happened to be more than usually bigotted and submissive, their resistance was not unsuccessful. In all other respects it appears, even in these countries, to have had all the authority of law. Since the Reformation, it has gradually fallen into neglect. Even among those nations who still adhere to the Romish persuasion, its authority is for the most part confined to questions of church doctrine and discipline; while, in Protestant countries, it is only listened to as respectable argument on questions of tithes, patronages, and a few other points of ecclesiastical right, and only in so far as not inconsistent with Protestant principles. See Praefatio Greg. XIII. in Corp. Jur. Canon.; Encyc. Methodique, Art. Jurisprudence, voce, Droit Canonique; Black's Comm. &c. (j. b.)

CANOPUS, the name of an ancient city of Egypt, which was situated nearly on the spot where the modern Aboukir now stands. The columns of beautiful granite, which were found among the ruins of this once celebrated city, and the other splendid fragments of its ancient grandeur, have been recently employed by the people of Aboukir for repairing the dikes that shut out the sea. (w)

CANOSA, the Caesarius of the ancients, is a town of Italy, in the kingdom of Naples. The ancient city was situated in a plain between the river Ofanto (the Aurythus of the ancients) and the hills, and appears to have occupied a great extent of ground. The fragments of aqueducts, amphitheatres, tombs, baths, military columns, and two triumphal arches, still display the ancient grandeur of Canusium. The modern town stands upon the spot formerly occupied by the old citadel, and contains no buildings that are particularly deserving of notice. The cathedral, or church of Sabinus, which is a Gothic edifice, and is supposed to have been built in the 6th century, is particularly remarkable for six verde antico columns, which are considered as uncommonly large and fine. Under an octagonal cupola, in a court near the cathedral, is the mausoleum of the Chevalier Bohemund, who is immortalised in Tasso's Jerusalem Delivered.

Count Stolberg remarks, that the bread of Canosa is still stony as it was in the time of the Romans, a circumstance which he attributes to the softness of the mill-stones which are employed in grinding it. Number of houses, 300. See Stolberg's Travels in Germany, Switzerland, Italy, and Sicily; and Swinburne's Travels in the Two Sicilies, vol. ii. p. 391. (o)

CANOUGE, or CANOGGE, a town of Hindostan, situated about two miles from the banks of the Ganges, and supposed to be the Palibothis of the ancients, from the extent, magnificence, and grandeur, which are ascribed to it in the Indian histories. Its walls are said to have been 100 miles in circumference; and, in the sixth century, it is supposed to have contained 30,000 shops in which betel nut was sold, 60,000 bands of musicians, and 3000 jewellers.

There is now only one single street remaining in Canouge, and even this is no indication of the former greatness of the place. A canal, which has been cut from the Ganges, makes a bend towards the town, and brings the water close to the citadel, which is placed upon a steep eminence. No building of any importance now remains, and the brick-walls, which do not seem to be very ancient, are hastening to decay. Two mausoleums, of the same magnitude, and of handsome architecture, are erected to two musulman saints, on an eminence covered with trees, from which there is a fine view of the plain, covered with ruined temples and tombs. "Tamarind trees, and mango topes," says Lord Valentia, "were scattered everywhere; and the whitened tomb of an English officer, who was drowned here, raised its pointed head above this scene of desolation. On the inside of the tomb were inscribed several names and dates, with quotations not inappropriate. We next visited another tomb on the most lofty point. It consists of a quadrangle and mosque, similar in miniature to the one at Juanpore. Several pillars in the mosque are formed of two pieces, taken from a more ancient building, the rude base of one of which being placed uppermost, serves for a capital. A great many little images were lying under the trees, but they were too much broken to be interesting. In the centre was a well now filled up, where large sums of money are said to be secreted." For nearly eight miles, the mixture of small pieces of brick, and the vestiges of buildings, attest the former extent of this place. East Long. 80° 13', North Lat. 27° 3'. See Rennel's Memoir; Valentia's Travels, vol. i. pp. 187, 188; and Civil Architecture. (π)

CANSIERA, a genus of plants of the class Tetrandra, and order Monogynia. See Botany, p. 192.

CANTAL, one of the departments of France, is
bound on the north by the department of the Puy de Dome; on the west by the departments of Corrèze and Lot; on the south by that of Aveyron; and on the east by those of the Lozère and the higher Loire. This department is in the middle of the mountains of ancient Auvergne, the highest of which, called Le Plomb de Cantal, gives name to the department, and is about 1917 metres, or 984 toises, above the level of the sea. The quantity of grain raised in this department is not very great, but the pasturage is excellent, and supports a great quantity of cattle of all kinds. Cheese is one of the most considerable articles of commerce. There are mines of copper, antimony, and pit-coal in the department; and quarries of marble and slate. In the canton of Vic-en-Carnadex there is a celebrated mineral spring. The department contains about 5800 square kilometers, or 383 square leagues of 2000 toises. The forests occupy about 29 or 30 hectares, of which two thirds belong to individuals, and the rest to the nation and the communes of the country. The contributions in the year 1803, were 2,058,302 francs. Aurillac is the chief place of the department. Population, 237,524. (w)

CANTÉEN, the name of a vessel generally made of white-iron or wood, in which soldiers carry their liquor. Wooden canteens are now very common in the British army, and are made of a cylindrical form, 6 inches long, and 4½ inches diameter, so as to hold three pints.

A set of ingenious machines, for the manufacture of canteens, has been erected by Mr. George Smart, of Ordnance Wharf, Westminster Bridge, who makes them in great quantities for government. The limits of our work, however, prevent us from giving any account of this machinery, by which Mr. Smart has so simplified all the operations, that a good workman, working 14 hours a day, will head and hoop 200 canteens each day. Wainscot, or foreign oak of the best kind, is the wood which is now employed, and is flanked by two lofty round towers, which are occupied as a prison. This gate was built at the expense of Archbishop Sudbury. The place where the Northgate stood forms the principal entrance from the Isle of Thanet. St George's gate, which resembled Westgate, was built about the year 1470. It contained the water-reservoirs of the city, and was pulled down in the year 1801. Burgate, which had been rebuilt of brick, with stone coins, in 1475, was demolished a few years before St George's gate. The Riding-gate, which has been recently pulled down, has its place occupied with a modern arch, over which is the terrace walk, which was formed in 1790, upon this part of the city wall.

The ruins of the castle are situated on the south-west side of the city. Its outer walls included an extent of more than four acres. The Keep, which is the only part now remaining, is about 88 feet long, by 80 broad, and the present height of its walls is 50 feet. A large malt-house and other buildings, now occupy a part of the castle-yard; and the north-west division has been used as a depot for military stores.

About 300 yards to the south-east of the castle is a circular artificial mount, included within a salient angle of the city wall. Its name Dane John, or Dungeon Hill, has given rise to the opinion that it was the work of the Danes. In the year 1790, and 1791, the broad and deep ditch which encompassed about two-thirds of its base was filled up, and serpentine walks were cut round its sides. These walks were connected with a terrace 600 yards long, formed on the top of the high rampart within the wall, and additional walks were formed in the adjoining field. The principal of these, which is 1110 feet long, is flanked with a double row of limes, and unites with the terrace walk at each end. On the top of this mount is a stone pillar, erected to the memory of James Simmons, Esq. by whom these improvements were made.

The principal public building at Canterbury is the cathedral, which stands on the north-east part of the city, and which, with the various edifices that belong to it, occupies a very great extent of ground. It contains specimens of the style of architecture of almost every age, from the arrival of the Normans to the time of the dissolution, and is equally remarkable for the magnificence of its general appearance, for the splendour of its architecture, and for the excellence of its monumental sculpture. The general form of this noble pile is that of a double cross, with a circular termination at the east, and two massive towers at the west end; while a third tower, which is more elegant than the other two, rises from the intersection of the nave and the west transept. The whole of it was newly paved with plain Portland stone in the year 1788. The principal parts of the cathedral which are deserving of notice are, the west front with its large and elegant window between two towers; the south porch, which forms the principal entrance to the cathedral; the chapel of the virgin, which is a fine specimen of the pointed style of architecture; St Michael's chapel; the choir, which is reckoned the most spacious in the kingdom, and is fitted up in a very handsome manner; the chapel of the Holy Trinity, which contained the shrine of Becket, the treasury, the audit room, the library, the chapter-house, and the cloisters.

The interior length of the cathedral, from east to west, is 514 feet; the length of the choir 180 feet; the length of the nave to the bottom of the choir steps, 178 feet, and from thence to the screen at the
entrance of the choir, 96 feet; the breadth of the choir is 40 feet, the length of the east transept, from north to south, is 154 feet; the length of the west transept, 124 feet; the breadth of the nave and its aisles, 71 feet; the height from the pavement to the vaulting of Trinity chapel, 58 feet; height of the choir, 71 feet; height of the nave, 80 feet; height of the great tower, 130 feet; extreme height of the great tower, 255 feet; height of the south-west tower, 150 feet; height of the north-west tower, 100 feet.

At a little distance from the cathedral, in the eastern part of the city, are the remains of St Augustine’s abbey, which was the first Christian establishment in this kingdom. It was founded in 598, and at one period it almost vie d in magnificence with the cathedral itself. The precincts of the abbey included a space of about sixteen acres; and the surrounding walls are in a great measure entire. The west front was 250 feet long, with a gate at each extremity, which still remain. St Augustine’s gate, which formed the principal entrance, is an elegant building; but it is now much dilapidated, and has been converted into a brewery. The other entrance, called the cemetery gate, has been recently altered into a modern dwelling. The remains of the abbey church afford a beautiful specimen of Norman architecture. The west end, called St Ethelbert’s tower, is a lofty and elegant ruin, which displays various ranges of semicircular arches, beautifully ornamented with mouldings and sculpture.

The principal churches in Canterbury, are Holy Cross church, a low but spacious edifice, built in the reign of Richard II; St Alphage church, a spacious and respectable building containing many sepulchral monuments; St Margaret’s; St Andrew’s, which was built of brick in the year 1764; St Mary Breding, a small but ancient structure; St Mary Magdalen’s church; St Mildred’s church, which is spacious and well built; St Dunstan’s church, situated on the London road, near the entrance of the city; St Paul’s church, which stands without Burgate, in the eastern suburb; and St Martin’s church, which stands on a rising ground a little beyond the precincts of St Augustine’s abbey.

The town-hall, which was partly rebuilt in forming a new street, is a respectable building, and contains some good portraits. The public assembly rooms, in the high street, were erected by the generosity of East Kent. The ball room is a spacious and elegant apartment, and beneath it is a public bank. The theatre, which is a handsome building, stands in Orange-street, and was opened in the year 1790. The royal cavalry barracks, built of brick, were erected in 1794, and in 1798 additional barracks for 2000 infantry were constructed. New buildings, for a similar purpose, have been lately raised on the ground formerly belonging to St Gregory’s Priory. On the eastern branch of the river Stour, is a lofty and spacious flour mill, called Abbot’s Mill, erected from the design of the celebrated engineer Mr Screaton. It is capable of grinding and dressing into flour 500 quarters of corn weekly. Besides these buildings, there are numerous hospitals and other charitable establishments; two libraries, a free grammar school, &c. An agricultural society was established here in the year 1793, under the name of the Kent Society for the Encouragement of Agriculture and Industry, and upwards of £700 have already been distributed as premiums for promoting the objects of the institution.

The manufacture of silk goods was first established in Canterbury by the French refugees, who settled in this town after the revocation of the edict of Nantes, and the labouring classes found full employment in the fabrication of lustreings, brocades, satins, &c. From the rapid extension of the cotton trade, however, and other causes, the silk trade gradually declined; and, in the year 1789, Mr John Callaway introduced the manufacture of cottons, and discovered the method of fabricating the piece goods called Canterbury and Chamberry muslins, damasks, &c. in which silk and cotton twist are united in the same fabric. Though this manufacture is carried on in other parts of England, it still flourishes in Canterbury. According to Hasted, about 1000 individuals are employed in the different branches of the silk, cotton, and wool trades. Many of the inhabitants of Canterbury derive their support from the hop plantations round the town, which cover about 2000 acres of ground.

Number of houses in 1800, 1741. Population 9000, of whom 5195 were females, and 3805 males; and those employed in trade and manufactures amounted to 3925. Population in 1811, 10,200. For a full account of this interesting town, see Somner’s Antiquities of Canterbury, 1640; Goulby’s Walk in and about the City of Canterbury, 1774; Burnby’s Historical Description of the Metropolitical Church of Christ, Canterbury, 1783; Hasted’s History and Topographical Survey of the County of Kent, 12 vols. 8vo, 1797—1801; The Canterbury Guide, 1805; but particularly Brayley and Britton’s Beauties of England and Wales, vol. viii. p. 753, where a full account of the ancient and modern history of this town will be found. (π)

CANTHARIDES, in the Materia Medica, is the name given to the Meloe vesicatorius, commonly called the Spanish fly, which is found in Spain, Italy, and the South of France. A new substance, called the blistering principle, has been recently discovered in cantharides, by M. Robiquet. See Entomology, Materia Medica, &c. (w)

CANTON, or Quang-tche-foo, a large and maritime city of China, and capital of the province of Quang-tong, lies on the north-eastern bank of the river Pe-Kiang, or Bocca-Tigris, as it is called by Europeans, from a supposed resemblance of this animal seen upon approaching the entrance of one of the branches of it at the first fort. It is fortified by a strong rampart, about six or seven miles in circumference, and consists of three divisions, separated from each other by lofty walls, which, together with the rampart, are built of hewn sand-stones, and covered with all sorts of little trees and plants. Not above one third of the ground within the walls, however, is filled with buildings, the rest being chiefly appropriated to pleasure-grounds and fish-ponds; and the back part of the city is almost entirely occupied by two hills of considerable height, which are beautifully wooded, and cultivated with great care. But as no European is allowed to enter within the gates, we have no particular account of its interior; and all the accounts of the city of Canton are confined principally to its suburbs, which are indeed much more extensive and populous than the fortified part. The streets are in general long, but narrow and ir-
CANTON.

regular, paved with small round stones, and flagged close to the houses. They are ornamented at intervals with triumphal arches, are kept exceedingly clean, and some of them have a kind of awning extended from house to house, which prevents the sun's rays from incommoding the inhabitants. Each side is entirely occupied by shops, (the dwelling-houses being in general within the walls,) where every variety of manufacture is exposed to sale. These shops sometimes consist of several apartments, of which the next the street is generally quite open in front, and filled with coarse porcelain and toys; in the one behind, a finer sort of porcelain is sold; the third contains silks, velvets, and other kinds of cloth; and some have a fourth, where tea or other commodities of that description are kept. On great festivals, these long narrow vaults are thrown open, when they are illuminated and ornamented with flowers and trees. Most of the merchants, however, are content with two apartments, the outer one for containing porcelain, and the other for articles of every description.

Some of the streets are appropriated entirely to particular trades, especially cabinet-makers and painters; but in others, apothecaries, shoemakers, goldsmiths, tailors, bookbinders, &c. are all mingled together. In a very long street nothing but eggs are sold, and the accumulation of millions of them in every shop have a very singular appearance. Several canals run up from the river to the interior of the city, on which boats with merchandise are continually passing and re-passing; and when any of them cross a street, it is covered in by an arch, which is ascended on each side by a flight of twelve or fourteen steps. All burdens are carried here by porters, who in general go barefoot and bare headed. A horse is almost never seen in this town, and the only vehicle for both sexes are palanquins, which are only chairs similar to ours, but more elegantly decorated, and carried by poles supported on men's shoulders. The streets are daily crowded with an immense concourse of people, which renders it difficult for a stranger to make his way through them; and his ears are continually stunned with the cries of the porters, who, passing along at a round pace, keep bawling out Li, Li, "clear the way." The houses are in general built of brick, and seldom exceed two stories, except those of some of the most wealthy merchants and mandarins, which are spacious and lofty, and are sometimes elegantly fitted up in the English stile, and surrounded with an extensive garden, adorned with ponds and parterres. The principal public buildings at Canton are joss-houses, or temples, which are scattered over all the city and suburbs. These contain the images of Chinese worship, before which are placed, at particular seasons, a great variety of sweet-meats, dressed food, and incense, which is kept perpetually burning. The palace of the Tsong-too, or viceroy, is rather a handsome building, but quite in the Chinese taste, and disfigured with the images of monstrous animals. In the environs of the town there is a regular theatre, in a large square or market-place. The most beautiful part of Canton, however, is the quay which contains the European factories. They extend a considerable way along the banks of the river, and consist of a range of elegant buildings, with yards and warehouses, each having the flag of the nation to which it belongs hoisted before the gate from sun-rise to sun-set. Of these, the most splendid and extensive is the British factory, which has in front an elegant viandah, supported by handsome pillars, and paved with square marble slabs. This viandah reaches to the water's edge, and commands an extensive view of the river in both directions, and of a beautiful country on the opposite bank. These buildings are occupied by the supercargoes of their respective companies, who transact all the business with the Chinese merchants, disposing of the cargoes brought to market, and supplying the ships with others for Europe in return. About a league above Canton is the Boat-town, which consists of about 40,000 banks of various sizes, arrayed in straight rows, and forming a floating city, with regular streets. Each bark is covered, and lodges a whole family, with their grandchildren, who have also a small boat, in which they fish, or go on shore to follow their respective employments. The number of persons who are expressly prohibited by the law from settling on shore, and are thus obliged to live upon the water, may amount to nearly 300,000, including the women of the town, who are estimated at 40,000. They are chiefly composed of the poorer sort of Chinese, or rather the descendants of the Tartars.

As Canton is the only emporium of European commerce in the empire, a full account of its trade will be given under the article CHINA. Its principal article of exportation is tea, of which about 13,000,000 of pounds is said to be consumed by Britain and her dependencies, and 5,000,000 by the rest of Europe.

In 1795, while the English private trade in this commodity amounted to 23,735,810 lbs., the other nations of Europe and America received only 5,577,200 lbs., of which 4,096,800 lbs. were exported in Dutch vessels. Its other exports consist chiefly in porcelain, raw and wrought silks, nankeen cloths, camphor, alum, quicksilver, turmeric, &c.; and its imports from England are woollens, lead, tin, furs, &c. supposed to exceed a million sterling. All European vessels stop at Wampa, an anchorage opposite Danes island, about 12 miles from Canton, and here deliver and load their cargoes, which are transported to and from the factories in junk. None are on any account permitted to go beyond it; indeed, ships of great draught could not proceed much farther, by reason of the shallowness of the water.

The country around Canton is pleasant and healthy, abounding in all the necessaries and delicacies of life; and the approach to the city by water, presents the most beautiful and picturesque scenery that can be imagined. "In the back ground," says a late voyager, "high and fantastically shaped mountains raise their summits among the clouds, while all around, with very little exception, to the feet of these mountains, the ground seems a level verdant plain, inter-

* Under the article CIVIL ARCHITECTURE, we shall give a view of this building, and also of part of the celebrated temple of Fo, as specimens of Chinese architecture, from original drawings in the possession of PATRICK BEERIS, Esq. of Castlehill, who has kindly favoured the Editor with some new facts respecting Canton, and with the use of several beautiful and valuable plans and drawings of that city, which were executed by a Chinese.
CANTON, John, an ingenious experimental philosopher, was the son of a broad cloth weaver, and was born at Stroud, in Gloucester, on the 31st of July 1718, O. S. He made an early proficiency in mathematics, under the care of Mr Davis, the schoolmaster of his native place; and before he had reached his tenth year, he had been instructed in vulgar and decimal arithmetic. His attention was next turned to the higher subjects of algebra and astronomy; but while his mind was fully bent on these interesting pursuits, his father took him from school to educate him for his own profession. All his leisure time, however, was still devoted to the acquisition of science; and with the insufficient means which he was able to command, he made a rapid progress in his favourite studies. By the help of the Caroline tables, young Canton computed lunar eclipses and other celestial phenomena; and such was his ardour for science, that when the rest of the family were asleep, and with the assistance of a candle which he had secreted, he constructed, with a common knife, an upright sun-dial, which shewed the time of the day, the rising of the sun, and his place in the ecliptic. The display of this dial on the front of his father's house, introduced Canton to the notice of some of the neighbouring gentlemen, who offered him the full use of their libraries. A pair of globes, and Martin's Philosophical Grammar, which he obtained from these libraries, contributed greatly to extend his knowledge of astronomy and natural philosophy.

About this time, he was introduced to the Reverend Dr Henry Miles, a dissenting minister at Tooting, and a Fellow of the Royal Society, who, perceiving the abilities of Canton, obtained permission from his father to take him to the metropolis. Mr Canton, accompanied with his patron, arrived in London on the 4th of March 1797, and, after spending some time at Tooting under the roof of his friend, he articled himself for five years as clerk and assistant to Mr Samuel Watkins, who superintended an academy in Spital-square. In this new situation, the abilities and exemplary conduct of Mr Canton gave such high satisfaction, that, on the expiration of his clerkship, in May 1742, he was taken into partnership for three years; and on the death of Mr Watkins, he succeeded to the academy, which he superintended with great honour and usefulness during the rest of his life.

The attention of Mr Canton was at this time particularly directed to the subject of electricity, which was now beginning to assume the form and dignity of a science. In the year 1747, Mr William Watson laid before the Royal Society a method, discovered by Mr Canton, of determining the quantity of electricity accumulated in the Leyden phial. When the phial (Muschenbroek's phial of water) was filled with electricity, he hung a slender piece of wire to the suspended gun-barrel, which was for this purpose detached from the globes. On applying the wire of the electrified phial to the wire hanging at the gun-barrel, a small snap is perceived. This is discharged by touching the gun-barrel with the finger, which likewise snaps; and thus alternately electrifying and discharging, he proceeded till the whole electricity of the water was dissipated, which sometimes required 100 discharges. The acquired electricity of the water was then estimated by the number of shocks. Unless the electricity was discharged every time, the snaps from the wire of the electrified phial to the gun-barrel was scarcely perceptible. About the end of the year 1749, Mr Canton assisted his friend Benjamin Robins, Esq. in his experiments for ascertaining the height to which rockets ascended, and the distance at which their light is visible; and in January 1750, was read at the Royal Society his "Method of making artificial magnets without the use of, and yet far superior to, natural ones." The method described in this curious paper had been for some time known to its author, but from some motives of delicacy to Dr Gown Knight, who had kept secret his method of making artificial magnets, Mr Canton delayed the publication till he was urged to publish it by the president of the Royal Society. In 1750, Mr Canton was admitted a fellow of the Royal Society, and was honoured with the gold medal, for his valuable paper on artificial magnets. In 1751, he received the honorary degree of M. A. from one of the colleges in Aberdeen, and was chosen one of the council of the Royal Society.

In the year 1752, Mr Canton repeated with success Dr Franklin's celebrated experiments of drawing lightning from thunder clouds, by means of a kite; and having for a considerable period continued his experiments upon the electricity of the clouds, he found them sometimes negative, and sometimes positive; and he imagined, that rarefied air communicated electricity to the clouds, while their electricity was abstracted from them by condensed air. In 1755, he laid before the Royal Society, a paper entitled "Electrical Experiments, with an attempt to account for their several phenomena," which was followed, in 1754, with another paper on a similar subject. These valuable communications contain many interesting facts and discoveries, which we shall have occasion to notice in a future part of our work. The explanation of the phenomena of shooting stars having been proposed as the prize question, in the La-
CANTUA, a genus of plants of the class Pentandria, and order Monogynia. See Botany, p. 140.

CANTUE, king of Denmark, surnamed the Great, was, upon the death of Edmund, proclaimed king of England, A.D. 1017, after his countrymen had contended for possession of the country above two hundred years. As a pretext for the exclusion of Edmund's family, it was affirmed, but without truth, that the succession of Canute to the whole kingdom of England on the death of Edmund, had been stipulated in a late convention between the two princes. In the beginning of his reign, Canute struck terror into his new subjects, by the many sacrifices he made to his crown, and by the vigour of his administration. Under various pretences, he banished some of his nobles, put others to death, and sent the two young sons of Edmund out of the kingdom; but when he found himself securely seated on the throne, he relaxed the reins of government; and made himself popular by extinguishing national animosities, and by effecting a complete reconciliation betwixt his Danish and his English subjects.

To secure the affections of the English, and prevent any attempts for restoring the princes of the ancient royal family, he married Emma, the widow of the late king Ethelred, who resided with her two sons, Alfred and Edward, at the court of her brother Richard, duke of Normandy. By that marriage, and by giving his own sister in marriage to Richard, he artfully disarmed the resentment of that powerful rival, who had declared himself the protector of the young princes, and had threatened to attempt their restoration to the throne of their ancestors.

Finding the kingdom now in complete tranquillity, and having no reason to dread the revolt of the English, Canute undertook a voyage to his native kingdom of Denmark, which was then at war with Sweden. He carried with him a body of English troops, commanded by Earl Godwin, who gained a complete victory over the enemy, without the least assistance from the Danes. This brave action endeared the English to their new sovereign. Godwin was created Earl of Kent, and was honoured with the most distinguishing marks of royal favour. Upon his return to England, Canute directed his attention to the establishment of good laws, the building of churches and monasteries, and other pious and useful works.

In the year 1025 he undertook a second voyage to Denmark, which was again invaded by the Swedes, in which he was not successful; but, two years afterwards, he made ample reparation for his losses. Having revived an old pretension to the throne of Norway, then filled by Olaus, a weak prince, he made an unexpected descent upon that country with a large body of English troops, dethroned the reigning monarch, and took possession of the kingdom. This conquest of Norway fully satisfied his ambition. From that time he laid aside all his warlike schemes, and employed himself in building churches, endowing monasteries, importing relics, and in various acts of devotion; and might have had a much better claim to saintship than many who fill the Roman calendar. In the same spirit of devotion, he undertook a journey to Rome, and obtained for his subjects the important privilege of exemption from toll-duty, when travelling through Germany, France, and Italy, by which the pilgrims and other travellers were relieved from a great expense, and freed from many insults and oppressions to which they had formerly been subject. A letter written by himself, giving an account of that exemption, is still extant at Malmsbury. In his way home, he purchased at Pavia the arm of St Augustine, for one hundred talents of silver, and one talent of gold; a much greater sum than the finest statue of antiquity would have cost in those days. He died at Shaftesbury, A.D. 1035, in the 19th year of his reign; and was buried in the old monastery in Winchester.

Historians have surnamed this prince the Great, a title but too frequently bestowed on conquerors; as if true greatness consisted in invading the rights and properties of their fellow-creatures, and in overrunning foreign countries with their victorious arms. Canute's claim to that title might be better founded.
upon the wise and peaceful administration which distinguished the latter part of his reign. He who at first made no scruple to wade through the blood of the innocent, and set at defiance the sacred laws of religion and justice, when they opposed his ambitious schemes, was, in the latter part of his reign, not less remarkable for his sacred regard to religion, and for the exercise of every moral virtue; insomuch, that he gained the entire affection of his own subjects, and the universal esteem of foreigners. We need not be surprised, however, that a prince whose reign had been so prosperous, the sovereign of Denmark, Norway, and England, was surrounded with flatterers. Some of them, it is said, carried their adulation so far, as to declare that nothing in nature dared to disobey his commands. Offended at their extravagant praises, and desirous to make them sensible of their folly and impiety, he commanded that a chair should be placed upon the beach at Southampton, while the tide was advancing; and, seating himself in it, he thus addressed the approaching billows: “O sea, thou art my dominion, and the hand on which I sit is mine: I charge thee not to approach farther, nor dare to wet the feet of thy sovereign.” Regardless of his command, the waves advanced, and forced him to retire. Turning to his courtiers, he addressed them in language which might not be unworthy of the ears of sovereigns to hear; “Learn from this example the insignificance of all human power, and that the word of God alone is omnipotent.”

**CAOUTCHOUC.** A soft, dense, elastic, vegetable substance, well known under the names of *elastic gum*, and *Indian rubber*. It is remarkable not only for the above characters, but also for its wonderful inflammability; and for some very singular chemical and mechanical properties. In this country it is commonly to be purchased in the form of birds and bottles of a spherical shape. This substance appears to have been introduced into Europe about the beginning of the eighteenth century; but nothing was known of the mode of its production, until the year 1756, when M. De la Condamine presented a paper to the French academy, describing the tree from which it is obtained, and the mode of preparation. From De la Condamine’s statement, it appeared, that it was obtained from a tree that grows in the province of Esmeraldas, in the Brazils, and which is called by the natives *Hvev*. This tree, on being wounded, yields a milky juice, which becomes inspissated on exposure to the air, and forms caoutchouc. The same tree was afterwards found on the banks of the Maragon, by Don Pedro Maldonado; and in Cayenne, by M. Fresnau. The death of the former of these gentlemen prevented the publication of his observations respecting it. The latter read an account of it in the French academy in 1751. More recent observations have now determined, that caoutchouc is obtained from two South American plants, the *Havia caoutchouc*, and the *Jatropha elastica*. In South America, the juice, which is obtained by incision, is spread over clay, moulded into the desired form, in successive layers, until the vessel be sufficiently thick. The whole is then suspended over the smoke of burning vegetable matters, which hardens and colours it. Previous to this last mentioned process, the exterior of the vessel is ornamented by various means. When the whole preparation is completed, the clay mould is broken into pieces, and taken out. The vessel is then fit for use.

Besides the two South American plants already mentioned, there are several others that yield caoutchouc. The principal of these are, the *Ficus indica*, the *Artocarpus integrifolius*, and the *Urecola elastica*. The properties of the caoutchouc, obtained from the *Urecola*, have been accurately examined by Mr. Howison, surgeon at Prince of Wales’ Island: and he has determined the following facts: The thickest and oldest stems of the urecola yield the largest proportion of caoutchouc. On cutting these, a milky, pungent juice exudes. On exposure to the air, a decomposition takes place, and a firm coagulum, which is the caoutchouc, separates from the thin portion. This same effect is produced by time, when the air is carefully excluded. If oxymuriatic acid be poured into the milky juice when first exuded, the caoutchouc is precipitated, and the acid loses its peculiar odour. Fourcroy supposed, that this change was induced by the absorption of oxygen. Should Mr. Davy’s opinions be conclusive, some other source of the phenomenon must be sought for.

The chemical properties of caoutchouc have attracted the attention of philosophers since the time of Mr. Macquer, who published, in the Memoirs of the French Academy in 1768, an account of his experiments on it. Although this celebrated chemist determined many facts previously unknown, yet he adopted some erroneous opinions, the fallacy of which was pointed out by Mr. Berniard; whose paper contains the greater proportion of all the facts now known respecting this interesting substance. Fourcroy and Grossart have also contributed to our knowledge of this subject.

Pure caoutchouc, when recent, is of a yellowish white colour, which changes to a smoke grey on exposure to the air. Most commonly it is black, or blackish brown, particularly that which comes from South America; this circumstance is owing to the smoking during the formation of the vessels. Caoutchouc is tasteless and inodorous, except when heated; it then yields a faint peculiar smell. It is soft, pliable, adhesive, wonderfully elastic and tough. Its specific gravity is 0.9385.

Mr. Gough took thin slips of caoutchouc, previously rendered pliable by being immersed in water, observed the temperature, by applying these slips slightly extended to the lips, and suddenly stretched them, when a very sensible increase of temperature took place. When allowed to relax to the original degree of extension, the temperature was suddenly returned. The same gentleman also ascertained, that if these slips be plunged into cold water at the time that they are considerably extended, that they lose their contractile power, and retain nearly the same degree of extension; but if plunged into warm water, or if kept warm for some time in the hand, they become again elastic. The specific gravity of caoutchouc is considerably increased, by being weighed when in a state of tension under water. These facts are valuable, not only as they give new characters of this substance, but as they are beautiful illustrations of the theory of latent heat. See **CHEMISTRY**.
Caoutchouc is variously acted upon by different agents. When exposed to a high temperature, it is softened, becomes viscid, swells, emits a peculiar odour, and burns with a very bright flame. If a more moderate heat be applied, it retains its viscidity, never resuming its elastic state.

The atmosphere affects the colour; but we are not aware of any alteration which it produces on the other properties of caoutchouc.

Water was supposed, by Grossart, to be a solvent of this substance, merely because it is softened, and becomes somewhat transparent on the edges, on being immersed for some time in boiling water. It is very clear, however, that this effect depends on the increased temperature, rather than on the water itself. When boiled for a very considerable time, no alteration takes place, except in a way that is decidedly referable to the agency of heat. By this heating, the caoutchouc is rendered so adhesive, as to admit of being united very closely by simple pressure.

It was very soon determined, that alcohol does not dissolve it. It, however, renders it colourless. M. Macquer confirmed these observations.

The same chemist also found, that sulphuric ether was a solvent of caoutchouc; but Bernard afterwards repeated the experiment without success. He also tried the nitric ether, and found it to be a very imperfect solvent. Mr. Cavallo was the first that determined the causes of this discordance, between two chemists' remarkable for their accuracy. This philosopher found, that ether is a solvent, only after having been well washed with water. Subsequent experience has shewn this statement to be correct. It is evident, that Macquer and Bernard had used the same kind of ether in two different states. On evaporating the ether, the caoutchouc remains unaltered: hence, from the solution, various instruments may be made with facility. Pelletier found, that the solution is considerably facilitated, by boiling the caoutchouc for some time before it is put into the ether. Dr. Roxburgh did not find that the nitric acid dissolved the caoutchouc, which he obtained from the 

Urecola elastica.

The volatile oils dissolve caoutchouc; but on evaporation, it remains clamy and unfit for any use. The fixed oils have a partial effect when aided by heat; and melted wax dissolves a very minute portion.

Dr. Thomson discovered, that ammonical gas dissolves a very minute proportion of caoutchouc, although Bernard had denied the action of the alkalies. The Doctor has further determined, that all the alkalies produce similar effects.

The acids decompose caoutchouc very partially. Mr. Hatchett obtained about 12 per cent. of charcoal from caoutchouc that had been charred by sulphuric acid. When acted upon by nitric acid, azote, carbonic acid gas, pyretic acid gas, and oxalic acid, are said to have been formed.

Petroleum dissolves it, and it remains unaltered after evaporation. When distilled, it gives out ammonia, a watery liquid, empyreumatic oil, and charcoal.

Such are the leading properties that have been ascertained of this singular substance. It exists in many plants, in which it has usually been confounded with other matters. In the fluid state in which it is found in plants, it unites readily with water, by which means it may be easily separated from the stalks. This fact is a valuable one, as it may hereafter be employed in the manufacture of instruments made of caoutchouc. When combined with resin, it may be separated by alcohol; and, for its separation from gum, or extractive, the following formula is given by Hermstadt: "Digest a part of the plant containing it (caoutchouc), first in water, and then in alcohol, till all the substances soluble in these liquids are extracted. Dry the residuum, and digest it in four times its weight of rectified petroleum. Express the liquid part, by squeezing the substance in a linen cloth. Let this liquid remain several days to settle, then decant off the clear liquid part, mix it with a third part of water, and distil; the caoutchouc remains behind.

Opium is said to contain caoutchouc, and the insoluble part of mastic possesses some of its properties.

Caoutchouc is used for various purposes. In South America, whence it was first brought to Europe, it is formed into solid masses, with which the natives play at a game somewhat resembling that of fives. It is used for bottles and boote, for which it answers extremely well. It is also formed into torches, which burn with great splendour.

In Europe, it is commonly used to take out the marks of blacklead pencils; for syringes, bougies, catheters, elastic tubes, and varnish.

Many methods have been employed to fashion it into the forms necessary for the above instruments. The expense of ether, and the rapidity with which it evaporates, precludes its use as a solvent; and the peculiar effect of the oils, already noticed, unfit the caoutchouc, after solution, for any purpose. The best mode of forming tubes and bougies appears to be, to cut a bottle of caoutchouc into a thin narrow slip, which must be heated in boiling water, until the edges become transparent; then to wind the caoutchouc slip, accurately applying the edges to each other around a piece of cane, previously split into two, and having a slip of whalebone interposed between them. When the whole has been accurately applied to the surface of the cane, it may be plunged into boiling water again, and any inequalities on the surface removed. A slight varnish of the caoutchouc applied to the whole surface, may render the surface still smoother and more perfect. The slip of whalebone being withdrawn, the cane may be readily taken out, and the tube will be fit for use. Or should the surface be unequal, it has been proposed to immerse the tube or bougie into a glass tube filled with the ethereal solution; the diameter must scarcely exceed that of the bougie; the whole apparatus is then to be plunged into hot water, the ether will be evaporated, and a smooth coating given to the instrument. This will be too expensive for common use.

Cloth impregnated with the recent juice of the urceola is perfectly imperious to water, and may be applied to a multitude of economical purposes. The chief objection is the scarcity of the substance, which enhances its value. It forms the best varnish for balloons, and indeed for all those instruments that ought to be imperious to water and air. See Thomson's Chemistry; Murray's Chemistry; Annales de Chimie, vol. xi. xii. and xxiv.; Philosophical Magazine, vol. xxii.; Aikin's Dictionary of Chemistry and Mineralogy; Medical and Physical Journal, vol. iii.; Manchester's Memoirs, vol. ii. 2d series; Asiatic Researches, vol. v. (C. M.)
CAPE OF GOOD HOPE.

Cape of Good Hope, an extensive European settlement on the southern extremity of the African continent, lies between 29° 55' and 34° 47' S. Lat., and between 17° 36' and 28° 17' E. Long. It is bounded on the west and south by the ocean, on the east by the Great Fish River, and Caffreland; and on the north by the river Koussie, and the country of the Bosjesmans. Its mean length is nearly 550, and mean breadth 233 English miles, and it comprehends an area of about 128,150 square miles. These boundaries are, in a great measure, imaginary; and to the northward especially, might be extended very far beyond what is now accounted the limit, without encroaching upon the territory of any nation; while on the eastern side of the province, the Caffers have for many years been systematically pressing in upon the line of demarcation stipulated between them and the Dutch; and they actually held possession of a large tract of the most productive part of the province, to the westward of the Great Fish River, until a very few months ago, when they became more bold in their aggressions, and murdered the landroost, or chief magistrate of Graaf Reinet, the district contiguous to their country, with all his family, with the design of driving in the colonists, and adding to their cruelties. Colonel Graham was sent by the governor with an adequate force, and vigorously pushed into the part of the country they inhabited, routed them, and drove them within their limits. The Caffers have been classed amongst savages; but their steady perseverance in pursuing a uniform design for so long a period, would do credit to the policy of an European state. Their system of espionage is no less complete than their success in concealing their own circumstances from their neighbors; the British troops were, on the last occasion, astonished to find a very considerable extent of land in a state of high cultivation, at a very small distance from the residence of the magistrate.

We are not to estimate, however, the value of this settlement by its extent of surface. The greater part of it is covered with naked mountains, or sterile and unprofitable plains, many of which are totally incapable of any kind of culture, and even without a plant or shrub fitted for the support of animal life; while others are in the season, covered with verdure, and frequented by antelopes. These mountains generally run in the direction of east and west, except those in the Cape peninsula and the chain, which, beginning at False Bay, stretches along the western coast to the northward, as far as the mouth of Elephants river, and is about 310 miles in length. The most southern range extends along the coast, at between 20 and 60 miles distance from the sea; the central range, called Zwartheberg, or Black Mountain, runs parallel to it, is more lofty and rugged, and in many places is composed of double and sometimes triple chains; and the northern range, or Nieuwveld mountains, which are still higher, (supposed to be about 10,000 feet above the level of the sea,) have their summits sometimes covered with snow during the severity of the winter season. The chain which extends from the extremity of the Cape peninsula northwards, is terminated by the Table Mountain, and its two wings, the Devil's Hill, and Lion's Head. These three may be almost considered as one mountain, for though their summits are disunited, yet they are all joined at a considerable elevation above the common base. The north side of the Table Mountain, which faces the town, presents a bold and almost perpendicular front, extending nearly two miles in length, and broken into three divisions by two immense chasms, which give it the appearance of a mighty ruin. Its height is 3562 feet above the level of Table Bay, that of Devil's Hill is 3315, and the Lion's head is 2160. The mountains of this country, according to Mr Barrow, "at a distance, possess neither the sublime nor the beautiful; but the approach to their bases, and to the kloofs, (or passages by which the mountains are ascended,) are awfully grand and terrific; sometimes their naked points of solid rock rise almost perpendicularly, like a wall of masonry, to the height of three, four, and even five thousand feet, resembling the Table Mountain; sometimes the inclination of the strata is so great, that the whole mass of mountain appears to have its centre of gravity falling without the base, and as it momentarily threatened to strew the plain with its venerable ruins; in other places, where the looser fragments have given way, they are irregularly peaked, and broken into a variety of fantastic shapes." We are also informed, by the same traveller, that the component parts of those mountains consist of sandstone, resting upon a base of granite. This base, however, is in some mountains considerably elevated above the general surface of the country, and, in others, its summit is sunk far beneath it. In the Table Mountain, the granite base terminates only at about 500 feet above the level of the sea. From that commences a horizontal stratum of siliceous sandstone of a dirty yellow colour, which is covered by a deep brown sandstone, containing calciform ores of iron, and veins of hematite, and is surmounted by a mass of a whitish grey shining granular quartz, about 1000 feet in height. The rocks on the summit, which have entirely passed into sandstone, are surrounded with myriads of oval shaped and rounded pebbles of semitransparent quartz, which were formerly imbedded in them; but no shells, petrefactions of fishes, or impressions of plants, are to be found, as some travellers have asserted. The composition of the other mountains is nearly similar to that

† It has been observed, that wherever the granite rises above the general level of the country, numerous springs issue from the surface of the rock; and that the contrary position is invariably attended with a scarcity of water. This last, indeed, is the more general situation of the granite throughout the colony.

VOL. V. PART II.
of the Table Mountain; and the stratification of the whole colony is also much the same as that of the Cape peninsula. Blue compact schistus, generally placed in parallel ridges, in the direction of north-west and south-east, but frequently interrupted by large masses of a hard flinty rock, of the same colour, belonging to that class of aggregated stones, called, by Mr. Kirwan, *granitelles*, forms the substratum. This is covered with a body of strong clay, which is coloured with iron, and abounds with brown foliated mica; and in which are imbedded immense blocks of granite, so loosely cemented together that the constituent parts can easily be separated by the hand. The mica, the sand, and indeed the whole bed of clay, is supposed, by Mr. Barrow, to have been formed by the decomposition of the granite. Large masses of these aggregated stones are found lying entirely exposed between the Lion's head and the sea. They are mostly rent, and are falling asunder from their own weight, and some of them are so completely excavated that nothing but the crust or shell remains. Such hollow blocks are very common on the hills of Africa, and are frequently converted into habitations by runaway slaves. "There is neither a volcano, nor a volcanic product," says Mr. Barrow, "in the southern extremity of Africa, at least in any of those parts where I have been, nor any substances that seem to have undergone the action of fire, except masses of iron-stone, found generally among the boggy earth, in the neighbourhood of some of the hot springs, and which appear like the scoria of furnaces. Pieces of pumice-stone have been picked up on the shore of Robben-island, (or Seal Island, in the mouth of Table Bay,) and on the coast near Algoa bay, which must have been wafted thither by the waves, as the whole basis of this island is a hard and compact blue schistus, with veins of quartz running through it; and, of the eastern coast, iron-stone and granite."

The rivers, which intersect this extensive colony, are of very little advantage to it, either for the purposes of agriculture or navigation. Many of them are merely periodical torrents, which continue to flow during the rainy season, but which, during the summer, leave their deep sunk beds almost completely dry; and the rivulets, which are supplied by the mountain springs, have scarcely escaped from the lofty sources, before they are either absorbed or evaporated. The permanent rivers, some of which contain sufficient water for the navigation of small craft, for several miles up the country, are all, except the Krynna, rendered inaccessible, by a bed of sand, or a reef of rocks across the mouth: The principal of these, on the west coast, are, *Oliphant*, or Elephant's river, which runs in a northerly direction along the foot of the western chain of mountains, and falls into the Atlantic in S. Lat. 31° 30'; and the *Berg*, or Mountain river, which has its source in the mountains which enclose the vale of Drakenstein, and discharges itself into St. Helena bay. Those on the south coast are, *Broad* river, which falls into St. Sebastian's bay, and at its mouth is nearly a mile broad. *Gouritz* river collects its waters from the Black Mountains and Karroo plains, and during the rains is the most rapid and dangerous in the colony; *Cammuos* river, which is supplied from the same part of the country, but more easterly, empties itself into a bay of the same name, and, within the bar, is deep enough to float a ship of the line; *Sunday* river, which rises in the Snowberg, or Snow mountains, and falls into Zwart Kop's bay; and Great Fish River, called *Rio Infante* by the Portuguese, which taking its rise far towards the north, about 200 miles from its mouth, collects in its long course a multitude of tributary streams, and forms the eastern boundary of the colony. Besides these are *Zwart Kop's* river, *Keurboom* river, and Knyzna; and numerous streamlets on the southern coast, which continue their feeble course throughout the whole year, but whose channels are so deep, that little benefit can be derived from their waters to the lands in the vicinity. All these rivers are well stored with perch, eels, and small turtle; and the neighbouring shores abound with every kind of fish peculiar to these seas. The principal bays on this coast, besides those which have been already mentioned, are Plettenberg's bay, Mosel bay, False bay, Simon's bay, Haute or Wood bay, Table bay, and Saldanha bay. Of these, Saldanha bay is the most commodious, and affords at all seasons very excellent shelter and anchorage. It is about 15 miles long, in the direction of north and south, and its entrance, which is through a ridge of granite hills, is only between two and three miles broad: the scarcity of wood and water, however, in its neighbourhood, must always prevent it from becoming a place of general rendezvous for a fleet.

The soil of this country is in general of a stiff clay, soil or light sand, which requires nothing but water to make it most fertile in every vegetable production. Wherever springs are found, their vicinity is always enriched with the most luxuriant verdure; but these are so very rare, particularly in the northern part of the colony, that they scarcely interrupt the prospect of uniform sterility, and serve only to render more drear the surrounding wilderness. The immense plains, called *Karroo*, are, for many months, completely void of every appearance of vegetation; and the Great Karroo, which extends nearly 300 miles in length, and 80 in breadth, is uninhabited by a human creature, and scarcely ever moistened with a shower. Its unvaried surface of clay, sprinkled over with sand, is only broken by hills still more barren; and, should a blade of grass, or a stunted shrub, meet the eye, during the hot season, its parched appearance betrays the poverty of its parent earth, which can scarcely afford it sufficient nourishment to preserve its existence. Yet it is astonishing to behold the genial influence of the rains in clothing them with rich verdure, and then they are resorted to by the various sorts of antelopes, which again are followed by lions. In these Karroo plains, the botanist will find his choicest harvest of succulent and many other plants. The belt of land, however, which is inclosed by the southern range of mountains and the sea, possesses a deep and fertile soil, which, being refreshed by frequent rains, is clothed with grass, and in many places well wooded with fruit and forest trees; and, from its proximity to the ocean, it enjoys a more mild and equable temperature than the northern plains. The beauty and fertility of the country increase as we advance east...
ward; and the banks of the Great Fish River are covered with shrubbery of the most beautiful and varied foliage, and enlivened with numerous birds, and a variety of game, particularly of the antelope kind. There are also some fertile spots on the western coast, particularly between Berg river and Saldanha bay, and in some parts of the Cape peninsula.

The climate of the Cape is considered as very salubrious, and many invalids from India have been restored to health by its salutary influence. The year is here divided by the inhabitants into two periods, the good and the bad monsoon. The first commences in September, and answers to our summer. It is then the south-east winds prevail. They sometimes blow in squalls with great violence, and then every door and window in Cape Town is carefully closed up, to keep out the dust and heat. During the continuance of the storm, the Abbe de la Caillle observed, that "the stars look larger, and seem to dance; the moon has an undulating tremor; and the planets have a sort of beards like comets." These winds are of a dry and blazing quality, and destroy the foliage and blossoms of such fruit trees as are not sufficiently sheltered. The inhabitants also suffer from their baneful influence, as they relax and fatigue the powers both of the body and mind, and render them almost entirely incapable of exertion. But they are of great service in keeping up a constant circulation of the air, which in some measure counteracts the reflected heat from the face of the Table Mountain, which would otherwise be insupportable. The mornings, during this season, are in general hot and sultry, but the breeze springs up about mid-day, and, dying away towards the evening, leaves the atmosphere cool and refreshing. The thermometer, in the hottest months, varies from 70° to 90°; but often remains for days at 83° or 84°, and has sometimes risen to 105° in the shade. On the approach of winter, the south-east wind becomes less frequent and violent, and is at length succeeded by the north-west, which is generally attended with thick fogs and heavy rains. Thunder storms are also not unfrequent, and often last for two or three days. The rains descend in torrents, sometimes for many days, without the least interruption, particularly during the months of June and July. Such torrents have fallen after a thunder-storm, that in a few hours the water has been some feet deep in the road leading into Cape Town. It frequently occurs in the eastern part of the province, that what is called a river, is dry for perhaps eleven months in the year, and becomes an impassable torrent in a few hours. The air then feels chilly, raw, and disagreeable; and the common temperature of this season is from 50° at sunrise, to 60° at noon. It, however, sometimes falls so low as 40°; and on the more elevated Karroo plains, it is generally below the freezing point by night, and from 70° to 80° at mid-day. In the division of Roggevelds, the cold is very intense. The mercury in the barometer often rises higher in the clear cold days of winter than in the serene weather of summer; and its range in the former season is from 29.46 to 30.35 inches, while in the latter it is only from 29.74 to 30.10. One considerable inconvenience of this climate, which cannot but prove in some measure prejudicial to the health of the inhabitants, is the sudden change of temperature. It is not unusual for the thermometer to rise 30° in the course of five or six hours; and, indeed, the frequency of consumptive complaints, is, by many, ascribed to these vicissitudes. The most fatal diseases, however, which are common to the natives, arise from a different cause, and may, in general, be attributed to their excess at table, and want of exercise. Many of the inhabitants in the remote parts of the province, habitually use animal food three times a day, seldom accompanying their repasts with any portion of vegetables, and frequently without bread; and when an excess of ardent spirits is combined with such pernicious habits of life, affections of the liver and other diseases are the result. An instance of longevity is rarely to be met with, and few even exceed the age of sixty. The annual mortality at Cape Town, taken on an average of eight years, ending 1797, was about two and a half in the hundred among the white inhabitants, and under three in a hundred among the slaves. This latter class, however, who live in the country, from their coarse food and hard labour, and from their being exposed in all seasons, in the fields, to the severity of the climate, are very subject to bilious fevers, which annually carry off considerable numbers.

This colony is divided into five districts, or Doro-
dys, viz. the CAPE, STELLENBOSCH, DAKENSTEIN, ZWELLENDAM, and GRAAFF REYNIES. Of these the Cape, in which the principal town of the settlement is contained, although the smallest in extent, is by far the most populous and productive. Besides the peninsula, it includes the country lying north of Table bay, as far as the mouth of the Berg River in St Helen-bay, being about eighty miles in length, and twenty-five in breadth, and containing nearly 2000 square miles. Scarcely a fifteenth part, however, of its surface is under cultivation, and its most valuable productions are chiefly confined to the vicinity of the town. There, most of the European, and many of the tropical fruits, are cultivated with great success. Oranges, peaches, apricots, figs, grapes, guavas, pomegranates, quinces, and medlars, are very plentiful and good. Apples and pears, though they are abundant, are generally inferior in quality to what might be expected, probably from want of attention in propagating the best sorts. Almonds, walnuts, chestnuts, and excellent mulberries, grow in great

* In Canada, however, the range is infinitely greater; on the 18th January 1810, the thermometer, about six p. m., was waverings from 34° to 32°; at three A. M. next morning, the cold was intense, and the mercury stood about 13° below 0°; and at eight A. M. on the 20th, it had sunk to 30° below 0°; yet no malady ensued that could be ascribed to it.

† It is a prevailing hypothesis among some, that the Cape Peninsula must have been originally separated from the continent of Africa; and Lord Valenla affirms, without hesitation, that the isthmus between Table and False Bay was formerly covered by the sea. Mr. Barrow, however, thinks otherwise, and is decidedly of opinion that the sea is rather encroaching upon the land than retreating from it, and that the whole of L'Aguilas bank, stretching from Cape Point across the entrance of False Bay to the mouth of the Great Fish River, has once formed a part of the continent. See his Travels, vol. i. p. 65.
abundance. Strawberries are to be found ripe throughout the whole year; but raspberries, though tolerably good, are very scarce. The market is always well supplied with vegetables of every description, and the choicest fruits, both green and dry. The sweet luscious wine known in this country by the name of Constantia, made at two vineyards about eight miles from Cape Town, which produce annually from ten to fifteen thousand gallons; wheat, barley, and pulse, are cultivated throughout the district. The plains of the Cape peninsula are variegated with the most elegant and beautiful shrubs and flowers, and furnish an endless field to the researches of the botanist. The bulbous-rooted plants exceed in variety those of any other country; and, at the conclusion of the rainy season, the verdant carpet of trifolium melilotos, which covers the west shores of Table-bay, is enlivened with myriads of the large othonna, among which are intermingled the oxalis cernua, hypoxis stellata, ixia, iris, amaryllis, and geraniums of every species, exhibiting the most beautiful variety of foliage and colours. Extensive plantations of the protea argentea, or silver tree, the white poplar, and the stone pine, stretch along the foot of the Table Mountain; and most of the country houses are adorned with avenues of oak. But the timber of these is of small value, being generally shaken and unsound, from its rapid growth, and is seldom used for any other purpose than fuel, which at the Cape is extremely scarce. The fuel, however, which is now chiefly derived from the cultivated woods of Protea argentea, the oak, and the spontaneous productions of the neighbouring country to the Cape Town, is likely soon to become very scarce, if effectual means are not adopted to ensure the plantation of trees for future supplies.

The colonies of Stellenbosch and Drakenstein stretch from Cape l’Aguilas, the most southern point of Africa, to the river Kousseie on the north, an extent of 380 miles; its mean breadth from east to west being about 160, and its contents nearly 35,000 square miles. Though the greater part of this immense surface be barren and unprofitable, consisting merely of naked hills and Karoo plains, the subdividing which lies on the western side of the mountains between False bay and Elephant’s River, constitute the most valuable possessions in the colony. The extensive valley of Drakenstein is well inhabited, and enjoys a most delightful climate, and its soil is capable of every species of agriculture. Very little corn, however, is cultivated here. Grapes, and various kinds of fruit, are the chief productions of this part of the country, being not only the best adapted to the soil and climate, but the most profitable, from the vicinity of the capital; two-thirds of the wine which is brought to Cape Town is supplied by the vineyards of Drakenstein alone. The divisions of East Zwartland and Twenty-four Rivers are equally productive, and are considered as the granaries of the Cape. Wheat and barley are their principal articles of cultivation; but the crops depend so much upon the rains, that the profits of the farmer are precarious and uncertain. The country on the other side of the mountains consists chiefly of pasture farms, and the Roggeveldt, or rye-grass country, furnishes the largest and strongest breed of horses in the settlement. The principal villages of this district are, the Drostdy of Stellenbosch, the residence of the Landdroost, which is about twenty-five miles from the Cape, and consists of nearly seventy houses, most of which are very neatly built, and have out-houses and gardens attached to them; and the Pearl, or Pearl, (a village so called from a large mass of granite lying in its neighbourhood, which bears the name of the Pearl,) which lies twenty miles farther north, at the bottom of a hill, and contains about thirty habitations, surrounded with orchards, vineyards, and gardens, forming a street from half a mile to a mile in length.

Zwellendam comprehends the belt of country lying between the Black Mountains and the sea, and extends from the Breede River on the west, to Camtoos River on the east. Its length is about 300 miles, and its breadth from north to south 60, including an area of 19,200 square miles. The general aspect of this district, exhibits a greater variety of surface, and is more diversified by hill and dale than any other part of the colony. The mountains near the sea are clothed with impenetrable forests, and many of the plains abound in the common aloe, which constitutes a considerable article of commerce. The pasture in general is excellent in this district, but it is deemed by the Dutch farmers to be better adapted for horses than for oxen or sheep. The revenues of the farmer are derived from the sale of horses, timber, grain, butter, soap, and dried fruits. In the division of Autiniquas Land, a little east of Mossel-bay, the Dutch government reserved for itself about 20,000 acres of the most fertile land, consisting of an extensive meadow, which was always covered with the most luxuriant verdure. This is cultivated by an overseer, and is calculated to furnish annually 10,000 muids of corn, besides affording sufficient maintenance for 1000 horses, and as many cattle. The village of Zwellendam is composed of about thirty houses, scattered irregularly over a fertile valley. It contains the house of the Landdroost, and the only church in the district.

Graaf Reynst includes the tract of territory lying between the Griendy or Lion river on the west, and the Great Fish river on the east; and is bounded on the north by the country of the Bojesmans; and on the south by the Black Mountains and the sea. Its mean length is 250, and breadth 160 miles, comprehending an area of 40,000 square miles. Little grain is sown in this district, except what is necessary for the subsistence of the inhabitants, and this is very inconsiderable, as many of the inhabitants live entirely upon animal food. The difficulty of transportation to market, and the devastation of the locusts, which particularly infest the division of Sneuwig, renders it a very unprofitable article of cultivation. Sheep and horned cattle are reared in great perfection, particularly the former, which thrive so well here, that the eves very frequently produce lambs twice in the year. Perpetual hostilities are carried on by the Dutch boers who dwell near the boundary of the colony, with the Caffres and Bosjesman Hottentots. Graaf Reynst is the only village in this vast district, which bears its name, and even that contains little more than a dozen of small hou-
CAPE OF GOOD HOPE.

This extensive colony is in no circumstance more worthy of notice than in the wonderful variety of animals which inhabit its varied surface of mountain and valley, wood and Karroo plains. Amongst these are to be mentioned, the lion, the elephant, the rhinoceros, the buffalo, the hippopotamus, the leopard, panther, hyena, wolf, jackal, tiger-cat, the zebra, the quachas, the gnu, and the numerous family of antelopes, from the stately eland or oryx, to the pigmy antelope. From the increase of population, however, the antelope, together with every other sort of game, has gradually become more scarce; and some species are extirpated from parts of the country in which they abounded. The spring-bucks

* The Opgaaf is an annual statement of the number of his family, the amount of his live stock, and the produce of his farm, which every household is obliged by law to make to government. It was formerly given without any regard to accuracy; but since the capture of the settlement by the British in 1795, it has been required upon oath. In the above returns, however, the British army and navy, and British settlers, are not included.

† A legger, or sack, is equal to 37/8th Winchester bushels, and usually weighs 180 Dutch pounds.
Cape of Good Hope.

still traverse the plains of Graaf Reinet in flocks, consisting of many thousands. The gnuo, whose generic character is so indistinctly marked, or, we may more accurately say, the gnuo, which possesses those characteristics by which naturalists have thought proper to draw limits between the families of nature, and have by them been assigned to different families, is one of the most beautiful animals that have been found in Africa, to whatever genus he may belong. His head bears some resemblance to that of the African buffalo; he has an erect mane, and a mane, if we may call it so, under the neck, descending from the breast between the fore legs; his shoulders and body are somewhat like those parts of the horse; while he has the elegant limbs of the antelope. But he has what he ought not to have had, if he had been a good naturalist,—he has the *subocular sinus*, which, by all the laws of natural history, is the exclusive property of antelopes. There are also several species of hares; and in the mountains to the eastward is found the *dass*, or rock-rabbit, with short ears and no tail. Among the birds are eagles, vultures, kites, pelicans, flamingos, spoon-bills, cranes, ibises, wild geese and ducks, teals, snipes, quails, bustards, and partridges. Turtle doves, of many sorts, thrushes, humming-birds, and an immense variety of other small birds, of the most exquisitely beautiful plumage, are found in the woods. Ostriches in considerable numbers inhabit the Karroo plains; their eggs are less strong in taste than the eggs of ducks or geese. It is a remarkable peculiarity in the natural history of the ostrich, that it not only is gregarious, in the ordinary sense of the term, but it very often happens that two or three females deposit their eggs in a common nest, and incubate together, attended by the fathers of the brood. It is not unusual to find thirty-six eggs in a nest, the common stock of three females. Along the coast are various kinds of sea-fish, such as perchs, stone-breams, rock-fish, mackerel, soles, and skate; and abundance of muscles and oysters. The domestic animals of the Cape are not numerous, as none are reared but what are absolutely necessary. Their horses are not indigenous, but were first introduced from Java. Those from South America, however, are preferred, both for their beauty and hardiness; and though small are capable of sustaining great labour. A scientific English breeder would say, that the oxen at the Cape run to waste too much in their make, that is to say, they have long legs, long horns, and high shoulders. The sheep are remarkable for their broad, flat, and massy tails, usually weighing about six pounds, though, in some rare instances, they have amounted to 14; they have long legs, pendulous ears, and a small scraggy neck. The wool is hairy, and of no value; but that of the mixed breed of Spanish and English, which was first introduced into the colony by Colonel Gordon, is very beautiful, and might be rendered a very profitable article of commerce. The African goat is a very prolific and valuable animal. Hogs are almost unknown, and poultry is very scarce. The colonists of this settlement are divided into four classes, viz. the inhabitants of the Cape Town, consisting of the civil servants of government, those engaged in commerce and the arts; the cultivators of the vine; the grain farmers, and the graziers. The culture of the vine requires a greater capital than the other two branches of husbandry, from the labour necessary in pruning and dressing it, as well as the expensive utensils requisite for making wine, consequently the wine makers are the most opulent. By their vicinity to the town, and their frequent excursions thither with the produce of their vintage, they have an opportunity of procuring many comforts, which the boors in the eastern districts of the colony have not the means of obtaining. Many of them are descended from the French families, who took refuge here from the religious persecutions of their bigotted countrymen upon the revocation of the edict of Nantes, and were the first who introduced the vine into this country. They still retain some of the peculiarities of their nation. They are more social and communicative than the Dutch; visit one another with great familiarity, or take a summer jaunt into the country in their tent waggons drawn by a team of six or eight horses. Their houses are in general well built, and their domestic affairs are managed with considerable economy and cleanliness. The produce of their farm, which invariably exceeds their annual expenditure, enables them to support a style of living comparatively affluent. Their only public burdens consist in a small capitation tax for repairing the streets and avenues leading to Cape town, and the lion and tiger money for the exigencies of the district. The former of these, however, is either very ill applied, or very insufficient for the purpose, as the roads over the Cape isthmus are so wretched, that it requires fourteen or sixteen oxen to draw two leggers of wine, about 2½ ton weight. The tax upon their produce is also very moderate, being three rix-dollars for every legger of wine or brandy that is brought to the Cape market. All that is consumed at home, or sold to the other boors, is duty free. The grain farmers are next in rank and civilization to the wine-growers; and chiefly inhabit the districts near the town, from which they are seldom distant more than two or three days journey. Many of them are in easy and even affluent circumstances. They have not much intercourse with each other. Seldom, indeed, are they agreed about the boundaries of their respective properties; and the privilege of a spring or a water-course, is often a fertile source of quarrel and litigation. This continual jarring is a great impediment to general improvement. The men of this class are in general very tall and corpulent, but loose in their joints, clumsy, and awkward. Cold and phlegmatic in their temper, and never raised to exertion by the fear of want or the desire of gain, their lives are spent in the most listless inactivity. The same indolence extends to the women. The mistress of the family remains fixed to her chair, with a coffee-pot constantly boiling before her, from morning to evening, as if she constituted a part of the furniture; and her daughters sit beside her, equally indolent and idle. The year is varied by no incident that can awaken their anxiety or their hopes. They have no fairs, no visiting parties, no dancing, no music nor amusement of any sort. The history of a day is the history of their whole lives, and their only topics of conversa-
tion are, a journey to the city or church, a marriage, and the depredations of the locusts and Boisjessmans. Their style of farming is miserable in the extreme. The land is merely scratched with a huge unwieldy plough, drawn by eight horses, or a dozen of oxen. A rude harrow follows the sower, which always leaves the field in a rougher state than the coarsest sea-ploughing in Britain. They use no manure, except a little for barley, though the kraals, or pens, in which their cattle stand are as full of dung as the stable of Augus; and after this wretched preparation, they calculate upon a return of fifteen fold. In low situations, near rivulets, where they have a command of water, they usually reap from thirty to forty for one. Their public burdens are the same as those of the wine-growers; and the duty upon the grain which is carried to Cape-town amounts to nearly a tenth of its value. The graziers are by far the rudest of the Cape colonists, and can scarcely be said to be superior, either in intelligence, in manners, or in comforts, to many of the uncivilized hordes of savages that surround them; many of them, especially towards the northern and eastern boundaries of the settlement, have no fixed habitations, but wander about from place to place, and sleep with their families in waggons, or build temporary reed huts like the Hottentots. Those even who are stationary are scarcely better accommodated. Their huts being only destined for temporary accommodation, until a fountain dries up, or their flocks have consumed the pasture in its neighbourhood, are generally constructed of clay baked in the sun, or sods, covered with a thatch of rushes, carelessly put together, rarely water proof, and protected only by a door of reeds matted together. They have seldom more than one apartment, and here the peasants, with their children, and the house Hottentots, are huddled together during the night. The master's bed, which is an oblong frame of wood, standing on four feet, and reticulated with thongs of undressed leather, which supports a wool mattress or feather bed; a great chest, which contains all their moveables, and serves for a table; a few chairs, and a large iron pot, for preparing their provisions, are their principal articles of furniture. The dress of the men consists of a blue shirt, leather pantaloons, a broad brimmed hat, and a pair of shoes of rawhide. The women have a short jacket and petticoat, a thick quilted cap tied under the chin and falling down upon the shoulders, no stockings, and seldom shoes. Their principal food is mutton, which is served up three times a day. They have very little milk and butter, and but few vegetables. The master carves the meat with a large pocket-knife, and then every one helps himself. Wines is rarely seen at their tables, though they live in the midst of a soil and climate most favourable for the cultivation of the grape. A glass of strong ardent spirits is the favourite debauch of a Dutch African boor, and his greatest luxury is his pipe, which never quits his mouth except when he eats or sleeps. Such are the comforts and situation of many a peasant who possesses several thousand sheep, and as many hundreds of cattle. Indolence is the predominant feature in his character. It is only by the most urgent necessity that he can be brought to exert himself, even for his own convenience or interest. But though indolent in what concerns his own comfort, he is active in oppression towards the miserable Hottentots who are under his authority. Of these helpless beings, each family in Graaf Reynet possesses, on an average, about thirteen, who are, in general, treated with the most brutal inhumanity. The most trifling fault is visited with the severest punishments. The husband is frequently separated from his wife and children, and driven from his habitation, is compelled to join his persecuted, but still independent countrymen, among the mountains. Their cruelty is also extended to the Caiffres and Boisjessmans, with whom they are almost constantly at war. From the latter of these, however, they often experience the most terrible retaliation; and consequently, the murder of one of them is proclaimed by the Dutch as a most meritorious action. "A boor from Graaf Reynet," says Mr Barrow, "being asked in the secretary's office, a few days before we left the town (Cape), if the savages were numerous or troublesome on the road, replied, he had only shot four, with as much composure and indifference as if he had been speaking of four partridges. I myself have heard one of the humane colonists boast of having destroyed, with his own hands, near three hundred of these unfortunate wretches." Many of the farmers in the eastern parts of the Manners, settlement can neither read nor write. Their ignorance, however, is more to be lamented than to be wondered at, when the means of instruction within their reach are considered. The habitations are too widely scattered over the country to admit of the establishment of public schools; and the means of individuals are too circumscribed to admit of their hiring competent teachers in their families; for who, that had received a tolerable education, would bury his knowledge in the hut of an African peasant, whose supply, even of the necessaries of life, are often but scanty. A disbanded soldier, who had served the Dutch long enough to obtain his stipulated discharge, generally becomes the preceptor of a Boor's children; and he is frequently paid for his * Many and most shocking instances of barbarity inflicted upon this unfortunate race, are recorded in a pamphlet published at the Cape during the last peace, by Baron de P----, private secretary to Governor Jansens. Among these, is an account of the murder of fifteen innocent Hottentots, who, having come to a farm to beg some hemp and tobacco, were inhumanly tortured in order to extort a confession that they were come with an intention to plunder the colonists, and afterwards shot; and another, equally brutal, of which we give the following translation: "As soon as the English had abandoned the fort, (at Algo Bay), a boor named Ferrara, of a Portuguese family, made himself master of it, and kept possession till the arrival of a detachment of troops which government sent thither, under the command of Major Von Geltcr. The Caiffres, fully persuaded that the late peace had put an end to all disturbances between them, sent to the new commander of the fort a bullock to be slain as the test of reconciliation and friendship. The Caiffre sent on the occasion put himself under the guidance of a Hottentot; and Ferrara, by way of returning the kind intention, laid hold of the Caiffre, and brouille him alive; bound the poor Hottentot to a tree, cut a piece of flesh out of his thigh, made him eat it raw, and then released him."
instructions in sheep and clothing. If sober, which is not always the case, he amasses enough to become a farmer himself. The principal occupation of the greater part consists in learning to shoot, to drive a wagon, and to crack and use with dexterity an enormous whip. Notwithstanding their ignorance, however, they all affect to be very religious; and, though their religion seems to have very little influence in awakening feelings of benevolence and humanity towards their fellow-creatures, they are scrupulously exact in the observance of its forms. They are regular in their attendance at church, though it costs some of them a journey of several days; and such as are a fortnight or three weeks journey from the nearest place of worship, generally go with their families once a year. They always begin their meals with a long grace, pronounced by the youngest of the company; and every morning, before day-light, one of William Sluiter’s Gesanger* is sung by the whole family. Having enumerated those depravities which tarnish the character of the African Boor, we turn with pleasure to a more amiable part of his character, the hospitality which he cheerfully exercises to those strangers who visit his abode. His door is open to all who come; and, without a question being asked, the stranger is invited, in the laconic style of Dutch politeness, to enter. He is made welcome to his share of the repast, to a bed, or to a part of a bed, if the house only affords that accommodation; and “in the morning,” says Mr Barrow, “after a solid breakfast, he takes his glass of brandy, orders his slave, or Hottentot, to saddle the horses, shakes hand with the men, and kisses the women; he wishes them health, and they wish him a good journey. In this manner a traveller might pass through the whole country.”

Under such a climate, where the means of subsistence are so easily produced, where the country is but thinly inhabited, and the habitations are so distant from each other, and so far removed from the seat of government, as often to place their tenants beyond the reach of law, we are not surprised to find, that the vicious propensities have too often predominated over those of the opposite character, in men who have not originated from the Dutch, or from any common source, but have sprung from most of the nations of Europe. When they committed crimes, the threatenings of a distant and feeble authority, without the power of putting them in execution, served rather to encourage than to deter them from prosecuting their schemes of plunder; and the only hardship resulting from their disobedience, was being debarred from visiting the Cape. Thus many of them became perfect robbers, and lived in a state of almost constant hostility with the surrounding tribes. Liable to be attacked in their turn, they were compelled to wander from place to place, and to be continually on the watch; thus deprived of many comforts and conveniences which a state of peaceful society affords, and habituated to scenes of cruelty inseparable from such a warfare. Those who afterwards became stationary, did not think of renewing those comforts to which they had been long accustomed, and werecontent with little more than the bare necessities of savage life. The same system of plunder still continues in some of the distant parts of the colony; and many of the boors are under sentence of outlawry, on account of their depredations and disobedience.

The tenures under which the colonists hold their lands in this settlement, are of four descriptions, viz. loan lands, gratuity lands, quit rents, and freeholds. The first of these is the most ancient, and consists of certain portions of land granted to the early settlers, upon condition of paying to government an annual rent of twenty-four rix-dollars. Each of these is supposed to contain about nine square miles; and, though the lease was at first made out only for one year, yet the payment of the rent was considered as a renewal; and, consequently, this tenure is nearly similar to a lease held in perpetuity. Gratuity lands are those which were originally granted in loan, but have been since converted into a kind of customary copyhold, liable to an annual rent of twenty-four rix-dollars. Quit rents arise from pieces of waste land occupied by the owners of the estates to which they are contiguous, upon a lease of fifteen years, and at an yearly rent of one shilling per acre. Freeholds are such lands as were granted to the original settlers, in small portions of 120 English acres, and consist of the finest land in the colony. They are chiefly confined to the Cape district, and its vicinity.

The commerce of this settlement under the Dutch, was confined almost entirely to such ships as touched at the Cape for refreshments; and a scanty supply of a few European and Indian commodities for the immediate use of the colony. These, however, were allowed to be brought only in Dutch bottoms, all traffic with the other nations being considered as contraband; and such was the tardiness with which they were furnished, that the inhabitants were sometimes compelled to smuggle certain articles out of foreign vessels for daily consumption. The original design of its occupation, was merely as a point of communication between their Indian settlements and the mother country; and, though it was afterwards used as a military depot, for forming and preparing their troops for warmer climates, yet it has never been able to profit by the advantages of its situation. Were the absurd regulations, and jealous restrictions, with which it has been so long fettered, completely abolished, and the trade of our Indian empire thrown open to all British ports, the Cape might rise to be one of the first commercial cities in the world. Placed at almost an equal distance from India, Europe, and America, it would soon become an emporium for the manufactures and produce of each of these countries, and an influx of active settlers would raise it to be a most valuable colonial possession. It would not only open an extensive market for British merchandise, but it might be rendered a granary capable of affording us almost unlimited supplies during a scarcity. Little, however, can be expected from its present inhabitants, whose indolence has been fostered by the restrictive regulations of the

* Songs from the Bible, done into verse by William Sluiter, the Sternhold and Hopkins of Holland.
government, which seems to have thrown every impediment in the way of its becoming a flourishing settlement; and, consequently, a statement of its present trade, cannot be considered as any estimate of its real importance. Its principal articles of export consist of grain, pulse, wine, brandy, hides, skins, dried fruits, aloes, and ivory. The quantity exported, however, is very inconsiderable; and, during the last four years in which the settlement was in possession of the British, from 1799 to 1802 inclusive, the total value of colonial exports amounted only to 300,925 rix-dollars, or L. 60,185 currency; and its re-exportation of foreign commodities to about L. 170,000. Of 131,361 1/2 muids of wheat, which passed the barrier during that period, and paid duty, 30,000 muids were annually required for the consumption of the inhabitants of Cape Town and the army and navy; so that the average annual surplus which could be spared for ships calling for refreshments, was less than 4000 muids. The wine and brandy which passed the barrier in four years, amounted to 21,649 1/2 hogsheads of the former, and 1665 1/2 of the latter. Of these, the average quantity annually exported was about 600 hogsheads of wine, besides 23 of Constantia, and 60 hogsheads of brandy, estimated at 50,000 rix-dollars. The annual exportation of aloes was 85,482 lb. valued at 6416 rix-dollars; that of hides and skins amounted to between 5000 and 6000 rix-dollars; of dried fruits, in 1802, to 2542 rix-dollars; and of ivory to 1585 rix-dollars.

Besides these articles of colonial growth and produce, which this settlement, if properly managed, could furnish to almost any extent, it is capable of supplying several others equally valuable, and in equal abundance, particularly tobacco, wool, salt provisions, whale oil and bone, and soap.

The limited exportation of this colony, however, does not at all regulate the quantity of its imports. In most countries, it is according as the one or the other of these preponderates, that we estimate their poverty or wealth: But in the Cape settlement, though its exports scarcely amounts to one-fifth of its imports, a considerable balance is drawn in favour of the colony, which, however, is occasioned entirely by the consumption of the garrison and navy. The principal articles of importation from Britain, consisted in woollen cloths, Manchester goods, hosiery, haberdashery, millinery, boots, shoes, hats, cutlery, iron tools, stationery, bar and hoop iron, smiths' coals, household furniture, paints, oils, earthen-ware, naval stores, tongues, hams, cheese, and pickles; from India and China were brought piece goods, tea, coffee, sugar, pepper, spices, and rice; from America, deal planks, staves, balk, salt fish, pitch, turpentine, &c.; and from Denmark, Sweden, and Hamburgh, assorted cargoes of iron, plank, French wines, beer, gin, Seltzer water, coffee, preserves, pickles, &c. An abstract account of the whole importation is contained in the following Table:

This immense preponderance of imports, Mr Barlow disposes of in a very satisfactory manner. He supposes that the army, independent of the clothing and stores, &c. sent from home, and money remitted by the officers, could not expend less, in European and Indian goods, and colonial produce, than L. 180,000 per annum, which in four years is L. 720,000. The navy expenditure might, perhaps, amount to half that sum, 360,000. The re-exportation of India prize goods, and of European goods to the West India islands, the coast of Brazil, and Mozambique, in four years, about 170,000. Brought forward - L. 1,250,000

Surplus colonial produce exported, as above - 60,185

L. 1,310,185

Value of imports, as above - L. 1,195,507

Balance in favour of the colony, and merchants residing there, L. 114,677

According to the books of the custom-house, and the returns of the captain of the port, the vessels which sailed from the Cape amounted, In 1799 to 103;

1800 109;

1801 120;

1802 151;

Total, 473 ships.
Of these, 82 were Americans, 66 Danes, 24 Portuguese, 6 Swedes, 15 from Hamburg, 4 from Prussia and Bremen, and the rest English.

While this settlement was subject to the Dutch East India Company, its revenue was never adequate to the contingencies and extraordinary expenses of its government, and it was retained merely as a place of refreshment for the outward and homeward bound India ships, which they considered as an ample compensation for the annual expenditure of 300,000 gilders. In 1770, the deficiencies in the receipts for defraying the expenses of the colony amounted to £26,768;11:9 sterling, being nearly two-thirds of the expenditure; and in 1779, it was increased to £28,101. The average revenue from 1784 to 1794 was about 100,000 rix-dollars yearly; but, by the new regulations and impost of the Dutch commissionaries general in 1793, it was raised to 211,568 rix-dollars; which was farther increased to 450,713 during the last year of Lord Macartney's administration, while the settlement was in possession of the British, without a single additional tax having been laid upon the inhabitants. The public revenue of the colony arises from the following sources, to each of which we have affixed the amount for 1801.

Total amount rix-dollars, 450,713

Or, L. 90,142 13

The supreme government of this colony is vested by the king in a governor or lieutenant governor. Each district is placed under the authority of a Land-droost, assisted by a council of burgheers, six in number, called the Heemraaden. The office of Land-droost is somewhat similar to that of sheriff of a county in Scotland. The person filling that station is not only at the head of the police of his district, but presides in the provincial court, with authority to hear and decide civil actions, where the sum in controversy does not exceed 150 rix-dollars, and to try such criminal suits as do not infer a capital punishment. His decisions are open to appeal, and subject to the revision of the court of justice in Cape Town. The court of justice is composed of a president and six judges, appointed by the governor, forming a court of competent jurisdiction, to try all causes civil or criminal that may be brought before them, deciding by plurality of votes, as a special jury. An appeal lies from their judgment to the court of appeals, in which the governor or lieutenant-governor decides upon a statement of the case agreed upon by parties before the inferior court; and from the decision of the court of appeals, an action may be carried in appeal before the king and council. The legal proceedings are regulated by a code of laws, emanating from the Dutch East India company, called the Statutes of India, founded upon the basis of the civil law, and drawn up expressly for the jurisprudence of their possessions in the East. Beside the statutes of India, the proclamations of the governor were considered as laws, and were supposed to relate to such circumstances as were in their nature only local or temporary.

In Cape Town there is also an inferior court for the summary decision of petty suits, consisting of a president, vice-president, and four members; it is the duty of this court to grant licenses to parties intending to marry, without which no clergyman is authorized to perform the ceremony.

There is an excellent institution here, called the Orphans' Chamber.* The Orphans' Chamber, appointed by the government for administering the affairs of orphans and minors. This board is composed of a president, secretary, and four members. The fiscal is president ex-officio. Private executors are by law allowed 5 per cent. for their trouble, and property sold by them is liable to a tax of five per cent.; whereas the property managed by the Orphan Chamber is exempted from the tax on the transfer of immovable property, and is charged 7½ per cent., consequently 2½ per cent. are saved to those interested, in addition to the security derived by the most helpless part of the community, from having their effects vested in the charge of a public college established by law, instead of becoming victims to ignorance, to misfortune, or to fraud. The fiscal is the attorney general and public prosecutor in all criminal cases. He is also the chief magistrate of police, and in this capacity has authority to inflict corporal punishment upon such of the inhabitants as are not burgheers for petty offences, and is empowered to impose fines and accept perjury compositions for misdemeanors, and where the offender does not wish to risk a public trial this power was formerly subject to most enormous

* The Loan, or Lombard Bank, was established by the Dutch government, with a view of increasing their revenue, while, at the same time, they appeared to confer a favour upon the colonists. The acquired capital was about 650,000 rix-dollars, and paper money was issued as a loan to individuals, on mortgage of their lands and houses, with the additional security of two sufficient bondsmen, at 5 per cent. being 1 per cent. less than the legal interest of the colony. According to its regulations, the loan was never to exceed half the value of estates in town, and two-thirds of estates in the country; and at the expiration of two years, the directors could either call in the loan, or prolong it, as they thought proper. The sum issued was at first confined within the amount of the capital, but was afterwards increased to near one million rix-dollars.
Although Calvinism is the established religion in the settlement, there are many Lutherans. The ministers are paid entirely by the government; and there is no country in which this useful body are more highly respected. They hold the next rank to the president of the court of justice in town, and to the Landdroost in the country. The poor funds accruing from donations at the church door, legacies, and also from a tax upon the emancipation of slaves, are entirely under their management. In 1798, the funds belonging to the established church amounted to £22,168: 8: 8, and the relief granted to the poor was £14,829: 19: 2, and the poor received £194: 9: 2.

In the district of Stellenbosch, at a place called Bavian’s Kloof, is an establishment of Moravian missionaries, who, about ten years ago, had collected into one society more than six hundred Hottentots, whom they not only instructed in the Christian religion, but taught several useful trades. Each family possessed a small hut with a patch of ground for raising vegetables; and by the example and persuasion of these good fathers, had become both cleanly and industrious. “The deportment of this Hottentot congregation during divine service,” says Mr Barrow, “was truly devout. The discourse delivered by one of the fathers was short but replete with good sense, pathetic, and well suited to the occasion; tears flowed abundantly from the eyes of those to whom it was particularly addressed. The females sung in a stile that was plaintive and affecting; and their voices were in general sweet and harmonious. Not more than fifty had been admitted as members of the Christian faith by the ceremony of baptism. There appeared to be no violent zeal on the part of the fathers, which is the case with many other missionaries, to swell the catalogue of converts to Christianity, being more solicitous to teach their trades to such as might chuse to learn them. Adopting the idea of the humane Count Rumford, their first great object seemed to be that of making men happy, that they might afterwards become virtuous, which is certainly much sounder philosophy, than the reverse of the proposition.”

In the history of this settlement, there are few circumstances deserving of very particular attention. Its conquest was accomplished without bloodshed, and its natives have hitherto opposed but very feeble resistance to their European oppressors. The lofty promontory of the Cape was first discovered by Bartholomew Dias, an eminent Portuguese navigator, in 1487, and named by him Cabo Tormentoso, or the Stormy Cape, on account of the boisterous weather which he experienced near the coast, and which, with the shattered condition of his ships, and the mutinous disposition of his crew, prevented him from doubling it, or making the land. His sovereign, John II., however, gave it a name of more propitious import, and called it the Cape of Good Hope, thereby expressing his sanguine expectation, that the long wished for passage to India had now been found. These expectations were indeed completely fulfilled in 1497, by Vasco de Gama, who, having touched at the Cape, passed to the coast of Malabar. The Portuguese, in their subsequent visits to this country, made several attempts to establish a colony, but they all failed; and nearly a century and a half was allowed to pass, before any European power had formed a permanent settlement on its shores. During this period, the English and Dutch frequently touched at the Cape for refreshments on their way to India; and it was the general custom to leave dispatches for their respective directors, buried in a certain spot, which were taken up, and carried home by returning vessels. The Dutch, however, at last began to discover the advantages which such a position would afford to their India trade, both as a point of communication and refreshment; and upon the favourable representations which Van Riebeck, then a surgeon in one of the Dutch ships, gave of the mildness of the climate, and the fertility of the soil, resolved to form a regular establishment. This resolution was carried into effect in 1650, under the direction of Van Riebeck, who, having concluded a treaty with the natives, took possession of the Cape peninsula, and laid the foundation of the present town, by erecting a fort of wood and earth, and some other necessary buildings, which he called Kieder de Keu, “a defence against all.” This gentleman soon discovered, and took advantage of, the passion which these weak and peaceable Hottentots had for spiritous liquors; and by giving them a few casks of brandy, a little tobacco, iron, and some poultries, obtained from them a part of their country and their flocks. A piece of iron hoop was the price of an ox, and a cask of brandy the purchase of a whole district. A hundred male settlers constituted the first colony of the Cape; but these being afterwards joined by nearly an equal number of females from the houses of industry in Holland, and also by a number of French refugees, who were obliged to leave their country in 1685, its population rapidly increased. The principal difficulties which were at first experienced in the extension of the settlement, arose from the wild beasts that swarmed in every part of the country, and which committed their nightly depredations under the very walls of the fort. But these were by degrees almost completely extirpated; and, unless one ineffectual attempt of the natives to recover their lands, and to expel their oppressors, the Dutch continued without any farther interruptions, either from the Hottentots or Europeans, to extend their encroachments over the richest districts of the country, for nearly 150 years. This settlement, however, by the restrictive regulations on its commerce, though its inhabitants and territories were continually increasing, was unable to support the expence of its own government; and, except as a port of refreshment for their Indian ships, it became a burden, instead of a convenience, to the mother country. Soon after the breaking out of the French revolution, the mania for liberty and equality found its way into the settlement, and serious apprehensions were entertained, lest the colonists should declare themselves a free and independent republic. A convention was established, and proscribed lists were made out, of such of the inhabitants.
as were to be condemned to banishment or the guil-
lotine; and even the slaves had their meetings, and
began to hail the period of their complete emancipa-
tion. The appearance of a British fleet, however, in
1795, soon put an end to these proceedings. The
Dutch force was driven from the advanced posts of
Simon's Town and Muyscburg by General Craig,
with a very small body of the 78th regiment, aided
by corps of seamen and marines, landed for the oc-
casion from the fleet in False Bay, commanded by
Sir George Keith Elphinstone; and the important
advantage which had been gained was maintained in
the face of a superior force by that able general,
until the arrival of an army under Sir Alured Clarke,
when, on the advance of the British to Wynberg,
terms of capitulation were accepted of. During
the seven years it remained in our possession, a wise
and liberal policy had considerably increased its
revenue and commerce; and, on closing the public
accounts the year after the departure of Lord
Macartney, the governor, a balance of between two
and three hundred thousand rix-dollars remained in
the treasury, after defraying all the expenses of the
colony. By the peace of Amiens, in 1802, it was
delivered up to the Batavian republic in full sove-
reignty; but so far declared a free port, that the
ships of the British and French nations were to be
allowed to enter its harbours, upon paying the same
duties as those of the mother country. In 1806, it
was again taken by the British, under Sir David
Baird and Sir Home Poplum, under whose domini-
See An Account of Travels into the Interior of Sou-
thern Africa, by John Barrow, Ent. who, in the se-
cond volume of this valuable work, has treated, at
considerable length, of the value and importance of
the Cape of Good Hope, as a military and naval sta-
tion, as a seat of commerce, as a central depot for
the southern whale fishery, and as a territorial pos-
session; and by way of conclusion adds, "that, un-
der the present impecunious disposition of France to-
wards this country, and the insatiable ambition of its
government, Great Britain never can relinquish the
possession of this colony for any length of time, with-
out seriously endangering the safety of her Indian
trade, and the existence of her empire in the East."

Sketches at the Cape of Good Hope; and Perceval's
Account of the Cape of Good Hope. (p)

CAPE TOWN, the capital of the Cape of Good
Hope, and the only place in the colony that deserves
the name of a town, stands on a sloping plain at the
south-west corner of Table Bay, and is surrounded,
extcept towards the sea, by black and dreary moun-
tains. It is a regular and neatly built town, and well
watered by a plentiful stream which issues from the
Table Mountain. Many of the streets are of con-
siderable breadth, having canals of water running
through them, which are walled in, and planted on
each side with oak; but others are narrow and ill-
paved. They are all straight, however, being laid
out with a line, and intersect each other at right
angles. The houses are in general built of stone,
and white washed, and the greatest numbers are two
stories high, with flat roofs, and a kind of pediment
in the centre. The spacious squares give the town
an open and airy appearance; the public market is
held in one; another is the common resort of the
farmers and graziers with their waggons; and a third
is used as a parade for exercising the troops. This
last lies between the town and the castle, and has
two of its sides completely built up with large and
handsome houses. The castle stands a little east of
the town. It is a pentagon fort, surrounded with
a ditch and regular outworks, and contains with-
in its walls the Lombard Bank, the Orphan Cham-
ber, and most of the public offices of government.
It also affords accommodation for 1000 men with
their officers, and has magazines for artillery stores
and ammunition. But though it commands the town
and part of the anchorage, it is entirely indefensible
against the batteries which have been erected upon
the rising ground towards the Devil's Hill. The
barracks, originally intended for an hospital, gymna-
сies, &c. which, with its two wings, occupies a part
of one of the sides of the great square, is a large
and regular edifice, and has sufficient convenience
in the upper part of the building for 4000 men.
The other public buildings are the Calvinist church,
the Lutheran church, the court of justice, the guard-
house, and the theatre.

Behind the town, on the acclivity of Table Mount-
in, is the government house, and a beautiful pub-
lic garden, which is an oblong piece of ground, con-
taining about 40 acres of rich land, and divided into
forty-four squares by oak hedges. Part of it has
been appropriated for the reception of scarce and
curious native plants, and for experiments upon such
Asiatic and European productions as may seem most
likely to be cultivated with benefit to the colony.
Over the same acclivity are also scattered a number
of handsome villas, each of which is surrounded with
plantations and gardens. Besides the castle, Cape
Town is defended by several other forts, which have
been erected along the shore of Table Bay. On
the east side of the town is Fort Knokke, which is
connected with the castle by a rampart called the
sea-lines; and a little farther on is Craig's tower and
battery. On the west side, and surrounding the
Lion's Rump, are Rogge-bay battery, Amsterdam
battery, and Chavonne battery, which all bear upon
the anchorage; and the entrance of the bay is com-
manded by a small battery, called the Mouillé.

This town contains 1145 dwelling-houses, which
are inhabited by 5500 whites and people of colour,
and about 10,000 blacks. The greatest portion of
the day is devoted to drinking and smoking by ma-
ny. They have no relish for public amusements,
and no taste for literature and the fine arts. Indeed,
there is not a bookseller's shop in the whole town;
and the only library of the place was left by an indi-
vidual for the use of the public. It is under the di-
rection of the church, but it is very little used. A
public school even has never yet been established in
the colony, though the exhortions both of the gov-
ernment and the clergy have been united in the attempt.
Many of the inhabitants are in easy circumstances,
although there are not many who can be called rich,
a circumstance which results in a considerable degree from the republican law of the province, by which property inherited is equally divided amongst children, male and female, without regard to sex or primogeniture. From the operation of this law, much family feud and dissension have often arisen, from the children becoming rivals and competitors for the effects of a parent at a public sale.

Such luxuries as are imported from Europe or India are costly; but the necessaries of life may be procured at a moderate price. While a labouring slave earns from 2s. to 2s. 6d. a day, and a mechanic or artificer from 5s. to 6s. a day, the pound of butcher's meat is seldom above 2d.; even in the year 1801, when the demand was increased by the addition of 5000 troops and 300 seamen, the supply for the garrison was nearly higher than at the rate of 2 ½ pounds for 6d. A pound of wholesome bread sells for 1d.; a pint of good wine for 3d.; and all kinds of fruits and vegetables are abundant and cheap.

The inhabitants of this town have a remarkable propensity for public sales, and many of them live entirely by such traffic, exposing to sale in the evening what they probably bought at the same place in the morning. All property, however, sold by public auction, is liable to a duty of 5 per cent.; and such was the rage for vendues, that during four successive months of 1801, the value of property sold in this way amounted to $500,000 rix dollars; a sum," says Mr Barrow, "equal to the whole quantity of paper money in circulation; which, indeed, may be considered as the only money of late years that has circulated in the country."

The slaves used in this colony are imported from the west coast of Africa, from Mozambique, the Malay Islands, or they are the offspring of slaves born in the country. The African negroes are the best adapted to field labour; the Malas are esteemed the most acute in point of intellect, and the most docile; the artificers, therefore, are generally taken from this class; but they are capricious and vindictive; they set so little value upon their own lives, that they do not hesitate to commit the most atrocious and unprovoked murders, to gratify their revenge for injuries received or supposed. Their dispositions were so well known to the Dutch government, that the colonists were prohibited from having Malas slaves; but many evaded the law, and forfeited their lives for their temerity.

It has been observed, that slaves at the Cape of Good Hope are well treated by their masters, a position which we are the less disposed to controvert, because we suppose it to have been founded on compassion for the condition of the most unfortunate of our fellow creatures in this and other countries, where the horrors of the slave-trade exist; but since it is self-evident, that the comfort and happiness of the slave must necessarily depend upon the temper, habits, and character of his master, we need not cite examples to demonstrate, that cruelty is the necessary and inseparable concomitant of slavery, even in its mildest form. For the commerce and government of Cape Town, we must refer to the preceding article, and the authorities thereto subjoined. S. Lat. 33° 55' 42", E. Long. 18° 23' 15". *(p)

CAPELLA, a star of the first magnitude, in the left shoulder of Auriga. See Astronomy, p. 747.

CAPIAS, in the law of England, is a writ or process, of which there are several kinds.

Capias ad respondendum, is a writ sued out before judgment, where an original is taken out, &c. to take the defendant, who had neglected to appear in the previous process, and make him answer the plaintiff. If, therefore, the defendant, being summoned, makes default, or if the sheriff returns a nihil, or that the defendant hath nothing whereby he may be summoned, attached, or restrained, the capias usually issues, commanding the sheriff to take the body of the defendant, and keep him, so as he may present him in court on the day of the return. This writ, and all others subsequent to the original,—not issuing out of chancery, but from the court into which the original was returnable, grounded on what has passed in that court, in consequence of the sheriff's return, issuing under the private seal of that court, and not under the great seal of England; and testa'd,—not in the king's name, but in that of the chief justice only, are called judicial, or original, writs. And these several writs must respectively bear date, the same day on which the writ immediately preceding was returnable. But it is now the usual practice to sue out the capias, in the first instance, upon a supposed return of the sheriff; and, afterwards, a fictitious original is drawn up, and a proper return thereupon, in order to give the proceedings a colour of regularity.

If the sheriff of the county, in which the injury is supposed to be committed, and the action is laid, cannot find the defendant in his jurisdiction, he returns non est inventus; upon which another writ issue, called a testatum capias, directed to the sheriff of the county where the defendant is supposed to reside. But in this case, also, it is usual to make out a testatum capias at the first, on the supposition that not only an original, but a previous capias had been granted, although in reality they never were. When a defendant absconds, however, and the plaintiff would proceed to an outlawry against him, an original writ must be sued out regularly, and after that a capias. And if the sheriff returns a non est inventus upon the first capias, then there issues an alias, and after that a pluries writ; and if a non est inventus be returned upon all of these, then a writ of exigent may be sued out in order to outlawry.

Such is the first process in the Court of Common Pleas. In the King's Bench, also, they may, and frequently do, proceed by original writ, with attachment and capias, particularly in actions of ejection.

* Such of our readers as are acquainted with the different works which contain an account of the Cape of Good Hope, will readily perceive that we have had access to much valuable and original information which has never been published, and that we have thus been enabled to correct many errors which the latest writers have committed. For these important communications, the Editor has been indebted to William Somerville, Esq. Inspector of Military Hospitals, who spent many years at the Cape, and who was peculiarly fitted, both by his situation and talents, to obtain the most correct information respecting that important colony. We trust that in many other parts of our work we shall have occasion to acknowledge assistance from the same quarter; and in the mean time we look forward with much impatience to the publication of that gentleman's Travels into the interior of Africa, which we hope he will soon be induced to give to the world.

us.
CAPILLARY ATTRACTION.

Phenomena of Capillary Attraction.

**Exp. 1.** If water, or any other fluid, excepting mercury and the metals in a fluid state, be poured into a clean vessel, the fluid in contact with the sides of the vessel will be raised above the level of the fluid in the middle of the vessel, and the fluid surface will be terminated by an elevated ring of fluid. See Plate CX, Fig. 1, where A, B are the sides of the vessel, and c, d, the elevated fluid.

**Exp. 2.** If a solid body is immersed in a fluid, the fluid will be raised round the sides of the solid, as in Fig. 2, where S is the solid, and c d the elevated fluid.

These phenomena may be seen most distinctly, by viewing the image of a rectilineal object, seen by reflection from the fluid surface. The rectilineal image will indicate, by its change of form, the magnitude and extent of the elevated ring.

**Exp. 3.** If the fluid, used in experiments 1 and 2, is mercury, or any metal in a state of fusion, the fluid in contact with the sides of the vessel in Exp. 1, or with the sides of the solid body in Exp. 2, will be depressed below the general level, as is exhibited in Figures 3d and 4th.

**Exp. 4.** If a glass tube A, whose internal diameter or bore is less than the 10th of an inch, be immersed at one end into a fluid in the vessel MN, the fluid will rise to A to a considerable height above the fluid surface. If another capillary tube B of a greater bore is immersed in the same fluid, the fluid will also rise in the tube above its level, but not to such a height as in the tube A. By comparing the heights of the fluid in the two tubes, with the diameters of their bores, it is found that the heights are inversely as the diameters. That is, if D be the diameter of the larger tube DB, d the diameter of the smaller tube CA, A the altitude of the fluid in the former, and a its altitude in the latter, we shall have A : a = d : D, and consequently AD = ad. Hence it follows, that the product formed by multiplying the diameter of any capillary tube, by the altitude to which any fluid rises in the tube, is a constant quantity.

The following are the heights to which water has been observed to rise in capillary tubes, reduced to a tube whose diameter is 1/10 of an inch:

† These gentlemen found, that in a tube whose diameter was one thousandth part of a metre, water rose to the height of 13.57 thousandths, hence the product of the diameter and height will be .039371 × 13.57 × .009371 = .021034.
The great discrepancy between these results, which amounts to more than a half of the whole altitude,  

Exp. 5. If the preceding experiment is tried with fluids of different kinds, it will be found that they rise to different altitudes. M. lars Hauy and Tremery found, that oil of oranges rose 6,744 thousandths of a metre, in a tube whose diameter was one thousandth of a metre, which reduced to a tube of an inch in diameter, gives only 1.0447 inch, or 0.010447 for the constant quantity. Mr. Benjamin Martin made a variety of experiments on different fluids, with a tube of an inch in diameter, and obtained the following results.

Exp. 6. If tubes of different lengths are employed, the fluid will never ascend to the top of the tube, however short. Thus in Fig. 5, if the tube AC is broken off at P, the fluid will stand at p below the top P, though it formerly rose as high as A. We have tried this experiment repeatedly with a tube 0.96 of an inch long, and 0.043 in diameter, and have found that the fluid always rises to the very top of the tube.

Exp. 7. If a capillary tube, composed of two cylinders of different bores, be immersed in a fluid first with the widest part downwards, as at E, Fig. 5, and afterwards with the narrowest part downwards, as at F, Fig. 6, the fluid will ascend in both cases to the same height.

Exp. 8. When the widest part of the tube is not capillary, but is of such a magnitude that the fluid will not rise spontaneously to the smaller part, let the wider part be filled by suction, and the fluid will stand at the same height in the smaller part of the tube, as it would have done had the whole tube been of the same bore with the capillary part.

Exp. 9. If the tube, when filled by suction, as in the preceding experiment, is placed in the receiver of an air pump, and the air exhausted, the fluid in the wider part of the tube will not remain suspended in the tube as formerly, but will fall down into the vessel.

Exp. 10. If one tube is placed within another so that their axes coincide, the water will rise in the space between the tubes only to half the height that it would have done in a single tube, in which the diameter of the bore is equal to the interval between the two tubes.

Exp. 11. When the internal diameter of several capillary tubes are equal, the fluid will rise to the same height whether the tubes are thin or thick.

Exp. 12. Having plunged a capillary tube into water, let the lower extremity of it be closed with the finger, and when the tube is taken out of the water, let its external surface be gently wiped. Upon withdrawing the finger, the water is seen to subside in the tube and form a drop at its lower base; but the height of the column is always greater than the elevation of the water in the tube, in the common experiment of plunging it in water. It has also been observed, that the increase in the elevation of the water is more considerable, the smaller the diameter of the drop beneath.

Exp. 13. If a drop of water is introduced into a conical capillary tube, open at both ends, and held in a horizontal position, it will move towards the vertex of the cone.

Exp. 14. When water is forced through a capillary tube, of such a bore that it is discharged only in successive drops, it will flow in a constant and accelerated stream when the tube is electrified, and the acceleration will be inversely proportional to the diameter of the bore. This fact seems to be denied by Cthony. See Journ. de Physique; xlvi. 106.

Exp. 15. A capillary syphon which discharges cold water only by drops, will discharge water of a higher temperature in a continued stream.

Exp. 16. Let a capillary tube be held in a position inclined to the horizon, and let a drop of liquid be let fall upon its surface, then bringing the tube into a vertical position at the instant when the drop has arrived at the inferior orifice, the fluid will run through the orifice, and rise in the interior of the tube.

Exp. 17. If the preceding experiments with capillary tubes, excepting Exp. 9, be made in the exhausted receiver of an air pump, the fluids will rise to the same height, as in the open air.

Exp. 18. If the bore of a capillary tube be lined with a very thin coating of grease, or any unctuous substance, the water will not ascend in the tube.

Exp. 19. By observing carefully the upper surface of the column of fluid, elevated in capillary tubes, it will be found to be concave upwards. M. Hauy found, that in capillary tubes of glass, of very small diameters, the concave surfaces of water and of oils differ very little from the form of a hemisphere.

Exp. 20. If the capillary tube is taken out of the fluid in which it is immersed, and inclined to the horizon so that the included fluid may obey the action of gravity, the concavity will appear at both ends of the column, and suffers no variation either in its shape or size, whether the tube be held in a vertical, a horizontal, or an oblique direction.
Exp. 21. When the column of water is thus made to move along the tube, it seems to suffer a resistance as it approaches to either end, and it does not completely reach the extremity of the tube till the tube is almost inverted.

Exp. 22. When a capillary tube is immersed in mercury, or in any metal in a state of fusion, the fluid, instead of rising, is depressed in the tube below the general level. See Fig. 4. Gellert found that when a glass tube was immersed in melted gold, the depression multiplied by the bore was 0.054. Messrs. Hauy and Treemey found, that the depression of mercury in a capillary tube one thousandth part of a metre in diameter, or 0.0000371 of an English inch, the product being 0.01177. The ultimate product inferred from Lord Cavendish's experiments is 0.015.

Exp. 23. If a drop of mercury be introduced into a conical capillary tube, held in a horizontal position, the mercury will move towards the wide end.

Exp. 24. By observing the surface of a column of mercury depressed in a capillary tube, or inclosed in a barometer tube, it will be found to be convex upwards. Mr. Hauy has endeavoured to show, that this convexity differs very little from the form of a hemisphere. Dr. T. Young maintains that this result is inaccurate, and that the angle formed by the surface of the mercury with the side of the tube is 140°. He obtained this result, by observing in what position the light reflected from the mercurial surface began to reach the eye, and he found it correct, from the comparison of a great variety of experiments of different kinds. This ingenious philosopher has prosecuted this branch of capillary attraction with great ability and success. He has calculated the precise form of the surface of the mercury in a variety of cases. In order to confirm these calculations, he employed another method, which consists in finding the mass of the quantity of fluid, supported by the tension of the surface at each concentric circle, and inferring from this the inclination of the curve to the horizon, assuming for the mean height the height of the external circumference of each portion; a supposition which almost compensates for the omission of the curvature of its surface.

As a specimen of these methods, we shall insert the following Tables, by means of which the curves may be correctly delineated. They are suited to a central depression of 0.007.

First Method by the Curvature.

Dr. Young has embodied the results of these calculations in the following formula, which gives the central depression without any perceptible error, 

\[ e = \frac{0.015d}{dd + 0.16} \]

This approximate formula supposes the surface to be spherical, and is corrected by a comparison with the results of the calculations, so as to agree with them all without an error of one two-thousandth of an inch in the most unfavourable cases. Dr. Young has also found a formula, when the diameter of the tube is moderate, for shewing the difference between the central and marginal depression, which may be of the greatest service in correcting the height of the barometer, whether we have obtained a measure of the highest or lowest point of the surface.

\[ g = \frac{5d + 100d^3}{15(5d + 100d^3)} + \frac{18}{5} \]

If \( d \) were very large, it would require some farther correction, \( g \) being ultimately too great by 0.0059. As our limits will not permit us to pursue this interesting subject any farther, we must refer our readers to Dr. Young's able paper on the Cohesion of Fluids, published in the Phil. Trans. for 1805, and in his Lectures on Nat. Phil. vol. ii. p. 666—669.

Exp. 25. When the mercury and the capillary tube are perfectly dry, the fluid will rise above the general level, like all other liquids. This was ascertained by Professor Casbois of Metz, who boiled the mercury several times, in order to free it from all humidity, and expel any foreign particles. By drying the mercury and the tube to a very great degree, Messrs. La Place and Lavoisier constructed barometers, in which the mercurial column was terminated above by a plane surface, and they even succeeded in rendering the upper surface of the mercury concave. The observations given under Experiment 24 are referable to barometers constructed in the usual way.

Exp. 26. If two plates of glass be placed parallel to each other, at the distance of about \( \frac{1}{2} \) of an inch, the water in which they are immersed will rise one inch above its level in the vessel; and when the plates are placed at different distances, the heights to which the water will rise, will be reciprocally proportional to the distances of the plates.

Exp. 27. If a capillary tube be taken of such a magnitude, that the diameter of its bore is equal to
the distance between the plates in the preceding experiment, the water will rise in it to the same height as between the plates. See Newton's Optics, p. 366.

Exp. 28. If a fluid is either elevated or depressed between two vertical and parallel planes, the planes will tend to approach each other.

Exp. 29. If two plane polished plates of glass, three or four inches broad, and twenty or twenty-five long, be laid one of them parallel to the horizon, the other upon the first, so as at one of their ends to touch one another, and contain an angle of about 10 or 15 minutes, and the same be first moistened on their inward sides with a clean cloth dipped into oil of oranges, or spirit of turpentine, and a drop or two of the oil or spirit be let fall upon the lower glass at the other end; so soon as the upper glass is laid down upon the lower, so as to touch it at one end as above, and to touch the drop at the other end, making with the lower glass an angle of about 10 or 15 minutes; the drop will begin to move towards the concourse of the glasses, and will continue to move with an accelerated motion till it arrives at that concourse of the glasses. For the two glasses attract the drop, and make it run that way towards which the attractions incline. And if, when the drop is in motion, you lift up that end of the glasses where they meet, and towards which the drop moves, the drop will ascend between the glasses, and therefore is attracted.

And as you lift up the glasses more and more, the drop will ascend slower and slower, and at length rest, being then carried downwards by its weight as much as upwards by the attraction. And by this means you may know the force by which the drop is attracted at all distances from the concourse of the glasses. Now, by some experiments of this kind, (made by Mr. Haupsbee,) it has been found that the attraction is almost reciprocally in a duplicate proportion of the distance of the middle of the drop from the concourse of the glasses, viz. reciprocally in a simple proportion, by reason of the spreading of the drop, and its touching each glass in a larger surface; and again reciprocally in a simple proportion, by reason of the attraction growing stronger within the same quantity of attracting surface. The attraction therefore within the same quantity of attracting surface is reciprocally as the distance between the glasses. And therefore, where the distance is exceedingly small, the attraction must be exceedingly great. 11 Newton's Optics, p. 367.

Exp. 30. If the plates in Exp. 26. are inclined to each other at a small angle, and are immersed in water with the line of their intersection vertical, the water will ascend between them, and will form a beautiful curve. This experiment is represented in Fig. 6. By measuring the ordinates and abscissae of the curve \( a, m, b, m, b \), Mr. Haupsbee found it to be the common Apollonian hyperbola. This indeed follows from Exp. 26., from which it appears that the altitudes are reciprocally as the distances of the plates. The heights of the fluid being the ordinates of the curve, and the distances of the plates being as the abscissae, the ordinates are inversely proportional to their respective abscissae, which is the property of the common hyperbola.

The preceding experiments, though numerous and varied, are obviously insufficient to form a proper basis for a philosophical theory. The enormous discrepancy among some of the results, as obtained by different philosophers, is completely bewildering; and, if we did not know that they were all made in the eighteenth century, we should have imagined that they were obtained in the dullest age of experimental philosophy. The height to which water ascends in a capillary tube, the diameter of whose bore is \( \frac{1}{2} \) of an inch, has been stated in the latest elementary works upon natural philosophy, at 5 inches and 3-tenths, according to the experiments of Mr Atwood; while, according to the more recent experiments of Messrs Hayu and Tremery, made at the desire and under the eye of La Place, the water rises only to the height of 2 inches and 1-tenth. The difference between these quantities amounts nearly to two-thirds of the whole; and what is still more perplexing, we are unacquainted with the particular manner in which the experiments were made, so that we are unable to discover any ground of preference, from the various precautions which were probably taken by the different observers to ensure accuracy, and to avoid error.

Under these circumstances, the writer of this article resolved to repeat the experiments himself; and he was particularly anxious to bring his apparatus into such a state, that he could always obtain the same result by repeated trials. After much trouble, he succeeded in this attempt to such a degree, that the water uniformly stood at the same height in the tube; and the same degree of accuracy was obtained for the other fluids, which were submitted to examination. To enable the reader to form a proper estimate of the degree of confidence which these results should inspire, we shall describe the precautions which were found necessary in the course of the experiments.

Having obtained a glass tube, 7.9 inches long, and of a uniform circular bore, we took a wire of a less diameter than the bore of the tube, and formed a small hook at one of its ends. This hook was fastened to the middle of a worsted thread, of such a size, as when doubled, to fill the bore of the tube. The wire was then passed through the tube, and the worsted thread drawn after it; and when the whole was plunged in an alkaline solution, the worsted thread was fixed at one end, and the tube was drawn backwards and forwards, till it was completely deprived, by its friction on the thread, of any grease or foreign matter which might have adhered to it. The tube and thread were then taken to clean water, and the same operation was repeated.

When the tube was thus perfectly cleaned, it was fixed vertically, by means of a level, in the axis of a piece of wood \( D \), supported by the arm \( A B \), fixed upon a stand \( A B \); and it was also furnished with an index \( m n \), which was moveable to and from the extremity \( b \). On the arm \( C E \), moveable in a vertical direction by the nut \( C \), was placed a glass vessel \( F \), containing the fluid, and nearly filled with it. The nut \( C \) was then turned till the extremity \( b \) of the tube touched the surface of the fluid, which was indicated by the sudden rise of the liquor round its sides. The fluid then rose in the tube till it remained stationary, and the index \( m n \) was moved till its extremity \( n \) pointed out the exact position of the upper surface of the fluid. In this situation, the distance \( n b \) was a measure of the ascent of the liquid above its level in the vessel \( E \). In order to ascertain, how-
ever, whether the fluid was stationary in consequence of any obstruction in the tube, or of an equilibrium of the attracting forces, the vessel with the fluid was raised a little higher than its former position, by means of the nut C, and then depressed below it. If the fluid now rose to a, a little above n, and afterwards sunk to p, a little below it, so as always to rise and fall with facility and uniformity along with the surface of the fluid in the vessel, it was obvious that it suffered no obstruction in the tube, and that

\[
nb \text{ was the accurate measure of its height. By separating the extremity } b \text{ of the tube from the surface of the fluid, the fluid always rises above } n; \text{ but upon again bringing them into contact, the fluid resumes its position at } n. \text{ If there should be any portion of fluid at the end } b \text{ of the tube, when it is again brought in contact with the fluid surface, the water would rise around it before it had reached the general level, and therefore the height of the fluid, obtained by measuring from the end of the tube, would be too small. In order to avoid this source of error, the index should have a projecting arm } mr. \text{ Fig. } 7 \text{. No. } 2. \]

Carrying a screw st, whose sharp point c can be easily brought on a level with the end } b \text{ of the tube. When the extremity } t, \text{ therefore, which can always be kept dry, comes in contact with the fluid surface } PQ, \text{ the extremity } b \text{ must also be exactly in the same level, even though the fluid had already risen around it. The tube was then cleaned, as formerly, for a subsequent observation. The results which were thus obtained for a great variety of fluids, and with a tube } 0.0561 \text{ of an inch in diameter, are given in the following Table.}

\[
\text{The method of measuring capillary attraction, by ascertaining the altitudes to which different fluids will rise in a glass tube, is not only liable to numerous objections, and to much uncertainty in the results, but is applicable only to the single substance of glass. We are thus left completely in the dark respecting the action which all the other solids exert upon fluid substances.}
\]

In order to remedy this defect, an instrument of very general application was some time ago proposed by Dr Brewster, the object of which was to measure, upon an optical principle, the diameter of the elevated circle of fluid, which any solid raises above the general level. Thus, in Fig. 8, let MNOP be the plan of a vessel filled with any fluid A the section of a solid cylinder of any substance immersed in the fluid and at right angles to its surface, and BC the diameter of the circle of the fluid, which is elevated by the action of the solid A. This elevated fluid is not terminated abruptly by the circle BC, but there is obviously a certain distance from A, where the ordinate of the curve becomes a perceptible quantity, either when examined by the eye or by a microscope. The apparent boundary of the circle at B is determined by observing the image of two delicate parallel fibres fixed in a frame at D, as seen by reflection from the surface of the fluid at B, to an eye at E, assisted by a powerful microscope, adjusted to a distance equal to EB + BD. When this image is seen by reflection from any part of the fluid surface without the circle BC, it will suffer no change of form; but when it is seen by reflection from any portion of the elevated fluid, the fibres will appear distorted, and they will therefore indicate, by their return to a rectilinear form, the apparent termination of the circle BD. The same observation is made at D, on the other side of A; and a measure is thus obtained of the circle BC, by means of the micrometer screws, by which the microscope at E, and the frame at D, are moved along the sides of the vessel. By this instru-

\[\text{Dr Young found the height of ascent of water and diluted spirit of wine to be as 100 to 64.}\]
CAPILLARY ATTRACTION.

Theory of Capillary Attraction.

Dr Hooke, who was one of the earliest writers on capillary attraction, ascribed the ascent of fluids, in capillary tubes, to the unequal pressure of the atmosphere, arising from a diminution of the pressure of the air in consequence of its friction in the tube. This opinion was maintained till the experiment was tried in the receiver of an air pump, and when the fluid was found to rise as high in vacuo as in the open air, a new cause was sought for the phenomenon. Sir Isaac Newton and Mr Hawksbee were of opinion, that the attraction of the tube was insensible at sensible distances. Dr Jurin ascribed the suspension of the fluid to the attraction of the ring of glass to which the upper surface of the water is contiguous, and adheres. Dr Hamilton and Dr Matthew Young maintained, that the fluid was elevated by the lower ring of glass contiguous to the bottom of the tube, and that this ring raises the portions of fluid immediately below it, and then the other portions in succession, till the column thus elevated was in equilibrium with the attraction of the ring.

Clairaut had the honour of being the first mathematician who gave any thing like a theory of capillary attraction. After pointing out the insufficiency of preceding theories, he enters into an analysis of all the forces by which the fluid is suspended in the tube, of which we shall endeavour to give our readers a brief account. Let ABCDEFGH be the section of a capillary tube, MNP the surface of the water in the vessel, I i the height of its ascent, VIZ the concave surface of the fluid column, and IKLM an indefinitely small column of fluid reaching to the surface at M. Now the column ML is solicited by the force of gravity which acts through the whole extent of the column, and by the reciprocal attraction of the molecule, which, though they act the same in all the points of the column, only exhibit their effects towards the extremity M. If any particle e is taken at a less distance from the surface than the distance at which the attraction of the liquid generally terminates, and if m n is a plane parallel to MN, and at the same distance from the particle e, then this particle will be equally attracted by the water between the planes MN, mn. The water, however, below m n, will attract the particle downwards, and this effect will take place as far as the distance where the attraction ceases.

The column IK, on the other hand, which is in a state of equilibrium with ML, is acted upon by the force of gravity through the whole extent of the column, also by other forces at the upper and lower extremities of the tube. The forces exerted at the upper part of the column, are the attraction of the tube upon the particles of water, and the reciprocal attraction of these particles; but as every particle is as much drawn upwards as downwards by the first of these forces, the consideration of it may be dropped.

In order to estimate the other force, let a horizontal plane VX touch the concavity at I, a particle p, situated infinitely near to I, is attracted by all the particles above VX, and by all below it whose sphere of activity comprehends that particle; and as the particles above p are fewer than those below it, the result of these forces must be a force acting downwards.

In order to estimate the value of the forces which act at the lower end O of the tube, let us suppose that the tube has a prolongation to the bottom of the vessel, formed of matter of the same density as the water. Let a particle R be situated a little above the extremity of the tube, and another Q as much below that extremity, they will be equally acted upon by the water above that place, and by the water between the fictitious prolongation of the tube, and therefore these forces will destroy one another. By applying to the case of the particle R the same reasoning that was used for the particle e, it will appear, that the result of its attraction by the tube is an attraction upwards. The particle R is likewise attracted downwards by the supposed prolongation of the tube, and the difference between these is the real effect. The other particle Q is also drawn upwards by the tube with the same force as R, since, by the hypothesis, it is as far distant from the points D, G, as the particle R is from the points d, g, where, with respect to it, the real attraction of the tube commences. The particle Q is attracted also downwards, by the supposed prolongation of the tube, and the difference of these actions is the real effect. Hence the double of this force is the sum of all the forces that act at the lower part of the tube. These forces, when compared with those exerted at the top of the tube, and with the force of gravity, give the total expression, which should be combined with that of the forces with which the column ML is actuated.

Clairaut then observes, that there is an infinitude of possible laws of attraction which will give a sensible quantity for the elevation of the fluid above the level MN when the diameter of the tube is very small, and a quantity next to nothing when the diameter is considerable; and he remarks, that we may select the law which gives the inverse ratio between the diameter of the tube and the height of the liquid, conformable to Exp. 4.

It follows from the expression obtained by Clairaut, that if any solid, AB, possesses half the attracting power of the fluid CD; the surface of the fluid will remain horizontal; for the attraction being represented by DA, DE, and DC, and DA and DE may be combined into DB, and DB and DC into DE, which is vertical. The water will, therefore, not be raised, since the surface of a fluid at rest must be perpendicular to the resulting direction of all the forces which act upon it.

When the attracting power of the solid is more than half as great, the resultant of the forces will be GF in Fig. II, and therefore the fluid must rise towards the solid, in order to be perpendicular to GF. When the attractive power of the solid is less than
that of the fluid, the resultant will be HP in Fig. 11; and therefore, as in the case of mercury, the surface must be depressed, in order to be perpendicular to the force.

The subject of capillary attraction was next taken up by Segner in 1751, who referred all the phenomena to the attraction of the superficial particles of the fluids. He deduces this principle from the doctrine of attraction. He supposes the attraction of the tube to be insensible at sensible distances; and he has shown that the curvature of each part of the surface of a fluid is proportional to its distance from the general level; and without much error, he has obtained from experiments the magnitude of this curvature at a given height both for water and mercury.

M. Monge has followed Segner in ascribing the capillary phenomena to the cohesive attraction of the superficial particles of the fluids; and he maintains that the surfaces must be formed into curves of the nature of lunettes, resulting from the uniform tension of a surface resisting the pressure of a fluid, which is either uniform, or varies according to a given law.

Dr Young's Theory.

In a very ingenious paper on the cohesion of fluids, which was read by Dr Young in the Royal Society in 1805, that able mathematician has given a new theory of capillary attraction. He has reduced all the phenomena of cohesion to the joint operation of a cohesive and a repulsive force, which balance each other in the internal parts of a fluid, where the particles are brought so near that the repulsion is exactly equal to the cohesive force by which they are attracted; and he assumes only, that the repulsion is more increased than the cohesion, by the mutual approach of the particles. By this means Dr Young has connected together a variety of facts which had hitherto been unexplained; and we regret that our limits will not permit us to give a more detailed account of his ingenious speculations.

Theory of La Place.

More than a year after the publication of Dr Young's paper, M. La Place published a Supplement to the Mecanique Celeste, upon capillary attraction, where he has proposed a theory which has led him to several conclusions that Dr Young had already obtained by a more simple route. It is a very singular circumstance, that La Place should take no notice whatever of Dr Young's labours, as the volume of the Transactions which contained them, and several periodical works in which they were noticed, must naturally have found their way to Paris. M. La Place supposes, from Exp. 11. and 18. that capillary action, like the refractive force, and the chemical affinities, is only sensible at imperceptible distances; that a narrow ring of glass immediately above the surface of the fluid, exerts its force on the water; and that this force, combined with the weight of the water and the cohesion of its particles, produces the concave surface or meniscus of fluid with which the column is always terminated. He supposes this meniscus to be sustained by the action of the glass, while it exerts its own attraction on the fluid particles immediately below it, by means of which their gravity is diminished, and the water consequently rises in the tube; and he has determined the form of the meniscus to be that of a hemisphere, and its attraction to be equal to that of a sphere of water of the same diameter. Hence the attraction of the meniscus will be inversely as its diameter, or the diameter of the tube, that is, as the weight of the elevated column, and therefore the heights of ascent must be inversely as the diameter of the tube. "Since it has hitherto been usual with natural philosophers," says La Place, "to consider the concavity and convexity of the surfaces of fluids in capillary spaces, as a secondary effect of capillary attraction only, and not as the principal cause of phenomena of this kind, they have not attached much importance to the determination of the curvature of these surfaces. But the theory which has been here advanced, having shown that all these phenomena depend principally on the curvature, it becomes of consequence to examine it." In opposition to the high authority of La Place, we agree with Professor Playfair in thinking, "that the principal and primary cause is that attraction, which sustains the meniscus, and enables it to act on the water below without being drawn out of its place. It is not the concavity of its surface that makes the water in the tube press less in the bottom than if its surface were plain; but it is the attraction of the glass that produces in a manner equally direct, both the concavity and the diminution of pressure." The fact mentioned in Exp. 12, has been ascertained by La Place to the action of the drop upon the column, in consequence of its convexity; while Mr Playfair supposes the additional elevation to be occasioned by the action of the bottom and outside of the tube upon the drop, by which the column of water is lifted up to a higher level. We are disposed, however, to think, that the column of water, after being raised above its ordinary height in the tube, is prevented from obeying the force of gravity by the force with which the drop below adheres to the bottom of the tube, and the force by which it resists any change of form; for the descent of the column to its usual height could only take place, either by detaching the drop altogether from the tube, or by giving it a more spherical, or a more elongated form. If the other explanations were true, then the column might be raised above its usual height in the tube, by placing a drop of water on the outside, and allowing it to descend to the bottom of the tube, where it would exert its force, according to La Place, or be acted upon by the tube, according to Mr Playfair, which is not the case. CAPITANATA. See Naples.
CAPITOL. See Rome.

CAPO D’ISTRIA, the Egidia and the Justinopolis of the ancients, is a sea-port town of Istria, situated upon an oval island, which is connected with the continent by means of a causeway half a mile long. This town is one of the largest places in that part of Istria which formerly belonged to the Venetians. It is about two miles in circumference; is the see of a bishop suffragan of the archbishop of Udine, and exclusive of the cathedral, which was built in the 18th century, it has forty churches or chapels, and thirty convents; two hospitals, and a pawn-bank, where money is advanced on pledges. The principal articles of its commerce are derived from its salt-pits and vineyards. By means of an aqueduct which passes under the salt-works, the town is well provided with spring water. The air is here more salubrious than in the other maritime towns of Istria.

This town was taken by assault by the Venetians in the year 932, but it was retaken by the Genoese in the 14th century; and, in 1478, it was restored to the republic of St. Mark. East Long. 13° 48' 30", North Lat. 45° 38'.10". See Voyage Pitorresque et Historique de l’Illyrie et de la Dalmatie, redigé d’apres l’Itineraire de L. F. Cassas, peintre, par Jean Lavallé. Paris, 1802. (o)

CAPPODOCIA was, in ancient times, a province of Lydia in Asia, extending from Mount Taurus to the Euxine Sea; but was divided first by the Persians, and afterwards by the Macedonians, into two divisions. The northern division, which, from its situation, received the appellation of Cappodocia ad Pontum, was soon denominated Pontus, and under this title its history will more properly appear. The southern division, which we are now to describe, was at first called Cappadocia ad Taurum, or Cappadocia Magna; but when the other division took the name of Pontus, it claimed to itself the name of Cappadocia. This country, bounded on the east by the Euphrates and Armenia Minor; on the south by Lycaonia and Armenia Major; on the west by Galatia; and on the north by Pontus; stretches from the 36th to the 41st degree of north latitude. The name of the region, according to Pliny, was derived from the river Cappadox; according to Herodian, from Cappadocus, who is said to have been the founder of this dynasty, whose existence is more than doubtful. Besides Maza, the metropolis of this kingdom, which was afterwards called Caesar by Tiberius, in honour of Augustus, Cappadocia could boast of the following cities: Comina, Diocesaria, Neocesaria, Tyana, Sebastia, and Sebatopolis. The principal rivers which fertilize this region, are the Melas, the Iris, now Casalmez, and the Hymas. The district on the south-east, which lies around the Antitaurus, is mountainous and barren. The other parts are fertile, abounding with fruits of every kind; enriched with mines of silver, brass, iron, and alum; and producing alabaster, crystal, jasper, and onyx. The horses which were reared in this country were so excellent, that they were purchased by the surrounding nations, and became at last so famous at Rome, that none but the emperor was permitted to possess them.

Ant.C.548. From the feeble light of ancient history, we find that this country was a province of Lydia in the reign of Croesus. When that kingdom yielded to the superior destiny of Persia, Cappadocia bowed to the conqueror, and the annual tribute of 1500 horses, 2000 miles, and 5000 sheep, stamped its submission till the time of Cyrus. When that monarch was engaged in hunting, Pharnaces, one of his nobles, rescued him from a lion which was ready to devour him; and the crown of Cappadocia, and the hand of Atossa, the sister of Cyrus, marked his gratitude, and the valour of his deliverer. Pharnaces fell in a war with the Hrycanians; and Smerdis his son, cultivating the friendship of Persia, joined Darius against the Scythians, and took Marasgetes, the brother of their king, prisoner. Anaphas, who succeeded him, equalled his father in military renown, and in fidelity to the Persians. His name and kingdom descended to his son, who again was succeeded by Datames, the first of his race, who waged war with the Persians, and who atoned for his rashness on the field of battle, by the loss of his army and of his life. Ariaramnes his son, who succeeded him, suffered much from the superior power of Persia, yet, at the end of a reign of 50 years, he left his throne to his son Ariarathes I. This prince wisely courted the friendship of Artaxerxes Ochus, and with him waged war against the Egyptians, in which he acquired the most distinguished honours. Induced by affection to his brother Holophernes, he resigned to him a share of the government, and, at his death, that prince succeeded to the sovereign power, probably upon account of the youth of his brother's children; for at his death, he set aside his own family, and in return for his brother's kindness, restored the kingdom to his son Ariarathes II. This prince signaled his fidelity to the Persians, by setting at defiance the fame and the power of Alexander; but though the king of Macedon, by engaging in nobler conquests, was prevented from inflicting upon him signal vengeance, yet, at his death, Perdiccas conducted into Cappadocia a powerful army, and having routed the forces of Ariarathes, whom he took prisoner, and barbarously crucified, with all his nobles who fell into his hands, placed upon the throne his brother Eumenes, to whom that country had been assigned by the division of Alexander's dominions, which then took place. Ariarathes III. escaping from the slaughter of his father and brethren, wandered as an exile in Armenia till the death of Eumenes and Perdiccas, and the war between Antigonus and Seleucus occupied the whole attention of the Macedonians, and inspired him with the hope of recovering his paternal dominions. At the head of an army which he received from the friendship of Ardaorates, king of Armenia, he entered Cappadocia, defeated Amyntas the Macedonian governor, and ascended the throne which his valour had purchased, and which his wisdom taught him to enjoy during a long and a happy reign. Ariaranes II. his son, succeeded him; and cultivating the friendship of Antiochus Theos, king of Syria, obtained Stratonice, the daughter of that monarch, in marriage to his son, whom he associated with himself in the government, and advanced the prosperity of his country by a wise and peaceful administration. His son Ariarathes IV. inherited the dominions but not the peaceful disposition of his father. Invading the territories of Arsaces, the founder of the Parthian dynasty, he overcame that monarch in a bloody engagement; and,
as the fruit of that victory, took possession of part of his kingdom. At his death, Ariarathes V. assumed the sceptre of his father; married Antiochis, daughter of Antiochus the Great; joined that prince in a war against the Romans; beheld the confederated armies scattered by superior discipline and bravery; purchased the peace and friendship of the Romans by promising them 200 talents, which were mitigated to 100 at the intercession of the king of Pergamus; assisted his new allies against Perseus-king of Macedon; and as the reward of his services, was stiled by the senate the friend and ally of the Roman people. His queen being at first barren, imposed upon his credulity, by persuading him that she had two sons, who were called Ariarathes and Holophernes; but afterwards, when she really became pregnant, she confessed the imposture, and bore to her husband two daughters, and a son who was called Mithridates. When this son arrived at manhood, his dutiful conduct inspired his father with such affection, as to induce him to resign the sceptre to his hand; but the son proved that he was worthy of his father's virtue, by declaring, that the only instance of disobedience which he would ever exhibit, would be to refuse a crown which his father wore with such honour to himself, and such happiness to his people, and thus merited the surname of Philopater. This prince, at the death of his father, ascended the throne by the name of Ariarathes VI., and signalized the beginning of his reign by an action, no less glorious to his generosity than to his valour. Artaxias, king of Armenia Major, after having routed the forces of Mythrobusanus, king of Armenia Minor, and forced him to seek an asylum at the court of Cappadocia, stained the glory of his victory by offering Ariarathes one half of the conquered kingdom, as a reward for taking away the life of the exiled monarch. The answer which the wounded virtue of the Cappadocian returned to this insulting proposal, was given on the field of battle, where he routed the forces of Artaxias; and, with a magnanimity bordering on rashness, restored Mythrobusanus to his throne, though he had too great reason to dread the ingratitude of that prince, who soon joined Artaxias against his benefactor. When the confederates were about to invade his dominions, the Romans interposed; and in gratitude for the peace which their authority procured, he presented to the senate a crown of gold, who, in return, honoured him with a rod and chair of ivory. The cultivation of the arts and sciences in every part of his dominions dignified this interval of peace, which was soon interrupted by Demetrius Soter, king of Syria, whose sister Ariarathes had refused to marry, dreading the resentment of the Romans. As the instrument of his revenge, Demetrius incited Holophernes, who pretended to be the eldest son of the late king, to claim the crown of Cappadocia; and assisting him with the power of Syria, defeated Ariarathes and Euymes, king of Pergamus, who, at the command of the Romans, joined him with his army, and having driven the former from his dominions, raised his rival to the throne. An appeal was made by both parties to the Romans, who, with their usual policy, adjudged the rivals to share the kingdom between them, without affording Ariarathes the means of recovering any part of his authority. Holophernes, however, soon shook the foundations of his power, by exercising it in acts of oppression, of cruelty, and of sacrilege; and Attalus, now king of Pergamus, espousing the cause of the exiled monarch, dissipated the forces of the usurper on the field of battle, forced him to abandon the country, and restored Ariarathes to the throne. When his affairs became doubtful, Holophernes had deposited 400 talents of gold with the inhabitants of Priene, a city of Ionia; and Ariarathes sullied the fame, which his former conduct had so justly merited, by employing his arms, and those of Attalus, in ravaging the territories, and besieging the walls of that city, because its inhabitants refused to surrender the treasure of his rival. The Priennians, however, not only conveyed the money to its owner; but defended the city till the irresistible mandate of the Roman senate, which they had solicited, arrived, and obliged the confederates to abandon the siege. Remembering former injuries, Ariarathes now entered into an alliance with Alexander Euphrates, who, pretending to be the son of Antiochus, assumed the kingdom of Syria, and joining his forces to those impostors attacked and defeated the army of Demetrius Soter, who was slain in the contest. Some time after he joined the Romans, who claimed the kingdom of Pergamus, in virtue of a will which Attalus had made in their favour; and along with P. Crassus, proconsul of Asia, attacked the army of Aristonicus, who, assisted by the Thracians and the Phocæans, asserted his right to that throne as the son of Lumentes. The avance of Crassus, which directed all his efforts to save his booty, consummated the shame of his defeat, and defrauded his captivity of the pity of his country; but the death of Ariarathes, which was distinguished by the most intrepid bravery, did not cloud his former reputation in arms. The Romans, to repair the loss of that day, added Cilicia and Libya to the kingdom of Cappadocia; and appointed Laodice, the widow of Ariarathes, during the minority of her children, to be regent. Intoxicated with the charms of royalty, and dreading the loss of her authority, she administered poison to five of the six children which were placed under her protection. The Cappadocians vindicated the honour of their country, by resisting the tyranny of the regent, and inflicting upon her that death which her crimes deserved. Ariarathes VII. recalled by the Cappadocians at the death of his mother, ascended the throne, and VII. married Laodice, sister of Mithridates, king of Pontus. This prince formed the ambitious scheme of annexing the kingdom of Cappadocia to his own; and employed a Cappadocian nobleman, named Gordius, privately to murder Ariarathes, that he might seize the country under the pretence of acting for his sister. But his sister prevented him from reaping the fruits of his fratricide; for suddenly marrying Nicomedes, king of Bithynia, who had long meditated the invasion of Cappadocia, she instigated that monarch to accomplish his design, which he soon did by expelling the son of the late king, and assuming the supreme authority. Mithridates concealed his ambition by espousing the cause of his sister's children; and pretending to restore his nephew, defeated the forces of Nicomedes, and took possession of the kingdom. The glory which he acquired by this action, was soon converted into infamy; for refusing to resign the
government to his nephew, he discovered the treachery of his designs, and roused the spirit of the Cappadocians; who, to avenge their wrongs, routed his forces, and placed Ariarathes VIII. on the throne of his ancestors.

This prince began his administration by concluding a peace with Mithridates; and, receiving from him a body of auxiliaries, prosecuted the war with Nicomedes, and wrested from him some of his provinces. Hostilities being thus happily terminated, Mithridates, trusting to his influence with Ariarathes, requested that monarch to recall Gordius from banishment, with the insidious design of again employing the dagger of that assassin against the Cappadocian king. Fear, and indignation, and revenge, roused the spirit of Ariarathes; and wielding the energies of his flourishing kingdom, he met on his frontiers the army of Mithridates, and disappointed the hopes which his enemy had formed of taking him unprepared. The gloomy soul of Mithridates had again recourse to his dark policy; and distracting the issue of a battle, in which he could have commanded 80,000 foot, 10,000 horse, and 600 chariots, he expressed the strongest desire of reconciliation; and inviting Ariarathes to a conference to settle all differences, plunged in his unsuspecting bosom a dagger which he had concealed in his garments. The Cappadocians, who witnessed this perfidious action, were struck with consternation; and, instead of avenging the inglorious blow, fled from the field. The regicide, by placing the Cappadocian sceptre in the hand of his son, a boy of eight years of age, completed his own triumph, and the degradation of that unhappy country. But when Gordius was recalled; and appointed governor, the spirit of the people, which was depressed but not extinguished, resented the insult; and railing from Asia, where he had been exiled, the brother of their late king, placed him upon the throne, by the name of Ariarathes IX. and expelled his rival. But Mithridates, to revenge that affront, again invaded Cappadocia with a mighty army, and meeting its monarch on the field, routed his forces, drove him from his dominions, and restored his own son. The exiled prince soon after died of grief, and was the last of the family of Pharnaces who governed that country.

At this time, the Bithynian prince had again recourse to the influence which his marriage with the widow of Ariarathes gave him, to overturn the power of Mithridates in Cappadocia. For this purpose, he asserted that Ariarathes had by Laodice three sons, and that the youngest, who had concealed himself that he might elude the fate of his brothers, was still alive in the Bithynian court. Laodice, with a young man whom she acknowledged as her son, went to Rome, and claimed in his behalf the protection of the Romans. The address of this artful princess imposed upon the wisdom of the senate; but scarcely had they promised their assistance, when Gordius, in the name of Mithridates, appeared before that august assembly; discovered the imposture of Laodice; and, with a tale equally deceitful, maintained that the prince, whom Mithridates had placed on the throne of Cappadocia, was a son of Ariarathes VI. The senate perceived the falsehood of both parties, and indifferent at the insult which they had offered to their wisdom, by endeavouring to deceive them, commanded Mithridates to abandon Cappadocia, and Nicomedes, Paphlagonia; and gave their freedom to both these states. The Cappadocians, however, requested the liberty of electing a king to themselves, which was granted by the senate, and Ariobarzanes was raised to the throne by the voice of his country.

This prince soon found that he had sacrificed his happiness for the splendor of royalty. Mithridates and Tigranes, king of Armenia, drove him from his throne, and restored the kingdom to the son of the former. Flying to Rome for protection, the senate commanded Sylla to reinstate him upon the throne; and that general, having defeated the numerous army of Gordius, obeyed their command. Again was Ariobarzanes expelled from his dominions by Mithridates; again was he restored by the arms of Sylla; again was he driven to Rome, and the country swept of its inhabitants by Tigranes, who planted them in Armenia; and again was the exiled monarch restored by the Romans under Pompey, who added to his dominions Sophene, Gordiæ, and part of Cilicia. Regretting the tranquillity which he enjoyed when a subject, the Cappadocian monarch completed the vicissitudes of an eventful life, by resigning the sceptre into the hands of his son.

Ariobarzanes II. inherited the kingdom of Cappadocia and the protection of the Romans; and, what is no less honourable to his fame, he acquired the friendship of Cicero when proconsul of Cilicia. At that time a conspiracy was formed against him, at the head of which was the high priest of Bellona, a man who was second only to the king, and who, both from his birth and office, could command a numerous army to take the field. But Cicero not only informed the king of his danger, but exerted his authority to avert the storm, and induced the head of the conspiracy to leave the kingdom. When the empire of the world was afterwards decided on the plains of Pharsalia, Ariobarzanes, who, from gratitude, assisted Pompey, not only shared in the defeat of the vanquished, but also in the clemency of the victor, who accepted of his submission, and demanded a large subsidy as the price of reconciliation. He, however, endeavoured to elude the demand, by declaring that his treasury was exhausted, by repelling an invasion which had been made upon his dominions by Pharnaces, king of Pontus. Caesar, therefore, after having terminated a war with the Egyptians, sought and routed the forces of Pharnaces; and having despoiled him of his Cappadocian provinces, restored them, with part of Cilicia and Armenia, to Ariobarzanes. The resentment of Brutus and Cassius, whose fortunes Ariobarzanes now abandoned, was roused against him; and the latter, having routed his troops, and taken himself prisoner, put him to death, and, as he left no children, the crown remained to his brother.

This prince, who is known by the name of Ariarathes X., did not immediately ascend the throne. X. Sisinnia, son of the high priest of Comana, and a descendant of Archelaus, who, though a Cappadocian, had acted as a general under Mithridates, laid claim to the sovereignty, in virtue of a donation from Mark Antony. This Roman, who seemed born to be the sport of passion, had formed an attachment to Glaphyra, mother of Sisinnia; and, as the price of her virtue, received the kingdom of Cappadocia for her
Archelaus. 
Ant. C. 31.

This prince testified his gratitude to his benefactor, by assisting him in his war with Augustus; and, in the fatal battle of Actium, partook of his danger and defeat. But at the earnest request of his subjects, he was pardoned by Augustus, and allowed to keep possession of his kingdom. He afterwards received Armenia Minor and part of Cilicia for assisting Tiberius in restoring Tigranes to the throne of Armenia Major; but the most valuable reward which he gained, was the friendship of Tiberius, who used all his influence in his behalf when he was accused by his own subjects before the emperor, and who thus saved him from destruction. He next extended his influence, by marrying Pythodoris, widow of Polemon, king of Pontus; which kingdom he governed in right of his wife during the minority of her children; and, likewise, by giving his daughter Glaphyra in marriage to Alexander, son of Herod the Great, king of Judah, with whom he had contracted an intimate friendship. But when Tiberius, to shun the hatred of the sons of Agrippa, and of their grandfather Augustus, obtained from the emperor the liberty of retiring to Rhodes, in a kind of honourable banishment, Archelaus forgot his former benefactor, whose friendship he now deemed dangerous; and paid all his court to his rival, Caius Cæsar, who, when governor of the East, was looked upon as heir to the emperor. When Tiberius afterwards ascended the throne, he made Archelaus feel his resentment, by summoning him to Rome to answer for his conduct. It is said that Livia seconded her son's revenge against the unhappy Archelaus, by informing him that his personal submission to the emperor would mitigate his punishment, and obtain forgiveness. Archelaus, ignorant of the snare prepared for him, or not daring to disobey, hastened to Rome; and being accused before the senate of fictitious crimes, was so overwhelmed with age and indignities, that he was reduced to a state of either real or assumed insanity, which soon terminated in his death, after a reign of 50 years.

Cappadocia was now annexed to the Roman empire, and its independence was for ever extinguished. When the neighbouring nations sunk into the same state of degradation, Paphlagonia and Pontus enlarged the bounds of this province, without adding to its fame, or enabling its enslaved inhabitants to recover their liberty. At a later period it was divided into ten prefectures; but when Constantine the Great ascended the throne, he reduced it to its ancient extent, by forming the territories which had been annexed to it into separate provinces. When Alexis Comnenus founded the empire of Trebizond, in 1209, Cappadocia was subjected by his arms; but when this empire was overthrown by the Turks, the subject of this narrative became a part of their dominions, and under their power it still remains. It is now called Amasia, from the city of that name, which is situated in that province, and where the Turkish beglerbey sometimes resides.

The annals of this country have not transmitted to us any particular account of its government; but we have reason to conclude, that the will of the prince was, in most cases, the rule of his conduct; and when this did not take place, the laws of Charondas, a celebrated legislator of Greece, prevailed. Their religion seems to have been a mixture of Persian and Grecian superstitions; which, instead of promoting the happiness of the state, by favouring useful employments, crowded in one temple, sacred to Jupiter, no less than 3000 ministers, to loll in luxurious apathy, or to plot in ambitious cabals; and, instead of inciting its votaries to praise God by the practice of virtue, incited them to practise the most senseless penances—to lacerate their bodies in honour of Bellona; and, if we can credit antiquity, to offer human sacrifices to Diana, and some other idols. The Cappadocians proved that the religion of a country directs its morals, when their wickedness become so proverbial that the neighbouring nations denominated every person distinguished by his depravity, a Cappadocian, as a term of peculiar reproach.

This country was never remarkably distinguished for learning or science; but the writings of Strabo and Pausanius, of Basil and Gregory Nazianzen, illumined the darkness of their horizon with a splendor which has continued to our day. In the later period of this kingdom, its armies were numerous, its revenues large, and its commerce considerable; but from the time that it became a province of Rome, its spirit in a great measure was broken, and its energies were paralysed. CAPRARIA, a genus of plants of the class Polyandra, and order Angio sperma. See Botany, p. 250.

CAPRI, formerly CAPPARES, is an island of the Mediterranean, situated on the south side of the Bay of Naples, and separated by a narrow channel from Cape Canapenna (the Promontorium Albuneum, or Minerve, of the ancients), the extremity of the tongue of land which forms the southern boundary of the bay, and separates it from the semicircular gulf of Salerno.

The island of Capri, which is of a triangular form, is about eight miles in circumference, and is distant from the coast of Naples about three Italian miles. Its appearance at a distance is extremely wild, from the steep cliffs and huge masses of rock; but this wildness is softened down, upon a nearer approach, by the appearance of patches of verdure, and clusters of white houses. A great part of the island is uncultivated, and incapable of cultivation; but wherever the hoe could be used, the ground is well tilled, and produces the richest crops. Near the palace of La Marina, the soil, which is extremely rich, consists of a deep stratum of good mould, upon a yellow bole beneath, which is a stone similar to the tufa of the volcanic hills round Naples. The upper rocks of Capri, as we learn from Swinburne, are universally

Capri

calcareous, and the strata accord with those of the Sorrentine mountains on the Continent, from which the island appears to have been separated by some great convulsion. Mr Swinburne supposes, that "the lower tracts of land in Capri have been thrown up by fire in the midst of limestone mountains, in the same manner as the plain of Sorrento." The district of Anacapri, which is separated by rocks from the rest of the island, lies on a declivity inclining to the north, and bounded by a high and rocky shore. The communication between this and the other part of the island is kept up by a long flight of rude steps, winding up a cliff of tremendous height; and though the steps are very slippery, yet loaded asses are able to ascend and descend with safety. The southern and eastern sides of the island are flanked with rocky precipices of enormous height. The principal places in the island are Capri and Anacapri. Capri is situated in a bold but fertile spot of land, between two rugged eminences of great height, which form the extremities of the island. At a distance its cupolas and buildings give it the appearance of a considerable place, though it is only a small village. Anacapri is a small town, composed of a few streets and scattered houses, with a nunnery and a parish church, embosomed in groves of fruit trees, and encircled with luxuriant and well kept gardens.

At the chapel of Santa Maria, now inhabited by a simple unlettered Anchoress, stood the summer palace of Tiberius, who spent the greater part of ten years in this delightful retreat, abandoned to the most unhallowed debaucheries. See TIBERIUS. This emperor built twelve villas, in different situations, and dedicated them to the twelve greater gods. Extensive vaults and reservoirs at Santa Maria; the ruins of a lighthouse, and two broken columns, are almost the only remains of these ancient villas.

The winter residence of Tiberius at La Marina is still indicated by columns and fragments scattered on the sand. The conduit, from which the palace was supplied with water, is still to be seen; and Mr Swinburne is of opinion, that a semicircular recess of network, the opus recticulatum of Vitruvius, which is raised against the cliff, once formed a part of the theatre. In an adjacent vineyard," says that traveler, "some peasants were removing a pavement of black and white mosaic. The ruins stretch far into the sea, and that element has now resumed the territory from which it had formerly been expelled by the force of terraces and piers. The palace was built of this stone (tufa,) but in its corser parts, such as abutments and back walls, are inserted large pieces of lava in a rough state of torrefaction, like that of the crust of Vesuvian streams when cooled."

On the southern shore the Carthusians have a very spacious convent, founded in the reign of King Robert, by James Capri, a veteran commander. Terraces, supported by vaults, called Botteghe, or the shops of the ancients, are cut in the opposite hill, and tufts of caper bushes, laden with purple and white flowers, mingle most happily with the ruined arcades.

The island of Capri abounds with various birds of passage, but particularly with quails. The greatest part of the bishop's income is derived from the taking of these, and of other kinds of game, and hence the island has been called the Bispopor of Quails. "Across every track in the woods," says Swinburne, "or chasm in the hills, rows of nets are placed to intercept stock doves and quails in their annual flights; the quantity taken of each sort, especially the latter, is almost incredible. I have the best authority for saying, that even in bad years, the number of quails caught in Capri amounts to 12,000; in good years it exceeds 60,000; and in one remarkable year, one hundred and sixty thousand were netted; eight years ago, in the month of May, 45,000 were taken in the course of a single day." East Long. 14° 10', North Lat. 40° 52'. See Swinburne's Travels in the Two Sicilies, 2d edit. vol. iii. p. 1—12; and Nuova Guida de Forestieri per I'antichita Curiosissime di Pozzuoli, dell' isole adjacenti d'Iscia, Procida, Nisida, Capri, &c. Naples, 1751, 12mo. (a)

CAPRICORN, or the GOAT, is the name of one of the 12 signs of the zodiac. As the sun when it enters this sign ascends towards the north, like the goat when it climbs the sides of mountains, some authors have ascribed the origin of the name to this fanciful resemblance. In Ptolemy's catalogue this constellation contains 28 stars; in Tycho's 28; in Hevelius's 29; in Flamstead's 51; and in the catalogue printed in the article Astronomer, p. 770, we have given the position of 54 of the principal stars. (m)

CAPRIFICATION, the name of a method of ripening the fruit of the domestic fig-tree, by means of the cynips, or fig fly, practised in the islands of the Grecian Archipelago. These insects which are produced from the winter figs of the caprifocus, or wild fig-tree, are gathered by the peasants in the months of May and July, and are deposited on the fruit of the garden fig-trees. They enter the fruit by the eye; and the worms produced from the eggs which they lay, puncture the fruit, and not only accelerate the maturation of the fruit, but render it of a much larger size. Olivier, who resided long in the Archipelago, considers all this as founded on a vulgar error; and maintains that the practice is discontinued in several of the Grecian islands. In a subsequent part of our work, we shall have occasion to resume this subject at greater length. See Tournefort's Voyage au Levant, and the Nouveau Dictionnaire d'Histoire Naturelle. (p)

CAPSULE. See BOTANY, p. 44, col. 2.

CAPTAIN, in the law of England, is a certificate subscribed by commissioners, declaring when and where the commission was executed. These certificates relate chiefly to business of three kinds: to commissions to take fines of land, to take answers in chancery, and depositions of witnesses. All these commissions, and the execution of the commissions, must now be in English, by the statute 4 Geo. II. Jacob's Law Dict.

Caption, in the law of Scotland, is a letter running in the king's name, and under his signet, containing a command to messengers and to magistrates
to apprehend and imprison a debtor, who has disobeyed the charge given him on letters of horning. These letters pass on the warrant of a bill to the court.

Peers and married women are by law secured against personal execution by a debt upon civil debts; and pupils, by special statute, 1696, c. 41. No caution can be executed against a debtor within the precincts of Holyrood house.

Letters of caution contain an express warrant to the messenger, if he cannot get access to break open doors, and other lock-fast places, where he suspects the debtor may lie concealed. See Erskine's Institutes, b. iv. tit. iii. § 12, 13.; Bell's Dict. of the Law of Sc. (z)

CAPUA, a city of Naples, in the province of Lavora, is situated in a pleasant and fertile country, on the left bank of the Volturno, about 12 miles from the sea. The present town occupies a site about two miles distant from that of ancient Capua, which stood near to Mount Tifata. The streets are more spacious and airy, and the houses, many of which are built from the materials of the ancient city, are more elegant than those in other parts of the kingdom. As Capua is the only fortification that covers the approach to Naples, it has been rendered a pretty strong place. Its fortifications, which are good, consist of bastions, ravelines, and other works, and are covered with freestone. The river and the castle likewise contribute greatly to its strength. Besides the cathedral, which contains two fine pieces of sculpture by Bernier, Capua has one collegiate church, 16 parish churches, and 12 convents. There is a great number of ancient inscriptions, which have probably been brought from the ruins of the ancient towns. The population is about 8000. East long. 4° 9.30', North lat. 40° 7'. See CARThAGE. (w)

CAPURA, a genus of plants of the class Heterandria, and order Monogynia. See Botany, p. 194.

CARABAYA. See BUENOS AIRES, p. 48, 52.

CARABUS. See Entomology.

CARACALLA, the appellation by which Marcus Aurelius Antoninus, a Roman emperor, is generally known, though it was given to him as a mark of reproach, on account of his silly fondness for a Gaulish robe called by that name, which he himself usually wore, and which he distributed gratuitously among the soldiers and inhabitants of Rome. This infamous person was the son of Severus and Julia Domna. He was born in A.D. 188; invested with the dignity of Cæsar in 197; proclaimed "Augustus" in 199; and in 202, when he was only 14 years of age, in consequence of a successful war against the Jews, in which he held the title of commander, he had a triumph decreed him by the senate, he put on the toga virilis, and was appointed colleague to his father in the consulship. In the following year he married, contrary to his inclination, the daughter of Plautianus, the praetorian prefect, whose abuse of the power with which, as a favourite, he was intrusted, was ultimately the cause of his own death, and of the ruin of his whole family.

Severus died A.D. 211, and was succeeded by Caracalla and his other son Geta, both of whom he had raised to the sovereign power during his lifetime, and whom he nominated in his last will as his joint successors on the imperial throne. The ambition of Caracalla had scarcely allowed him to wait for this event. He hated Geta, who also hated him in return. Indeed, this mutual antipathy had begun when they were children: it increased as they grew up; and gave much distress to Severus, who adopted, but in vain, every method of promoting between them, if not a complete reconciliation, at least a mutual forbearance. It was for the purpose of allaying the animosity which he could not remove, that he took them along with him in his military expedition into Britain. But Caracalla, whose dark and savage mind was wholly susceptible of generous emotions, disappointed the expectations of his father, and, equally unmoved by the scenes of martial glory in which he acted, and by the continual expressions of parental affection which he experienced, he thought of nothing but of raising himself to the supreme power, by the destruction both of Severus and Geta. He endeavoured to prevail upon the army to acknowledge him as sole emperor. He attempted to murder his father. He then intrigued with the officers and soldiers to get him deposed. And failing in all these infamous measures, finally tried to hasten his death, by bribing the physician who attended him in his last illness.

No sooner had Severus expired, than Caracalla renewed his unjust and diabolical acts against Geta. But the army, from respect for the appointment of their late emperor, refused to enter into his views; and two violent attempts to murder Geta, one of them made during their progress homeward, and the other during the Saturnalian festival, proved unsuccessful. At length, however, he accomplished his guilty purpose, under the mask of returning friendship. Having persuaded Geta to meet with him in a private apartment on terms of peace, he introduced some centurions, who had been previously hired and tutored, and who assassinated Geta in the very arms of his mother; Caracalla himself standing by and instigating them to the bloody deed, or rather assisting in the perpetration of it, as appears from his afterwards consecrating, in the temple of Serapis at Alexandria, the very sword which he had used on that occasion.

The remainder of Caracalla's life was characterised by the same infamous duplicity and savage cruelty which had thus enabled him to attain the sovereign power. He persuaded the army, by the most unfounded pretences, that he had acted in self-defence; and compelled the senate, by demonstrations of violence, if not to believe in his false statements, at least to approve of his conduct. And in order to satisfy the people, he, with a strange inconsistency, permitted the memory of his brother to be so highly honoured, that by a decree of the senate, who were ready for every base compliance, he was enrolled among the gods! His detestation of Geta, however, appeared in a thousand ways. Not only was all the money bearing Geta's name melted down, and the inscriptions erased, but all his domestics and friends, some say to the number of 20,000, were inhumanly massacred, without regard to age, or rank, or sex; and the mere mention of his name, even on the stage, where it was familiarly applied to slaves, was punished as a capital crime.
Caracalla now woltaned in barbarity, gratifying his malignant passions without remorse, extorting money from the people without any regard to their circumstances, and squandering what he thus procured by rapine and oppression, on pursuits the most unworthy, and pleasures the most ignoble. There was in his whole behaviour a contempt of principle and reputation, such a uniform disregard of every quality and every action which could excite one feeling of genuine respect among his subjects, or lighten in the least degree those deep shades of guilt by which his general deportment was darkened, that we are at a loss to determine whether he was more the victim of mental derangement, or the slave of innate depravity and profligate habits. If any thing be wanting to render his character completely odious and contemptible, it may be found in his affected zeal for chastity and religion, in the midst of the most shocking impiety, and of the grossest debaucheries.

Such was Caracalla, when he resolved to imitate Alexander the Great, for whom he professed the greatest veneration, but whom he resembled in nothing that was laudable or good. He left Italy in 213, and engaged in a series of warlike expeditions, which were distinguished neither by honour nor success. In Gaul, which he visited first, he was abhorred for his cruelty. The Catti and Alemani whom he attacked, compelled him to purchase an inglorious peace, and the liberty of returning into his own dominions. And the rest of the nations in Germany, encouraged by this circumstance, took up arms and obliged him to grant them yearly pensions, for the payment of which he embraced the dishonourable, but necessary, expedient of coining false money. To compensate for these disgraces, he put all the youth of Noricum to the sword, after having ordered them to take up arms and join him; and for this pernicious massacre, which he affected to call a signal victory, he assumed the title of Alemannicus. Having gained some paltry advantages over the barbarians on the lower Danube, and entered into an alliance with the Dacians, he went to Flum to pay his devotions at the supposed tomb of Achilles; and there he poisoned his favourite freedman Festus, that he might get up a funeral resembling that of Patroclus, and thus imitate the Grecian hero in affection and respect for his departed friend!

He next procured the unwilling submission of Artabanes king of Parthia, and, by an act of the basest perfidy, got the kings of Edessa and Armenia into his power. And though these advantages were far more than counterbalanced by the defeat of his general Theocritus, and the disgrace which he himself brought on the arms and character of Rome, he scrupled not to write letters to the senate, boasting of his exploits, and glorying in his success. Having gone to Alexandria, he reduced that flourishing city to a state of desolation. The Alexandrians had formerly, it seems, thrown out some sarcasms against him on account of his folly. This kindled in his savage breast the flames of hatred and resentment, which could not be quenched except in the blood of the people, who had thoughtlessly offended him. And that his revengeful purposes might be more easily and effectually executed, he proceeded to the accomplishment of them in the most deliberate manner, and under the guile of piety to the gods, and friendship for the devoted inhabitants. He proposed to render personal homage in the temple of Serapis, and peculiar honours at the tomb of Alexander; and, in doing this, he sacrificed whole hecatombs, burnt a great quantity of incense, and engaged in ceremonies of the most pompous and imposing kind. But when the people, flattered by the presence and the condescension of the Roman emperor, and little suspecting that any treachery was lurking in the heart of the imperial devotee, had assembled to gratify their curiosity, and indulge their superstition, by witnessing or engaging in the festivities of the day, the soldiers of Caracalla at his signal, suddenly fell on the unthinking multitude, and involved them in one dreadful indiscriminate slaughter. This cruel and pernicious massacre was succeeded by a universal pillage, and by severities of the most wanton and atrocious kind—those who fell, and those who escaped the carnage, being, according to the letters of its infamous author, equally deserving of punishment. From this tragic scene, Caracalla directed his steps towards Parthia, and determined, on a pretext equally false and feeble, to break the peace which subsisted between the two empires. He marked his progress by ravaging the country through which he passed, plundering the cities, despoiling the inhabitants, and even violating the repositories of the dead. His presumption was equal to his barbarity; for though he had never seen the Parthians, and received no proofs of submission, he pretended, in his communications to the Roman senate and people, that he had conquered them, that he had subdued all the East, and compelled every nation on the other side of the Euphrates to acknowledge their authority. The senate and people, in consequence of this alleged success, decreed him a triumph, and granted him the appellation of Parthicus.

Caracalla intended to renew the war next season. But while pursuing his journey from Edessa, where he had spent the winter, to Carrhae, where he proposed to offer a sacrifice in the temple of the Moon, he was assassinated by a centurion, at the instigation of M. Opilius Macrinus, a pretorian prefect. This event happened in 217, when Caracalla was in the 29th year of his age, and had reigned only a little more than six years. The record of his short life is so full of crimes and follies, as to have the appearance of a libel on human nature. How melancholy to add, that this monster in the moral world had divine honours de-creeed to him by the Roman senate, and had a temple, with all its solemn appendages, established for his worship in the capital of the Roman empire! See Crevier's History of the Emperors; Gibbon's History, &c.; Dion Cassius; Herodian, &c. (t)
CARACAS.

An extensive district in the eastern part of Terra Firma, in South America, comprising the province of Venezuela in the centre, the government of Maracaibo on the west, Guiana on the south, the government of Cumana on the east, and the island of Margarita on the north-east. This district is bounded on the north by the Atlantic ocean, from 72° 33' to 60° west longitude, that is, from the Cape de la Vela to the point of Magilones or Paria; the ocean likewise forms its eastern boundary, from 12° to 8° of north latitude; on the south it is bounded by Dutch Guiana and Peru; and on the west by the kingdom of Santa Fe.

A country extending from the twelfth degree of latitude to the equator, might be expected to suffer all the relentless severity of a tropical sun. In some places, indeed, the heat of the torrid zone is felt without any abatement; but in a great proportion of this wide province, the inhabitants enjoy the mildness of a perpetual spring. This peculiarity of temperature is occasioned by the link of a chain of mountains, which, commencing at one of the Andes of Quito, traverses Merida and the government of Various, then stretches to the north as far as the coast, and, taking thence an easterly direction, insensibly diminishes in height till it finally loses itself in the island of Trinidad. That part of the chain which traverses the district of Caraccas, is, in its ordinary breadth, fifteen leagues, in some points twenty, but no where less than ten. In general the elevation of these mountains is so moderate, that they are not only habitable, but susceptible of all the operations of agriculture. The eastern Picacho alone, towering in sullen majesty to the stupendous height of 1278 fathoms, bids defiance to the efforts of human industry. Next to it in grandeur is the Tumeriquiri, which rises 935 fathoms above the level of the sea. The variety of temperature which these eminences produce, is extremely favourable to the diversity of vegetable productions.

After passing these mountains from north to south, we find immense plains stretching from east to west, from the village of Pas, in 64° 35' of west longitude, to the bottom of the mountains of Santa Fe. In these plains, which are bounded on the south by the river Orinoko, the heat is so intense as to be nearly intolerable. The strong vegetation which prevails in general upon these mountains, and the calcareous substances with which they abound, seem to prove, that they are of the second order of mountains, accumulated strata of different substances, formed by various revolutions of the globe, or by violent convulsions of nature. Yet, upon the Saddle mountain, the highest of that chain, Baron Humboldt has found some fine granite, of which quartz, fels-spar, and mica are the constituent parts; a clear indication, according to the same system, that this mountain, at least, is either primitive, or has emerged at a much earlier period than its companions from the bosom of the waters. Whatever support may be derived from the structure of these mountains to any, or to both of the contending theories, by which geologists are at present so keenly agitated, they afford at least to the agriculturist, in the rich variety of their productions, a field of speculation and of industry, amply sufficient to occupy his time, and to gratify his fondest hopes of gain.

The gradual changes of temperature, the delightful blending of the seasons, which so agreeably diversify the year in the temperate climates of Europe, are unknown to the inhabitants of the Caraccas. Winter and summer here complete the year: nor are these seasons distinguished so much by the various degrees of heat and cold, as by the rains which prevail during the former, and the drought by which the latter is characterized. The rainy season, or winter, continues from the end of April to the beginning of November; during the six remaining months, which constitute summer, the rains are less frequent, and in some years even rare. There are some days, even in the rainy season, when not a drop falls; but there are others, though not very frequent, when it rains incessantly. M. Depons calculates that, taking one day with another, it rains for the space of three hours each day; and oftener in the evening than in the morning. The quantity of rain which falls during that season, is nearly equal in the provinces of Venezuela, Cumana, and Guiana; and the benefits and disadvantages which the rains bring along with them, are participated by the plains, mountains, and valleys. The drizzling rains of the polar regions are never seen in this part of South America; nor can an inhabitant of countries even within the temperate zone form any adequate idea of the sudden heavy falls common in these latitudes; the discharges from water-spouts rushing down with the violence of a torrent, and producing more moisture in a single day than the rains of Europe do in six. During the greater part of the rainy season, all the rivers inundate the adjacent plains; channels, formed by the violence of the floods, which remained dry during the rest of the year, are now converted into torrents, and overflowing their banks to an immense distance, form a kind of temporary sea, where the traveller can despise only the tops of the loftiest trees, which then serve him as landmarks. The northern plains of the Orinoko are overwhelmed by such an annual deluge, to the extent of one hundred and fifty leagues in length, and forty in breadth. Previous to the year 1792, the rains were uniformly accompanied with vivid lightnings and tremendous peals of thunder; since that period, however, at least till 1804, rain falls in great abundance without any of the usual accompaniments of a storm. The atmospheric electricity appears to have been attracted and accumulated in that mass of matter which forms the Cordilleras; and to this cause are to be ascribed those earthquakes which were so dreadfully experienced at Cumana, in the month of December, 1797. (See Cumana.) Though placed between the
Antilles, where earthquakes are frequent, and Peru, where they are still more so, Caraccas enjoys intervals of repose, which we might be disposed to consider as almost miraculous, did we not know, that its air being less rarified, gives less action to electricity, and that its soil contains in its bosom a smaller portion of the principles of fermentation and combustion. On the 1st May 1802, at eleven o’clock in the evening, there was a pretty strong shock felt at Caraccas, with an oscillation from west to east. On the 20th of the same month, at five minutes past four o’clock in the afternoon, there was another of a vertical direction, which lasted one minute, nor did the earth resume its horizontal position for two minutes afterwards. Two strong shocks were experienced on the 4th July following, at 48 minutes past two o’clock in the morning; and nearly two hours after, there was another not so strong. A dreadful earthquake has lately (March 26th 1812) desolated La Guayra and Caraccas; by which many public and private buildings have been thrown down, and an incredible number of the inhabitants are said to have perished. The local origin of these earthquakes appears to be in the province of Cumana, for they are there more violent than in any other part of the district of Caraccas.

The natural history of a country, which, since its first discovery, has been occupied by Spaniards, indolent, void of curiosity, and extremely jealous of the visits of foreigners, is, of course, very imperfectly known. The avidity of its first conquerors was exclusively directed to the discovery of gold and silver mines. Four gold mines were found; after a long and anxious search, and were wrought under the name of the royal mine of St. Philippe de Buria. They were abandoned, however, in the year 1554, in consequence of a revolt of the negroes who wrought in them, and of the natives, who now foresaw, in the establishment of the Spaniards, their certain subjection to tyrannical masters. To renew these works, became the favourite enterprise of several successive governors. With this view, Governor Villacinda built a city; which he called Palmes, the first year after the revolt; but it was scarcely finished, before it was destroyed by the Indians. A similar attempt was made, six months after, by Paradas, which was equally unsuccessful; he built the city of Nirgua, which he was soon compelled to evacuate. Gutierrez de la Perga built another city, with the same design, on the banks of the Nirgua, in 1557; for some years it withstood the attacks of the Indians, who at length, however, in 1568, succeeded in reducing it. Another mine was discovered in the environs of the city of St. Sebastian de los Reyes; but, when Governor Collado began to attend to the erection of its works, an insurrection of the Indians caused it to be abandoned. A deceitful peace, which was concluded with the Cacique Guacyrupo, seemed to afford a favourable opportunity for the renewal of these works; but they had not proceeded far, when a multitude of Indians, falling upon them unexpectedly, massacred all the workmen, and demolished the works; nor has any future attempt been made for their establishment. At Apa and Carapa, not far from the banks of the Tuy, Sebastian Dias discovered, in 1584, two mines, where the gold was very abundant, and at twenty-three carats. The country was so extremely unhealthy, however, that it became indispensably necessary to abandon treasures, which could not be procured without a much larger sacrifice of men than the colony could then afford. The reputed richness of these mines again tempted the avidity of Sancho Alquisas, in 1606; but the works had been so completely destroyed by the Indians, that, after the most anxious search, not a vestige of them could be traced. In 1698, Governor D. Francisco Berrocaran made similar efforts, and with similar success. Yet the Spaniards of Caraccas, thus unfortunate in their attempts to work the gold and silver mines, possess, in the jurisdiction of St. Philippe, mines of copper of a very superior quality, which, besides supplying the planters with the best materials for their boilers, cylinders of mills, and other implements, had furnished 171 quintals for exportation in 1804; and the quantity would have been much more considerable, but for the war.

Had the Spaniards been attentive or scientific observers, their search after mines would have made them acquainted with many important facts relating to the strata and mineralogy of the Caraccas. But such facts, however they might gratify the curiosity of geologists, could excite no interest in men whose curiosity sprung entirely from avarice, and who never thought of penetrating beneath the surface of the earth, except for the discovery of the precious metals. We knew scarcely anything, therefore, of the mineralogy of this district of Terra Firma, until it was lately explored by Baron Humboldt. According to his observations, it is composed of nearly the same strata as the ancient continent. On the Saddle Mountain of Caraccas, 360 toises above the level of the sea, he found folicular granite. He found it also at Cape Codera, at the height of 141 toises; and of this granite, he assures us, the whole coast is composed, from the Unara river to Santa Marta. The mountain of Capaya he found to be composed of a granite which changes into slaked talc, vitriolated feldspar, slanted chlorite, limestone grained with mica, rock crystal, primitive green rock, silvered galena, quartz, magnetic sand, red oxide of crystalized titan, quartz mixed with black lead. Porcelain earth, argillaceous earth, &c. are found scattered in the provinces in the same manner, and in the same proportions, as in Europe. Argillaceous earth is found in the greatest quantity. The whole coast north of the province of Venezuela furnishes salt of a beautiful whiteness; and that in the salt pit of Araya, in particular, may vie with any in America, not even excepting Turk’s Island. This salt pit consists of a mixture of fossil and marine salt. But the Spaniards, with their characteristic indolence, almost entirely neglect the working of it; so that they do not derive from it the one-hundredth part of what it might produce. The provinces of Caraccas abound likewise in mineral waters, both hot and cold. They are of various qualities, such as the ammoniacal, the ferruginous, the nitrous, and even the acidulous. The heat of some of these waters approaches to that of boiling water. Between Porto Bello and Valencia there are springs which rise to the seventy-second degree, and there is another still hotter in the valleys of Aragua.

On the first discovery of this country, the Spa-
CARACAS.

niards, disappointed in their expectation of wealth from its mines, engaged eagerly in the pearl fishery, which, for some time, was the most considerable source of their riches; and the most important branch of the royal revenues. This fishery was carried on between the islands of Cubagua and Margarita, at the expense of a great many lives, both of Spaniards and Indians. Several other untoward circumstances caused them at length to abandon their fishery, which has never been resumed. It is even pretended, that the pearls have disappeared from the eastern coast; and the first place on the leeward, where that fishery is carried on with some success, is a bay situated between Cape Chichibaca and Cape de la Vela, occupied by the Guibarios Indians, who sell their pearls to the Dutch and English.

The luxuriant soil of the Caraccas yields an inexhaustible store of the most valuable vegetable productions. Its mountains are clothed with forests, consisting of all the kinds of wood to be found in the Antilles, besides a great many species peculiar to themselves. The most extensive ship-yards might be supplied for ages from these mountains with timber of the finest quality; and carpenters and cabinet-makers find such variety of materials for their different purposes, that their principal difficulty is to make a selection. The wood called by the Spaniards Pardillo, is generally used for beams, door frames, and posts. In some places, instead of the pardillo, they substitute a species of very hard oak, which is the quercus cerus of Limneus, and the quercus gallifer of Tournefort. Cedar is much employed by cabinet-makers for doors, windows, tables, and common chairs. For ornamental furniture, they have several kinds of wood susceptible of the highest polish. Of these the most distinguished is the black ebony, which abounds in several places, but particularly on the banks of the Totonary,—a spot apparently intended by Nature as the nursery of those trees which contribute most to the necessities or to the pleasure of man. Yellow and red ebony are both very common in the forests of Terra Firma; but mahogany is neither so abundant here, nor so fine, as in that part of St Domingo which Spain has ceded to France; yet, in richness, and variety of colouring, no mahogany can vie with the chacaramay, a native of Caraccas, which, when properly polished, possesses a degree of beauty which no species of timber, perhaps, can exceed. For works which require timber of extraordinary hardness, they employ iron-wood, the ybera pentera of Maregraves; or red ebony, which is even harder than iron-wood. The only wood for dyeing which has yet been found in Caraccas is the Brazil wood; but, in truth, the forests of this favoured country have been so little explored, that their treasures are very imperfectly known.

Almost every part of this district abounds in medical plants, gums, resins, roots, and barks, which, if duly attended to, would augment incalculably the riches of the inhabitants, and produce the most essential benefits to mankind. The quantity of sarsaparilla which grows here is more than sufficient for the consumption of the whole of Europe; sassafras and liquorice abound in the neighbourhood of Truxillo; squillas are found on the sea-beach of Laguna;

tas; storaax in the jurisdiction of Coro; cassia in almost every part of the country; gayac on the coast; aloes are raised in Carora; a species of quinguaia is obtained on the mountains; in short, the pharmacopoeia of both the continents might be supplied from the vegetable stores of the Caraccas. In this enumeration of the native productions of this genial soil, we must not omit the vanilla, produced from a creeping plant, which, like the ivory or wild vine, entwines around trees. This plant, which requires the cultivation and moist ground covered with large trees, grows in great plenty in the forests of St Philip and Truxillo, on the banks of the Tuy. It is worth about 100 francs a pound; and the province of Venezuela alone, might, with some attention, be made to produce 20,000 pounds weight of it in a year. To propagate this valuable plant, nothing more is necessary than to insert some cuttings in the earth near a tree; they soon take root, and entwine firmly around it. A surer method to prevent the decay of the plant, is to graft the cuttings in the tree itself, about twenty inches above the ground. In the same list with vanilla may be placed wild cochineal, which grows in great quantities in the departments of Coro, Carora, and Truxillo. To be enabled to form a proper estimate of its value, the reader may consult a memoir lately published at Paris by M. Bruley, an intelligent and ingenious planter in Caraccas.

Nor does the animal kingdom, in this luxuriant Animals. country, yield to the vegetable in profusion and value. Within the captain-generalship of Caraccas, 200,000 horned cattle, 180,000 horses, and 90,000 mules, roam over the plains and valleys. Sheep are innumerable; and deer abound, particularly in Coro, Carora, and Tocuyo. In short, the account which M. Depons, after a long residence in this country, has given of its fertility and productions, amply warrants his assertion, that there are few countries to which Nature has been more lavish of her favours.

The fertility, as well as the beauty of these delightful regions, depends, perhaps, in no inconsiderable degree, on the number of fine rivers which pour down in all directions from the mountains. Not a valley is without its river, which, if not always large enough to be navigable, is at least sufficient to irrigate plantations, and would afford wonderful facilities to many important branches of manufactures. Those which have their source in the chain of mountains, flowing from south to north, are discharged into the sea; while those which spring from the southern declivities of the same mountains, traverse, in a southern direction, the whole extent of the intermediate plains, till they resign their tributary streams to the majestic Oronoko. The former, strongly fenced in by their banks, and happily favoured in their progress by the declivity of their channels, seldom overflow, and when they do, their overflows are not long or detrimental. The latter, flowing through smoother grounds, and in shallower beds, mangue their waters during a great part of the year, and lose all appearance of rivers in the general inundation. All these rivers diminish into insignificance when compared with the Oronoko, which, with the exception perhaps of the Amazon, is the largest river in the world. The particular descrip-
tion of this mighty river, with its tributaries, we
must reserve for a future occasion, and shall, in the
mean time, content ourselves with enumerating a few
of those streams, which Depons has thought worthy
of a particular description.

At sixteen leagues west from Carora is the river
Guzques, navigable for canoes and sloops for six
miles from its mouth. Twenty-five leagues to the
east of Guzques, the river Tocuyo discharges itself
into the sea. Its source is about fifteen leagues south
of Carora, upwards of sixty leagues from the coast,
and it is navigable as far as Hanagua, about forty
leagues from its mouth. Its vicinity furnishes abun-
dance of timber fit for every kind of building; and it
flows through a fertile, but neglected country. Ten
leagues to windward of the Tocuyo is the mouth of
the Aroa, of which the navigation is neither easy nor
beneficial, though its course be upwards of forty
leagues. Reascending along the coast, we come to
the mouth of the Yaracuy, three leagues distant
from that of the Aroa. It has a course of forty
leagues, but does not become navigable till within
two leagues east of St Philip. From that point it
is very useful for the conveyance of the produce
raised in the vallies of St Philip, and the plains of
Barquisimeto, which is sent by sea to Porto Bello,
the nearest port. There is no river of importance
between the Yaracuy and the Tuy, which falls into
the ocean thirty leagues east of the port of Guayra.
The source of this river is in the mountains of San
Pedro, ten leagues from Caracas. After flowing
through several extensive and fertile vallies, it is aug-
mented by the junction of the Guayra, and being
thus rendered navigable, serves for the transportation
of the produce with which these vallies abound, par-
ticularly cacao, which is there of the finest quality.
No river to windward of the Tuy fixes the traveller's
attention till he reaches Unara, the line of division
between the governments of Caracas and Cumanu.
It pursues a northerly course for about thirty leagues,
and is navigable about six leagues from the sea. All
that deserves to be mentioned of the Neveri and the
Manzanares, is, that the one is seventeen leagues,
and the other twenty-seven east of the Unara; the
former is too rapid and powerful to be navigated far,
the other is too small to admit even small vessels more
than a mile from its mouth. The latter stream
washes the city of Cumanu, to which, however, it is
of little consequence. After passing Cumanu,
we meet the Gulf of Cariaco, which receives, besides se-
veral other streams, a river of the same name. This
river passes by the city of Cariaco, about two leagues
from the gulf, and is only thus far navigable, nor al-
ways even so far; for as it receives a considerable
quantity of rain water, in dry weather it becomes
shallow, and, in rainy weather, is subject to inund-
ations, which are extremely inconvenient to the city.
A tradition prevails among the Guayqueris Indians,
that the Gulf of Cariaco was formed by an earth-
quake.

On all the northern coast, as far as the Cape of
Paria, which, with the Isles of the Dragons, forms
the great entrance of the Gulf of Paria, not a single
navigable river is to be found. Of those which dis-
charge themselves into the Gulf, the most consider-
able is the Guaramiche. This river, rising in the
eastern declivity of Mount Brigantin, is swelled by
many streams of considerable magnitude, so that it
rolls towards the Gulf with all the majesty of a river
of the first rank. To vessels of ordinary size, it is na-
vigable as far as the Fork of Fantanba. Beyond that,
the navigation is impeded, not so much by the shal-
lowness of the river, as by the mangroves and trees
which are thrown into it by the wind, or deposited
by the currents.

These rivers are joined by an infinite number of
smaller streams, yet they water only the high or
northern part of the provinces of Venezuela and Cu-
mana, and do not amount to the twentieth part of
the rivers which proceed directly to the sea. The so-
thern, or low part of Venezuela, is intersected by others
which flow from north to south, till they discharge
themselves into the great Orinoco. Of these, the
most considerable are the Mano, the Paria, and
Pao, the Chivata and Zoa, the Cachimano, the Ara-
cay, the Manapira and Espino. In this enumeration,
however, the first place must be given to the Apurl.
After receiving the waters of innumerable tributary
streams, which form altogether the figure of a fan,
occupying a space of upwards of thirty leagues, this
river discharges its mighty flood by several channels
into the Orinoco. Most of these rivers are navigable
for forty or fifty leagues, affording the most animat-
ing anticipation of the future prosperity of the coun-
try through which they flow, when its inhabitants,
more enlightened and industrious, shall have learned
to appreciate and to improve the advantages which
nature so profusely bestows.

The only lakes in Caracas which are worthy of
description are the lakes of Maracaibo and Valencia.
The lake of Maracaibo is nearly in the form of a de-
canter, lying from north to south, with its neck com-
municating with the sea. Its length is about fifty
leagues; its greatest breadth, thirty; and its circum-
ference, upwards of a hundred and fifty. It is na-
vigable to vessels of the greatest burden; but the en-
trance to it is considerably obstructed by a bar.
When strong breezes prevail, its waves are so vi-
olently agitated as to overwhelm the canoes and small
craft; but it is seldom visited by hurricanes. Its
water is fresh; but when a gale blows strongly from
the sea, it acquires a brackish taste from its mixture
with the waves. In this lake the tide is more per-
ceptible than on its neighbouring coasts. It abounds
with all the different species of fish which are found
in the rivers of South America: the tortoise alone
forms a singular exception. The shores of the Mar-
acaibo are so sterile and noxious, as to discourage
culture and population; insomuch, that the Indians
preferred dwelling in huts, erected by a particular
construction on the lake itself. In a place called
Mena, to the north-east of the lake, in the most bar-
ren part of its borders, there is an inexhaustible mine
of mineral pitch, the true natural pessaphalte, which,
when mixed with suet, is used for graving vessels.
The vapours exhaled from this mine are so inflam-
able, that during night phosphoric fires are con-
tinually seen, in their appearance resembling light-
ning. They serve as a light-house and compass to the
Spaniards and Indians who navigate the lake, anf
CARACCAS.

The lake of Valencia, though not so extensive as that of Maracaibo, is much of more interesting, both from its beauty and utility. It is of an oblong form, about thirteen leagues and a half in length, and its greatest breadth is four. Though twenty rivers discharge themselves into this lake, it has no visible outlet; yet neither its depth nor its extent appear to increase. To account for this singular circumstance, it has been supposed that there must be at the bottom of the lake a subterraneous channel, through which its waters are continually discharged; and in support of this theory it is observed, that boats sail with rapidity from the borders to the centre, where some dangers are encountered, but return to the borders with more difficulty. Nothing can be more magnificent and charming than the scenery round the lake of Valencia. The rich and beautiful valley in which it is situated, surrounded with mountains except on the west, and the numerous islands scattered over its bosom, give it a strong resemblance to Loch Lomond, the most interesting of our Scottish lakes. The unfading verdure which adorns its banks, the endless variety of birds which sport in the neighbouring woods, vying with each other in the beauty of their plumage and the melody of their notes, and the fine plantations which extend from it in all directions, fill the heart of the spectator with a kind of rapture, which only the magnificence of nature can impart. Mr. Simple saw on this lake the first sail which had ever been spread here, and naturally hailed it as the germ of future improvement.

On the northern coast of this country, from Cape de la Vela to Cape Paris, the tides are so irregular and imperceptible as to be entirely overlooked in nautical reckonings and calculations; whilst on the eastern coast from Cape Paris to Dutch Guiana, they are so powerful as to command the anxious observation of all navigators who frequent those latitudes. The bearings of the coasts are the obvious cause of that remarkable difference. The winds are much more regular on the coasts, where nothing deprives them of their natural direction, than in the interior of the country, where they are subject to local influence. The trade wind, which prevails at sea in these latitudes, is likewise the common breeze on the coasts; with this difference, that at sea it is constant, but on the coasts it blows only from nine or ten o'clock in the morning till the evening. It blows from north-east by east; and is succeeded every night by an opposite wind, which is called the land-breeze. But this periodical succession, though general, is not without exceptions.

Pursuing the same course which we observed in our enumeration of the rivers, we come first to the port of PORTETA, about six leagues east of Cape de la Vela. This port admits only small vessels: but in the harbour of BAYAHONDA, four leagues farther to the windward, vessels of the largest size can anchor without being exposed to the smallest danger from the winds. Both these ports are in possession of the Indians, who derive from a pearl fishery in the road of Bayahonda the only article they have to barter with the Dutch and English. As we proceed along the coast to the eastward, we come next to the port of MARACAIBO, which, though in itself an excellent harbour, is rendered almost inaccessible by a bar of quick sand at its entrance, which is never covered with water beyond the depth of ten or twelve feet. Proceeding in the same direction, we come to CORO, whose port lies open from north to north-east. In this port the water continues to deepen as we approach the shore; but neither its accommodations, nor its commodities, are such as to render it a place of great resort. After leaving Coro, we meet with nothing that deserves the name of a harbour till we come to PORTO CABELLO, better known by the name of Porto Bello, which, for space, beauty, convenience, and safety, is by far the finest harbour on the whole coast of America. The whole of the Spanish navy might ride here without confusion; and the high lands which encompass it are so happily disposed, as to shelter it from the fury of any wind that blows. In the unruffled tranquillity of its surface, it resembles a pond rather than a port upon those tropical seas, which are always agitated with more or less violence. PORTO CABELLO, the name given to it by the Spaniards, imports, that a vessel at anchor is more effectually secured here by a single rope, than elsewhere by the strongest cables. Its anchorage, which owes nothing to art, is so commodious, that the largest ships may lie alongside of the wharf, and load and unload without the assistance of lighters. Three leagues to windward of this port is the bay of TURIAMO, which extends one league from north to south, but which, having no shelter from the north wind, is seldom visited by merchants, to whom the commodities of the adjacent countries hold out no temptations. The same remark is applicable to the bays of Patanemo, Borburata, and Sieneega. Having passed these, we find ourselves next in the bay of OCUMARA, five leagues east of Porto Bello. This is a commodious and well sheltered harbour, defended on the east by a battery mounting eight pieces of cannon of the calibre of 8 or 12. At the distance of one league from the port is the village of Ocuma, watered by a river of the same name, which discharges itself into the bay at the bottom of the port. The next port of any consequence which we meet with is that of GUAYRA, whose road is always so open to the breeze, that the sea is kept there in a state of continual agitation; and the violence of the winds frequently occasions damage to the ships which ride at anchor. The surge is very strong; and acting at the bottom, as well as on the surface of the water, keeps the sand in constant agitation, and deposits it in such quantities upon the anchors, that before they have been fixed for a month it is impossible to hoist them. To avoid the certain loss of their cables, every vessel is obliged to hoist anchor once in eight days. The depth of water does not exceed eight fathoms at the distance of a quarter of a league from the beach; and to complete the catalogue of its inconveniences, that species of worms, called tarrets, which is so destructive to shipping, commits greater ravages here than in any port of the Caraccas. Yet, in spite of all these unfavourable circumstances, the harbour of Guayra is more frequented than any other upon the coast. Between Guayra

Tides, winds, &c.

Ports.
CARACAS.

Porta.

and Cape Codera, the distance is twenty-five leagues. The coast then takes a direction to the south-east, and conducts us to the lake of Tacaregua, about thirteen leagues and a half distance from the Cape. In its form this lake exactly resembles a bay, a name which it would certainly have obtained, were it not for a bar of quicksand, which frequently cuts off its communication with the sea. Its form is circular, and from the sea on the north-east to its deepest recess on the south-east, it measures about seven leagues. The next port we meet with is Barcelona, which is so shallow as to be incapable of admitting vessels of any considerable size, and affords no shelter but against the breeze. At the distance of one league to the north, however, the island of Borracha presents, on its south side, a safe harbour for ships of any magnitude. From Barcelona the coast runs to the north-east as far as Cumana, at the distance of two leagues. The intermediate space is filled with a chain of islands not far separated from the coast. Some of these are provided with bays and harbours, none of which, however, are of such importance as to merit particular notice. The port of Cumana is well sheltered against the inclemency of the weather; but we forbear giving any particular description of it, till we come to speak of the government and town of the same name. To the east of Cumana, at a considerable distance, is the Gulf of Cariaco, formed by a part of the coast of Cumana, the point of Araya, and the Barrigon. This gulf extends ten leagues from east to west, and is from three to four leagues broad. Towards the centre its depth is from 80 to 100 fathoms. Protected by the surrounding mountains from every wind except the trade wind, its surface is in general as smooth as a lake: to that wind, however, it is entirely exposed, and its waters of course are agitated in proportion to the strength of the breeze. In this gulf, the lake of Evoco, the Gurintar, and Juanaatar, are three places very convenient for loading. The point of Araya, lying east from the mouth of the river of that name, is rendered dangerous by its lowness, and by a sand bank, on the north-east, almost on a level with the surface, which advances two leagues into the sea. To this point, however, the attention of those who arrive from Europe must be directed, if they wish to make an easy entrance to the port of Cumana. For that purpose it is absolutely necessary to bear off from the north-east and south-west till they have doubled the point; after which they may coast along the shore for half a league. Advancing still to the east, we arrive at a large gulf, which the Spaniards call Golfo Thiste, but which is known to the French and English by the name of the Gulf of Paria. On the west of this gulf is that part of Terra Firma, called Paria, and on the east the isle of Trinidad. From these two lands on the north, two points jut out, between which lie two islands, with regard to these two points nearly east and west. These islands almost close the gulf on the north, leaving, however, between them, a space in which are four openings called the mouths of the Dragon, by which the superfluous waters of the gulf are discharged. The largest of these openings, being two leagues broad, lies on the west between Point Paria and the island of Cha cachacares. In this inlet to the gulf there is nothing dangerous except a rock which just emerges from the surface at two cables length from the island of Cha cachacares. Between this island and that of Navios is a second and smaller mouth, called the Vessels. Its channel, lying from north to south-east, renders it very good for the going out, but very bad for the entrance of ships. A third mouth, called the mouth of Huevo, (Egg's mouth), is formed by the isle of Navios on the west, and that of Monas on the east. Lying in a direction from north, north-east, to south, south-east, it is much more convenient for entering than going out. The fourth mouth is between Trinidad, and the point that is most to the west south-west of that island. It is called the mouth de Los Monos, (Monkey's Mouth), probably because it is rendered narrower and more difficult by a rock, which, from its position in the centre, occasions a continual commotion, while, at the same time, the land of Trinidad, by excluding the winds, occasions a calm which is but rarely interrupted by momentary gusts. This gulf is twenty-five leagues from east to west, and fifteen from north to south. In all that extent the anchorage is good, but the depth varies from eight to thirty fathoms: upon the coast of Paria, the soundings are much less. This gulf is in fact a real port, which, in extent and excellence, is scarcely surpassed by the finest in the world. Its bottom is muddy, except on the coast of Terra Firma, where there are shoals and banks of sand. Though the waters of this gulf have been said by some authors to be fresh, they are in reality as salt as those of the sea. A considerable volume of water is poured into it on the south south-west, by different mouths of the Oroonoko, with a velocity which greatly incommodates vessels steering that way on their passage. Depons thinks it probable that a part of those waters have, in the progress of ages, detached from Terra Firma what is at present called Trinidad, and that their ravages will not cease till they have opened the mouths of the Dragon, and thrown themselves into the ocean. The currents, which are always carried into the sea by the channels of these mouths, render it impossible to enter, particularly by the small ones, unless the winds be highly favourable. Nor is it less difficult to enter on the south than it is on the north. It cannot be attempted with safety unless the wind be from the south-east, and then it is necessary to coast to the south of the island of Trinidad as far as point Hicacos, which must be approached within two cables length, in order to pass between that point and a shoal in the middle of the channel, formed by the same point and the small island of Soldado. There are several ports and roads along the coast of Paria which greatly facilitate the communication with Trinidad.

After this detailed account of the climate, the natural history, and physical aspect of this country, it becomes an interesting inquiry, what improvement do the inhabitants make of the advantages which nature has so liberally afforded? Few parts of Spanish America are under better cultivation than Caraccas, because when its mines disappointed the expectations of its conquerors, they were compelled to depend on
Cacao, an indigenous production of this part of America, naturally attracted their first attention. It was soon adopted as one of their most favourite aliments; and in the mother country the relish for chocolate became so strong, that it was regarded as even more indispensable than bread. Plantations of cacao were accordingly multiplied in Caraccas, and the congenial soil, answering the fondest wishes of the planters, yielded crops of this valuable fruit no less excellent than abundant. To the merchant the best recommendation of cacao is, that it comes from Caraccas; but even there its qualities vary in different provinces. The cacao of Orinco is superior to that of other places, and weighs twenty per cent. more than an equal quantity of any other. Next to that is the cacao of the coast, which is preferred to that of the interior. The plantations of cacao are all either to the north of the chain of mountains which coast the sea, or in the interior country. Two principal crops of them are gathered in a year; one about St John's day, the other towards the end of December. The cacao ripens, however, and is gathered during the whole year. But in all seasons the planters of Caraccas endeavour, as far as possible, to collect their crops only at the wane of the moon, imagining that the nuts are then more solid, and less liable to spoil. Some of them, however, ridicule this practice, as so less inconvenient than absurd; because, if the harvest continue only during the fifteen days of the moon's decline, much of the ripe fruit must be left rotting on the tree, and a great loss would thus be incurred by suspending the harvest during the moon's increase. More attention is paid to the culture and preparation of cacao in the eastern part of Terra Firma, than in any other part of the world; and to this attention, as much perhaps as to the excellence of the soil, must we ascribe that superiority which the cacao raised here possesses over that of every other country.

Till the year 1744, cacao was the only article of cultivation in Caraccas. At that time two individuals introduced the culture of indigo, which, in spite of strong prejudices against it, succeeded so well, that all new plantations were now prepared for indigo. The valleys of Aragoa, where it was first cultivated, exhibited an unexampled and astonishing rapidity of increase. Over immense plains, lying till then in a state of nature, plantations of indigo rose as if by enchantment. And the concourse of cultivators gave rise to many new villages, and restored others from a state of ruin to the elegance and importance of cities. The culture of indigo has extended from the valleys of Aragoa to the south-west as far as Varinas. None of it appears on the coast, nor eastward of the town of Caraccas to the gulf of Pari, nor southward to the Oronoko. To enter into a detail of the process by which indigo is prepared, would be here out of place. We may only observe, that the inhabitants of Terra Firma, instead of suspending it in sacks, after fermentation, dry it under sheds. This method, though tedious, is favourable to the quality of the indigo. It thus acquires greater hardness and lustre, and its weight, in proportion to bulk, is considerably more than that of indigo dried in the sun. In packing this commodity, likewise, the Spaniards have adopted a better method than that which is usually followed. Instead of putting it into barrels, they pack it in sacks of coarse linen, over which a calf's hide is so hermetically sewed as to be quite impenetrable. These packages, which are called ceroons, possess great advantages over barrels. They are more solid, more convenient for transportation, nor are they liable to any damage from the rough usage which they may encounter on their conveyance from the place of manufacture to any European port, or from the carelessness and unskilfulness of carriers in their subsequent circulation.

Cotton, though long known in Caraccas, was so much neglected, that, previous to the year 1782, a hundred plants formed about the proportion of the largest plantation. The success of the indigo plantations, affording a sufficient proof that the soil of that country was not adapted exclusively to the culture of cacao, at length induced some planters to pay attention to the cultivation of cotton; and their success was so flattering, that the cotton plant soon occupied a considerable portion of the valleys of Aragoa, Valencia, Araure, Barquisimeto, Varinas, Cumana, and several other places in the provinces of Caraccas. As the cotton is destroyed by frequent or heavy rains, the coast from Cape de la Vela to Cape Pari, which attracts the clouds, is improper for its culture, and, of course, no cotton plantations are there to be found. In the dependencies of Caraccas, cotton is planted only in the months of May and June; because, as the plants blossom always in November, those planted in July and August would be surprised by the blossoming season before they had reached their natural growth, and had acquired the consistency necessary to perfect fructification. Contrary to the practice of the French colonies, who plant their cotton trees in a quincunx form, the Spaniards of Caraccas plant on straight lines, drawn with a cord, and separated by a space of seven or eight feet. The holes to receive the seed are four feet distant from one another, and into each are thrown five or six grains, not more than the half of which generally rise. The worms, so destructive to the cotton-plant in other countries, never attacked it in the valleys of Aragoa until the year 1802, and their appearance was probably occasioned by the abundant rains which fell in the four preceding years. Though less skilful, perhaps, in the culture and preparation of their cotton than the English, French, and Dutch, the Spaniards at least pack it more con-
Coffee, which, in the colonies of every other nation, had, for more than half a century, formed an important branch of commerce, was cultivated in the Transatlantic dominions of Spain merely as an article of domestic consumption, till Don Bartholomew Blandin, in 1784, devoted to its exclusive cultivation a property which he possessed in the valley of Chacao, within one league of the town of Caraccas. The valley of Aragosa, where all the enterprise and activity of the Spaniards seems to be concentrated, was the first to adopt this new branch of cultivation; and so rapid and general was the influence of its example, that not only all the new plantations, commenced since 1796, are in coffee, but many planters have abandoned cacao and indigo to make way for its cultivation. Still, however, the culture of coffee is so far from having attained the increase of which it is susceptible in this extensive and fertile country, that the quantity produced, independent of what is used for domestic consumption, does not exceed 1,000,000 pounds. Less attention is paid by the Spaniards to their coffee in the various stages of its growth, as well as in its preparation, than its importance demands. The weeding of it, in particular, is so much neglected, that the young plants have to struggle continually against weeds, which not only impede their growth, but threaten their existence. In gathering the crop they are equally careless. The cherry which has just begun to redden, as well as that which is thoroughly red, is indiscriminately gathered, and delivered to the process of fermentation, which is itself defective.

In all the other European colonies situated between the tropics, sugar is the prime article of commercial produce. In Caraccas, it enjoys only a secondary rank; for, though it is raised in considerable quantities for home consumption, scarcely any of it is exported. The quantities of sugar which the Spaniards devour, furnish a sufficient explanation of the deficiency of this branch of their commerce. The inhabitants of Caraccas, without distinction of condition, fortune, or colour, make sugar the principal article of their food. Guaro, a an intoxicating beverage, of which all classes, particularly those of inferior rank, are passionately fond, is produced by the fermentation of sugar in water. In the banquets of the rich, confectionery holds the most distinguished place. Their deserts sometimes consist of two or three hundred dishes of sugars, tastefully arranged and moulded into every shape that can be imagined to excite the admiration of the company. In a word, there is not a single negro, whether free man or slave, whose meal does not consist of a little cacao boiled in a great quantity of water, and a large lump of coarse sugar, which he eats like bread. It can scarcely be wondered, then, that sugar should make such a trifling figure among the exports of the Caraccas. The sugar plantations are generally in the vicinities of towns, because there the sale is readiest, and the greatest facilities are afforded to cultivation. The planters of Terra Firma are very skilful in distinguishing the qualities of soil which sugar requires, of which the excellence of their sugar affords an indisputable proof. Before the year 1796, all their plantations contained the same cane that is raised in the other colonies. At that time, the cane of Otaheite was brought from Trinidad, and its advantages seemed so great that it was generally adopted. Notwithstanding the excellence of soil in Caraccas, its sugar, from want of due care and skill in the different stages of its preparation, is much inferior in crystallization and whiteness to that of the other colonies. The alkali which they employ consists chiefly of ashes, which, besides giving the sugar a brown tinge, prevents it from acquiring the proper consistence. Their method of drying the sugar appears likewise very exceptionable. They spread it upon an elevated platform, covered by a grooved roof. In fair weather, they shove aside this roof, that the sugar may be exposed to the rays of the sun. The sugar, however, has time to regain, during the rains, or from the dampness of the night, the humidity which the sun had drawn off; and the transitions from dry to damp, and from damp to dry, necessarily destroy the grain of the sugar, and prevents it from being sufficiently consolidated to render it durable. Another cause of the general inferiority of sugar in Caraccas is, that the planters find their interest in selling as sugar a mass composed of all the molasses, and of eight tenths of the mucilage, which are justly regarded in the other colonies as heterogeneous particles. The poor, who subsist principally on this impure compound, procure it at a small expense, and habit makes them prefer it to clayed sugar. For the fabrication of the guaro, too, this compound is much preferable to clayed sugar, because it possesses, in a superior degree, the principles of fermentation. In a short time, the manufacture of sugar will probably be much improved in the provinces of Caraccas; for the valuable work of Du- trone on the history of the cane, and on the means of obtaining sugar in greater quantity, and of better quality, than by the ordinary process, is in the hands of several planters, who are prevented from applying its principles only by the difficulty of procuring the proper utensils.

The cultivation of tobacco was at first free; but Tobacco, the necessities of the state, and the expenses of the government of Caraccas and its dependencies, at length induced the king to reserve to himself the exclusive privilege of planting and selling it here, as he had done long before in the kingdoms of Mexico, Peru, and Santa Fe. A cedule, executed in 1779, severely prohibited all persons from sowing tobacco, and fixed upon the places which were considered the most suitable in the different provinces for cultivating and preparing tobacco on the king's account. In each of these places administrations were established, all subject to a director-general of tobacco, residing at Caraccas, with a salary of 4000 dollars. The persons entrusted with these administrations, distribute allotments of the land appropriated to the
The culture of tobacco to such as apply for them. The quantity allotted is proportioned to the abilities of the grantee, and to the number of cultivators which he engages to employ. Advances of money are even made to him, which are deducted from the amount of the first tobacco he delivers to the exchanger. An express injunction is laid upon him, to sow all the land given him with tobacco alone, and to deliver to the king's officers all the tobacco which he raises, without retaining a single leaf; and he is paid according to the quality. The Spaniards of Caraccas give their tobacco two kinds of preparation: one of which they term cura sec; or the dry preparation; and the other cura negra, or black preparation. The only distinction of the cura negra consists in the degree of fermentation which it receives. The object of this preparation is to obtain from it a juice highly esteemed in the country. For this purpose it undergoes an operation which blackens it, and from that circumstance it derives its name. Both the cura sec, and cura negra are divided into three qualities, the price of which, paid to the cultivators by the king, are very different. In classing them, great abuses take place, which the law has never been able to prevent. According to a wise, but ineffectual regulation, passed on the 2d of June 1787, the delivery, reception, weight, and qualities of the tobacco, must be determined according to certain forms, in presence of the factor, book-keeper, administrator of the magazines, the visitor or inspector, the cultivator, and the commissary-general of the plantations. The tobacco is classed by the inspector, who is not to be impeded in the discharge of his duty. The cultivator, if dissatisfied, may appeal to the assistants, whose unanimous voice can change the classification; if they are divided in opinion, they refer the decision to persons of experience. Though the tobacco may not have all the qualities requisite to preserve it for a length of time, it is received according to its class and value, provided its corruption does not take place within five or six months. While the tobacco is weighed in presence of the above-mentioned company, the steel-yard is held by one of the guards nominated by the administration. Two invoices are made of it, and signed by all the assistants. One of them remains at the factory, the other is consigned to the commissary-general of the plantations. The cultivator is paid for his tobacco at the following rates: For a quintal of the cura negra, first quality, eleven dollars; second quality, ten; third quality, seven. For a quintal of the cura sec, first quality, ten dollars; second quality, eight; third quality, three.

A stranger, in travelling through this country, the most lovely and luxuriant perhaps in the world, is astonished to find its plantations so trifling and unproductive. A planter is considered rich, whose annual income amounts to 4000 or 5000 dollars; nor are there twenty plantations within the captain-generalship of Caraccas which yield a greater revenue. This is not owing to an over-minute division of property; but it is rare to see one-tenth of a plantation cultivated. It is a fact, extremely disgraceful to the government of Caraccas, or to the inactivity of its inhabitants, that, in this wide and fertile district, there is raised not one-tenth part of the produce which the industry of the French extorts from St Domingo, a country 200 times less spacious, incomparably less watered and less fertile, and with not more than one-half of the white population.

Five causes are assigned by Depont for this backward state of cultivation. The first is, the number of mortgages with which every estate in Caraccas is more or less burdened. As the Spaniards never alienate any property, however poor they may be in reality, they must still maintain the appearance of wealth. When in want of money, they borrow it at an interest of 5 per cent. on their landed possessions: loans, which are the more easy, because the low state of commerce prevents money from rising to a high rate.

A still more serious evil arises from the pious legacies and prebends with which many estates are encumbered. These legacies, augmenting from generation to generation, cannot be bought up by payment of the capital, but keep the planter under an obligation to pay regular interest, and thus deprive him of the means of increasing his productions. It would be infinitely more conducive to the public prosperity, if these pious donations were discharged in full, even though it should be necessary to sell all or part of the front property, rather than suffer them to accumulate on the possessions, the annual interests of which consume their revenues, and paralyse the industry of the most active proprietors. Adverse seasons, which destroy two or three crops successively, ruin for ever a planter, however industrious he may be, who is burdened with mortgages. The debt is continually augmented by expenses; chagrin overcomes his activity; his property is sequestered, and passes with the same charges to another planter, who is threatened with the same fate.

A third obstacle to culture, more pernicious, if possible, in its operation than the two former, is the pride of the planters, who disdain to take any charge of their plantations, which they entrust wholly to overseers. To this is added their extravagant mode of living. Every proprietor has his residence in a city, where his retinue of servants and household expenses are regulated according to the revenue of the plantation, which is generally calculated on the proceeds of the most fertile and prosperous year. The expenditures, of course, almost invariably exceed the receipts; and the planter accuses the seasons or the laws for the difficulties in which he is involved by his own indiscretion.

The ambition of the Spanish Americans for public employments, is another circumstance which operates nearly in the same way as their extravagance to the prejudice of agriculture. The prospect of unbounded wealth from a large and rich plantation could not induce a Spaniard to relinquish his desire of a military rank, a place in the finances, a judiciary office, or the cross of an order. To secure these grand objects, every planter of consideration has his agent at Madrid, who collects for him all the necessary information, and takes the proper measures for obtaining any place or appointment which he thinks will suit the inclination of his client. Before this be done, however, he must be handsomely paid; and every Spaniard in America considers a remittance of
money to Madrid as a preliminary6ential to the
success of his solicitation. Many plantations are
mortgaged, in order to raise these necessary remit-
tances: the source of landed wealth is thus dried
up; and, at any rate, men aspiring to public distinc-
tions, cannot stoop to the concerns of an estate,
which, whatever riches it might yield, can confer no
splendid honour.

The character of the overseer is, in general, such
as might be expected amidst this universal misma-
agement. Without honour, emulation, or intellec-
tive, they are indebted, even for the indifferent
crops which they raise, to a fertility which seems to
defy their ignorance and carelessness. The few plan-
tations which prosper, are conducted by proprietors
themselves, ambitious to increase their revenues, and
proud of the name of cultivators. Those which de-
cline, belong invariably to persons who only visit
them as strangers, and who, in the indulgence of
extravagance and dissipation, or in the pursuit of fa-
vours and employés, disdain the low cares of a plan-
ter, and would think themselves insulted by being
supposed to know any thing of the condition of their
own estates.

The last cause assigned by Depons for the decline
of culture, is the want of a sufficient number of
negroes. Though the Spaniards were never allow-
ed the direct importation of negroes from Africa,
they were permitted to purchase them in the Antilles,
to pay for them in the produce of the country, ex-
cepting cacao, and to resell them in Terra Firma.
But the revolt of the negroes in St Domingo, in
1791, spread such an universal alarm, that for twelve
years, not a single negro arrived in Caraccas. The
labours of the country of necessity languished, its
productions were diminished, and a new supply of
labourers became indispensably requisite. Caution,
however, was necessary, lest negroes should be im-
ported from the French colonies, who would bring
along with them the seeds of revolt. With a view
of supplying the provinces, permission was given by
the king to Edward Barry & Co. for the introduc-
tion of 4000 negroes; but the granter's death ar-
ested the operation, and only particular permissions
were given. Two merchants obtained, in May 1804,
two of these permissions, each amounting to fifteen
hundred negroes. By this regulation, those who in-
roduce black slaves are known, and can be made
answerable for any irregularity in their behaviour.
Still, however, these supplies are very inadequate to
a country which does not contain the 20th part of
the population necessary to cultivate it; where the
births of slaves are far less numerous than the va-
cancies made by their deaths, and where the benevo-
ence and piety of the masters annually transfer a
considerable number of individuals from the class of
slaves to that of freedmen. We can hardly agree
with Depons with regard to the strong necessity of
facilitating the introduction of negroes; but we cor-
dially agree with him in considering the employment
of the idle hands of free men of colour, and of the
Indians of doctrinaries and missions as a measure of
the last importance to the agricultural prosperity of
Caraccas. The Canary Islands, whose youth have
a decided predilection for America, might also fur-
nish a considerable number of active and useful la-
bourers; and were the salaries of workmen punctu-
ally paid, and their emulation excited, idleness would
give place to activity, and agricultural operations
would go on with spirit and effect. Mr Semple,
who visited Caraccas little more than a year ago, in-
forms us, that charming plantations extend in all di-
rections from the town of Maracaibo, and have an air
of prosperity and activity which he was at a loss to
account for, till he learned, that on these plantations
work was chiefly performed by free labourers, and
that the use of slaves for the great purposes of so-
ciety was, comparatively speaking, little known.

From this view of the state of agriculture in Ca-
raccas, it follows almost as a corollary, that its com-
merce must be in a very languishing condition. A
nation, which, even at this day, estimates the value
of its colonies by the quantities of gold and silver
which they furnish, cannot be supposed to derive
much advantage from the more substantial riches of
their soil, or to be aware of the resources, almost in-
exhaustible, that a well-regulated commerce would
open in a country, which, in fertility, in climate, in
the abundance and value of its vegetable productions,
has no parallel in any quarter of the globe. So lit-
tle were the Spaniards capable of appreciating the
value of their possessions in Terra Firma, that, for
upwards of a century after the discovery of Carac-
cas, it furnished to the parent country no article of
commercial produce: one vessel alone arrived an-
nually from Spain, not to receive any valuable cargo,
but to convey the necessaries of life to a country ca-
pable of maintaining the whole of Europe. It was
not till the Dutch settlers in Curacoa had commen-
ced a traffic with the neighbouring continent, about
the middle of the 17th century, that the inhabitants
of Caraccas began to perceive the advantages of their
situation; and the merchants of Spain thought it an
important favour, to have permission to send two tra-
ding vessels to Venezuela. The absurd policy of
the court, whose permission to trade with its colonies,
after being obtained with much difficulty and ex-
pense, was rendered of little value by the enormous
duties imposed on every article of merchandise, de-
prived the Spaniards of all chance of successful com-
petition with the traders from Holland, who could
supply the same articles free of duties, and directly
from the manufactories of Europe. The two Spa-
nish vessels were compelled to sell their cargoes at a
loss of sixty per cent.; and the other merchants of
Spain, warned by their failure, left the Hollanders'
in the undisputed enjoyment of the trade of Carac-
cas. The remainder of the 17th century elapsed
without the arrival of one vessel from Spain; and,
during that interval, the inhabitants, animated by
the advantages of their commerce with the Dutch,
had so far enriched their country by cultivation, that
the annual amount of cacao, in the province of Ve-
nezuela alone, exceeded sixty-five thousand quintals.
The Spanish government, anxious to exclude for-
igners from any participation of the riches of this
flourishing province, established a severe inspection,
for the purpose of preventing all communication
with the Dutch; but, in spite of this expedient,
not above one third of its produce found its way to
Spain, or its possessions, while the residue went off in a contraband trade, which, as it was favoured by the situation of the country, and the interests of the people, no efforts of government could prevent. At length, some merchants of Biscay proposed to the king, in 1728, to destroy, at their own expense, the trade of foreigners with the province of Venezuela, on condition that they should be permitted to supply the country, and export its produce to the metropolis. To this proposal his majesty acceded, though not without imposing conditions, which seemed calculated to deprive the company of almost all the advantages which they expected from the grant. The justice, moderation, and activity of this company, while they conciliated the favour of the colonists, afforded complete satisfaction to the court, from which they obtained the privilege of an exclusive commerce. Though this privilege does not appear to have been abused, it excited in Venezuela a general dissatisfaction, which was ready to break out into rebellion, when an expedient was adopted to remove the suspicions, to which the hideous form of a monopoly had very naturally given rise. It was agreed, in 1730, that an assembly should be formed of an equal number of members of the company, and cultivators belonging to the country, in which the governor-general of the province of Venezuela should preside. By this assembly the price of cacao to the company was to be decided; no variation of which was, in any case, to be permitted, without the formal assent of the assembly. Such of the planters as were not satisfied with the established price, were allowed to send a sixth part of their cacao to Spain, on their own account, and in the vessels of the company. Notwithstanding the restrictions with which this company was hampered, its success was so great, and its influence on the cultivation of the province so beneficial, that, in less than thirty years, the quantity of cacao exported annually rose from 65,000 quintals to 110,659; and Venezuela acquired an air of prosperity unknown in any other Spanish colony. In time, however, the company so far forgot the principles of honour and moderation, as to employ its wealth in tampering with the assembly, destined to curb its cupidity, and even to engage with the Dutch in the contraband trade, which it had solemnly pledged itself to destroy. Such irregularities necessarily occasioned its dissolution; and by a decree of the Spanish government, of the 12th October 1778, the commerce with Caraccas was declared free to all natives of Spain, and, in effect, to all the Spanish colonies. The import and export duties underwent at the same time such a reform, as seemed calculated to combine the advantages accruing to the revenue from the proceeds of the custom-house, with the necessary protection to national industry and commercial enterprise, and the supply of Spanish America. Articles exported to the colonies are divided into three classes. The first class includes articles of the growth or manufacture of Spain, which are called free articles, because the duties to which they are subjected are comparatively trifling, though they exceed nine and a half per cent, both on their leaving Spain, and on their entry into America. The second class, named articles of contribution, are those which, though of foreign production, have received in Spain a degree of workmanship, sufficient to change or to improve their form. The duties on these articles amount to about twelve and a half per cent. The third class comprehends all articles imported from foreign countries to Spain, and ultimately sent to America. The duty on such articles, on their entry into Spain, is fifteen per cent.; on their departure for America, seven per cent.; at their arrival, seven per cent.; besides other moderate duties, which raise the price of all foreign merchandise, imported from the mother country, about forty-three per cent. With the exception of cacao, colonial productions pay but trifling duties on leaving America and on entering Spain, and are totally exempt from duty on their exportation for foreign markets. The trade to Caraccas is far from being lucrative to the Spanish merchants. Cargoes delivered in America acquire, by a common calculation, a value of thirty per cent. above their price in Spain; and a merchant thinks himself fortunate, when he can sell the whole of his commodities at thirty-three and a third per cent. above first cost, having thus a neat profit of only three and a third per cent. Even this profit, scanty as it is, may be regarded as in a great measure fictitious; for it is doubtful, if it cover the losses to which the merchant is exposed, by the credit which he is obliged to give.

In the year 1796, immediately before Spain declared war against Great Britain, the importations from Spain to Caraccas amounted, in value, to 3,118,8114 dollars, the importation duties on which were 291,929 dollars. The exports to Spain, in the same year, were estimated at 2,098,516 dollars, the duties on which amounted to 138,052 dollars. Since that period trade has rapidly declined, owing partly to the war, but much more to the indolence and pride of the inhabitants, among whom commerce is considered as degrading to people of rank; to the injudicious restrictions imposed by government; and to the carelessness of those employed by the court to detect and remedy abuses.

Almost the whole commerce of this country is now carried on by European Spaniards, chiefly Catalonians, and by Icelanders, or islanders from the Ca-

naries. A spirit of union, and a strong provincial dialect, binds the Catalonians together, and gives them a considerable advantage in all commercial trans-

actions. When a cargo arrives, one or two Cataloni-ans conclude the bargain, when all the rest, who have any interest in it, appear for their share in the di-

vision. The indolent natives, far from being jealous of this appropriation of their commerce by strangers, are accustomed to boast that their rich and abundant productions, while they exempt them from the necessity of going to Europe, draw Europeans to their country, and convert them into their servants. "In this manner," says Mr Semple, "reason the Chinese, vain of their supposed superiority over all mankind. And in this manner might argue the sa-
vages of the South Seas, who behold Europeans vis-
iting them, but who never visit Europe."

Though in Caraccas, as in all the provinces of Re-
Spanish America, the taxes are numerous and oppressive, the government establishment is so expensive, that, till a very recent period, the expenditure exceeded the revenue by at least two-thirds. While the receipts of the treasury continued thus insignificant, both the civil and military administration were concentrated in the person of the captain-general.

As the revenue became more considerable, the system of management was changed; and, in 1777, an intendant was placed at the head of the finances, whose authority extends over the whole district. In his own department, the intendant is totally unconstrained. He has power to ordain any regulation which may seem necessary for the interior government of the finances, and nominates provisionally to every vacant office in the administration. In the different provinces, he has delegates or governors, who in their respective jurisdictions administer the public money, direct the ordinary expenses, and determine provisionally on all difficulties arising within their limits, on the collection of duties. They can authorize no extraordinary expenditure, however, without the concurrence of the intendant; and to him, in case of any dispute about the collection of revenues, there always lies an appeal. To agriculture, commerce, and navigation, the intendant is bound to direct his principal care. With regard to agriculture, he can make no regulation, but only transmits to the king his observations on the measures most proper for its encouragement. In regard to commerce and navigation, he is under no such restraint. Without any responsibility, he may repress the abuses he perceives, or issue ordinances for improving their system. The office of the intendant continues five years, during which he enjoys the rank of a field-marshall. His annual salary is 9000 hard dollars, and his other emoluments amount to double that sum.

The business of the principal customhouses is conducted by a cashier or contador, and treasurer, who are royal officers, and whose duties are nearly the same. The accounts of the customhouses and receivers are subject to the control and revision of a tribunal de cuentas, or of accounts, which is composed of two officers, called contadores mayores, or chief auditors. These contadores must verify all accounts before they can be sent to Spain; they regulate all questions of account, and enjoy their office during the same time as the intendant. From the decisions of the court of accounts and the intendant, an appeal lies to the supreme chamber of finance, of which the intendant is president. In this system of financial authorities appears abundantly simple; but, in reality, there is no part, even of the Spanish dominions, in which the persons employed in collecting taxes are, in proportion to the amount of the revenue, more numerous than in Caraccas.

Our limits do not allow us to give a detailed account of the different taxes levied in this government. We shall, therefore, content ourselves with giving, in the following table, a statement of the receipts and expenditures of the different provinces, for five years, commencing in 1793.

This statement does not comprise the sums arising from the culture and sale of tobacco, which belongs exclusively to the crown, because these sums are administered separately, and have their own peculiar bank and approbation; nor the receipts from bulls, the power of distributing which was first granted by the Pope to the Spanish monarch, for the benefit of his subjects, who took arms against the infidels in the holy war. Though this war has long been at an end, the bulls still continue to arrive from his Holiness; and the blessings which they impart are considered too precious, and their advantage to the exchequer is too important, to allow them to be easily renounced. These bulls annually produce 26,000 hard dollars; and the exclusive sale of tobacco, deducting all charges, brings in 700,000 hard dollars a year.

The first settlements of the Spaniards in this part of Terra Firma, were completely similar, in their history, to their other settlements in America. To this, as to the other regions of the New World, they were at first impelled by their thirst for gold; and the provinces which now compose the captain-generalship of Caraccas, as they contained no mines which could be wrought to much advantage, were long neglected by the Spanish government. Before these mines could be explored, however, it was necessary that the original inhabitants of the country should be subdued. In this conquest the Spaniards had to encounter considerable difficulties. Many of their troops were cut off by sudden and unexpected onsets of the Indians; and they purchased, with no small loss of blood, a territory which they were soon inclined to abandon, as altogether unprofitable. In our account of the mines of this dependency, we have already mentioned the disasters to which the Spaniards were exposed from the Indians. They at length, however, succeeded in their total subjugation; and the same form of government was established here which had been framed for the other Spanish dominions in the western hemisphere.

All the Spanish provinces in America are governed by representatives of the king, some of whom, as the governors of Mexico and Peru, are named viceroys; and others, as the governor of Caraccas, have the appellation of captains-general. The power of this governor is supreme in military affairs in the province of Venezuela, and its dependencies, Maracaibo, Varinas, Guiana, Cumana, and the island of
Margaretta. He is likewise president of the royal audience, and of all the tribunals, excepting those which relate to the royal treasuries and to commerce. Although in the capacity of captain-general he may form whatever regulations he pleases without advice and without control, he generally submits any case of importance to a junta de guerra, composed of the first military officers. He is exclusively charged with all political relations between the colonial government of foreign powers, and his particular district. In civil matters, his jurisdiction is confined to the province of Venezuela. Maracaibo, Margaretta, Cumaná, and Guiana, have each a governor, who exercises the same civil powers in his own province that the governor of Caraccas enjoys in his. As the qualities of a good soldier are not always combined with the knowledge and habits essential to the proper administration of justice, the governor is obliged, in all judicial affairs, to have recourse to a counsellor at law, entitled his assistant, who records and signs the sentences. These sentences have no validity without the signature of the governor; and if they do not meet his approbation, he can pass the documents to another person, termed assistant adiuc, who furnishes a new sentence. The governor may even give a decision contrary to the advice of these legal counsellors—a power which he never employs, however, except in cases where it appears necessary, and may be readily justified. Though president of the royal audience, he has no voice in its deliberations, nor any influence, even by vote, on its decisions. That court, where he represents the majesty of his sovereign, is the only tribunal which is permitted to investigate his actions. Great as the power of the captain-general is, he is in general prevented from abusing it, by the responsibility which he incurs, and the certainty of being called to a rigid account for every act of his administration. His office terminates in seven years, and no sooner is his successor nominated, than a commissary is appointed to receive his resignation. This commissary immediately announces, in the most public manner, the time and place appointed for the examination of the transactions of the late governor; and all who have any complaints against him are invited to attend and substantiate their charges, that strict justice may be awarded. The results of these examinations are forwarded to the council of the Indies, who decide on them definitively.

The Royal Audience is a council, composed of a president, (the captain-general), a regent, three oidores, two fiscales, one for civil and criminal affairs, the other for the finances; a reporter, and an alguazil mayor. This audience is invested with a power of superintendence over all other constituted authorities, not even excepting the ecclesiastical tribunal. The captain-general is charged by the king to consult the audience on every extraordinary emergency; and they enjoy the very uncommon privilege of corresponding with his majesty without the knowledge of the governor.

The members of this audience are distinguished by the title of highnesses; and, according to a royal decree, the viceroy is commanded to treat them with all respect, as their brethren, and as magistrates whom the king honours with his confidence; to admit them immediately whenever they visit him, and listen to them as fathers, chiefs, protectors, and presidents.

The Cabildos are courts invested with the charge of police and of municipal affairs in the different towns, villages, and districts. They are composed in general of alcaldes in ordinary, or municipal officers, regidores, and a syndic. By the constitution of the cabildos of Caraccas, the governor is president of all the cabildos within his district. The alcaldes are elected every year, on the first of January. In places which have no cabildos, the police, and administration of justice, is committed to a lieutenant of justice, whose jurisdiction generally extends over three or four villages. For the exercise of his authority, which is almost unlimited, the lieutenant of justice is accountable only to the governor. His office continues for two years, but he may be re-elected.

The forms and proceedings of all these tribunals are complicated, tedious, and expensive. No nation is so much addicted to litigation as the Spanish, both in Europe and America; hence the number of judges, advocates, attorneys, notaries, scriveners, alguazils, and clerks, is quite incalculable, and the citizens are divided into two classes, one of which is duped and ruined by the chicanery of the other, which supports and enriches itself by the follies and miseries of the simple and litigious.

There is perhaps no country where an invading army would meet with fewer obstacles than in Caraccas. Its sea-ports, indeed, are in general pretty well fortified, and might repel, with considerable success, an attack upon the single point in which they are situated. But their great distance from each other would render them totally useless for general defence. On the wide extent of shore, many places would be found of easy debarkation; and, with proper guides, a hostile army might, with the utmost facility, overrun a country abounding in every kind of provisions, while its protecting force, at the best but small, would be rendered still less efficient, by being distributed in a number of remote garrisons.

The defence of all the provinces included in the government of Caraccas is committed to the captain-general. The governors of particular provinces may adopt such provisional measures as exigences require; but for these measures they are accountable to the captain-general, whose orders they must eventually execute. One great and obvious disadvantage attends this system. The immense distance by which the provinces are separated, prevents the union of their forces, without much difficulty and delay; while the governors are often prevented from adopting the proper provisional measures, by the fear of giving offence to their superior. But were there nothing to prevent the united action of the whole military force of Caraccas, it would still be very inadequate to the defence of such an extensive and valuable country. The whole army consists of 13,136 men, who, before the present civil war, were distributed among the different provinces in the following proportions: In Caraccas and its environs, 918 troops of the line, 900 artillerymen, 1630 militia; in Valencia, 1530

Military establishment.
Among the evils which repress the energies and retard the improvement of the inhabitants of Caraccas, the first place ought doubtless to be assigned to the Roman Catholic religion, which is here accompanied with all the horrors of the Inquisition. This dreadful tribunal has the power of condemning to fine, confiscation, banishment, the galleys, or the flames. In proscribing books hostile to their ideas of true religion or sound policy, the most pernicious exercise of their prerogative, the members of the inquisition are particularly vigilant. No book is allowed to be imported, circulated, or read, till it has received the seal of orthodoxy from the commissaries of the holy office. Every bookseller must provide himself with a catalogue of the books proscribed, and is bound to furnish, in the two first months of every year, an inventory of the books he has for sale, with his oath subscribed, that he has no other books than those named in the inventory. Even private persons, who enter the country with books, must make a detailed declaration of the contents of their library, confirmed by oath, which declaration is sent to the tribunal of the inquisition, or its commissaries, who have power to permit the introduction of the books, or to seize them. Should this declaration be omitted, or imperfectly made, the books are confiscated, and a fine of 200 ducats is exacted for the expenses of the holy office. Books, when imported, are generally deposited at the custom-house, nor can the officers release them but by express permission of the commissary of the inquisition. Catalogues procured from abroad for the selection of books, must be sent before any use is made of them, to the holy office, which may retain or restore them. Should any person succeed in eluding the vigilance of the inquisition, he still possesses proscribed books by a very dangerous tenure, for he is perpetually exposed to those domiciliary visits which the commissioners of the inquisition have a right to make at any hour, either of the night or day. When we examine the list of books condemned by this rigid tribunal, we despair of the rapid progress of improvement among a people, from whom the richest treasures of literature, and even of science, are withheld, lest their eyes should be opened to the absurdities of a pernicious superstition, or to the abuses of an oppressive government.

From the difficulty of procuring permission to emigrate to any of the Spanish colonies, and the scrupulous care of government to ascertain the moral purity and sound orthodoxy of those to whom the permission is granted, we might naturally think that the inhabitants of Caraccas must be particularly exemplary in their character, and attached to the government. But the indolence and indifference natural to the Spaniards, seem to be so much increased by the heat of the torrid zone, as to form almost the only features in the character of the European as well as the Creole inhabitants of the captain-general of Caraccas. The moment a Spaniard is transported to South America, he seems to forget that he has a native country, and loses all desire to return. In the Creole, attachment to the parent country becomes, of course, more feeble. To obtain some public employment, which might distinguish him among his American countrymen, is the only motive which can induce him to visit the land of his forefathers; and to be adorned with the badge of office, is the only connection he desires with a government, to which, in other respects, he may be perfectly indifferent. However deeply, therefore, the Spanish government may seem to have laid the pillars of its sovereignty in Caraccas, and its other American colonies, we may expect to see the mighty fabric very speedily and generally subverted.

To become independent of Europe, was a wish very naturally inspired by the oppressive load of taxes necessary to support the government of a European monarch, and by the restrictions necessarily imposed on commerce by a monopoly which government patronised. This wish was confirmed, and increased in arduous, by the example of the British colonies in America; and, so early as the year 1797, the flame had nearly broke forth with a destructive violence. In that year, three state prisoners in Spain had been condemned to perpetual confinement in the casemates of Guayra. These men, who represented themselves as the martyrs of freedom, and the victims of despotism, had the art to form a very extensive conspiracy against government; and had the wish for independence been seconded by the activity of the people, there is reason to believe that the conspiracy might even then have been successful. It was prematurely discovered, and crushed. But liberty had now exerted among the people the magic of her name; and had kindled throughout the district of Caraccas a spark of discontent, which, however dull the materials on which it had to operate, was not likely to be extinguished till the fabric of the old government was violently shaken, if not entirely consumed.

Such was the state of the public mind when Mr. Revolution randa landed with an armed force on the shores of Caraccas, and unfurled the standard of revolt and independence. Round that standard the patriots were at first prevented from rallying, by the immediate danger of rebellion, and by the inherent indolence and timidity of their dispositions. But when the attention of government was withdrawn from the colonies to the distresses which began to multiply at home; when Spain was perfidiously invaded by the oppressor of Europe, robbed of her monarch, and her territory overrun by hostile armies; then insurrection began to appear more openly in Caraccas; and while the mother country was sunk in the lowest misery, her colonies were distracted by a fierce civil war.

From the very commencement of this insurrection, there appears to have been a strong faction in all parts of South America, determined to establish the abso-
lute independence of the colonies. The professions of attachment to Ferdinand VII., and the sentiments of loyalty which pervaded their early proclamations, were intended to deceive those who were more moderate in their views; while severe invectives against the old government were mixed up with those loyal professions, in order to influence the passions of the lower orders. After thus preparing the mind of the public for some great change, the congress of Venezuela assembled on the 1st of July 1811, and resolved to renounce all allegiance to the Spanish king, and to declare their provinces independent of every foreign power.

In consequence of this resolution, which was not promulgated till some days after it was formed, many individuals, who held public situations, resigned their offices, others retired from the country, while the Spaniards and Canary Islanders formed conspiracies against the new government. Upon the discovery of these plots, many of the ring-leaders were executed in Caraccas, while others were confined in unhealthy prisons, and denied all communication with their friends. These examples of cruelty alarmed the peaceable inhabitants, numbers of whom sold their property, and fled to the United States, or to some of the neighbouring islands.

The junta of the Caraccas, which had been formed merely for temporary purposes, perceived the necessity of assembling a general congress; and the first act of this assembly was to place the legislative and executive powers in the hands of three individuals, who appeared qualified for this high trust by their abilities and their moderate views. The measures of the government were now carried on with great activity and zeal, but were sometimes interrupted by the interference of an assembly called the Patriotic Society,* who met regularly to discuss political subjects, and who appear to have been influenced by the greatest hostility to the British government.

The city of Coro having refused to join the standard of the insurgents, the Marquis del Toro was sent against them with an armed force, but the Coreans quickly repulsed him with considerable loss. The town of Valencia, which stands upon the lake of the same name, formerly called Tacarigua, imitated the loyalty of the Coreans, and having been joined by an entire battalion of Pardos or people of colour, they openly proclaimed Ferdinand the Seventh. In consequence of this declaration, General Miranda marched against that city with the Caraquean army, amounting to about 2000 men. Having passed the mountains of San Pedro, and descended into the valleys of Aragua, he advanced without any molestation to La Victoria, from the heights of which he descended into the immense plains of Valencia. Several small gun-boats, equipped by the Valencians, were stationed on the lake, and concealed among the bushes and reeds which grow upon its banks; and when the Caraquean army came to the village of Maraira, where the road follows the margin of the lake, they received some unexpected and well-directed shots from the gun-boats. The resistance of the

The Caraccas, however, was very feeble, and Miranda marched without opposition to the Morro, which is a round height and pass that commands Valencia. At this pass the Valencians resolved to try their strength; but after opposing a brave resistance to the enemy, they were compelled to retire with the loss of their chief engineer, and several pieces of cannon. From the entrance of the city, where they had rallied, the Valencians were driven into the great square, where, after a second stand, they were routed with the loss of all their artillery. The spirits of the Valencians, however, were not subdued by these disasters; a shower of balls was discharged from the flat roofs and strongly grated windows of the adjoining houses; and in attempting to force their way into the houses, and to take possession of the barracks, where the battalion of Pardos were posted, the Caraqueans were every where repulsed. After having kept possession of the town for ten hours, they were forced to abandon it, with the loss of all their artillery, several prisoners, and two hundred men killed or severely wounded, and never halted till they reached Guacara, which is more than four leagues from Valencia. The number of Valencians who were armed did not exceed seven hundred men.

The army of Miranda, receiving reinforcements from various quarters, was, in less than a fortnight, enabled to advance upon Valencia, while, from the desertion of the whites, the Valencians were reduced to less 500 armed men. On the 8th of August he attacked the Valencians in the valley of Palotai, and on the heights of El Puto and Agua Blanca, which were taken after an obstinate resistance. The Caraquean light infantry followed the Valencians into the city, which they had defended by forming new ditches and intrenchments in the principal streets which led to the great square, and after being attacked on eight different points at the same time, they were at last closely hemmed in. Their strength being now greatly weakened by desertion, and being without water and provisions, they surrendered at discretion on the 13th August, and the flotilla of gun-boats, which had been equipped upon the lake, was also given up.

While the Caraqueans were thus establishing their power in Valencia, an army of Coreans had advanced for its relief, as far as San Felipe on the west, while the Guyanese, who had also remained steady to the mother country, had extended their troops nearly to Calvario on the west. In this state of affairs the government of the Caraccas adopted a system of severity and vigilance suited to the dangers that menaced them; They instituted a tribunal of vigilance, which paid domiciliary visits, and ordered arrests upon the slightest suspicion; the theatre was shut, and all balls and concerts, and even private parties, were at an end. The people were regularly trained to the use of arms, and it became the fashion for persons of the greatest distinction to sleep at the barracks; a law was passed for the abolition of torture, and the liberty of the press was established.

It would be out of place here, even if we were

* About six months after the arrival of General Miranda, he was elected president of this club, and he is said to have immediately introduced four Mulattoes as members.
CARACCI, Agostino, an eminent Italian painter, was born at Bologna in 1558, and died in 1602. He studied first in the school of Prospero Fontana, and became afterwards the disciple of Passerotti. He was chiefly indebted, however, to his cousin Ludovico, for that genuine taste and knowledge of the true principles of painting by which his pieces were distinguished. The merit of the few paintings which he executed, has made subsequent artists regret, that an uncommon dexterity in his own powers induced him to devote more of his attention to engraving, after the works of others, than to the extension of his fame by original productions. His most celebrated work in oil, is the Communion of St Jerome, which was formerly at the Certosa in Bologna, but is now with the rival picture of Domenichino, among the spoils of the Louvre. In the comparison of these two pictures, the preference has generally been given to that of Domenichino; “but surely,” says Mr Fuseli, “if Agostino yields to his scholar in repose, and the placid economy of the whole, he far excels him in the principal figure, the expression, and character of the saint.” Agostino is said to have assisted his brother Annibale, as well in the disposition, as in the execution of the Farnese Gallery; and it is even thought that Annibale has received the credit of several of the pieces which were finished by Agostino. A cultivated taste, a correctness and sometimes elegance of form, and correggiase colour, especially in fresco, are the distinguishing qualities in the style of this master. (a)

CARACCI, ANNIBALE, brother to Agostino, was born at Bologna in 1568, and died in 1609. From his cousin Ludovico, who first put the pencil into his hands, he not only learned the best principles of the art of painting, but caught an ardent ambition to excel in its various branches. For this purpose he studied, with keen emulation, the works of Titian, Tintoretto, and Paolo Veronese, at Venice, and those of Corregio at Parma. The genius displayed in his early productions excited great expectations of his future eminence. His fame soon extended itself to Rome; and he was invited by the Cardinal Farnese, to paint that gallery, which became afterwards so well known through all Europe. In this magnificent undertaking, he spent ten years of assiduous labour. The Farnese Gallery, while its colours withstand the influence of time, will remain an honourable monument of the talents of the painter, while it throws a shade of perpetual infancy over the memory of his employer, who could require such talent, laboriously and successfully exerted for ten years, with the paltry sum of five hundred crowns. Uniform vigour of execution is the distinguishing excellence of this celebrated work; an excellence, however, which is most unhappily contrasted by its imbecility and incongruity of conception. “If impropriety of ornament,” says Mr Fuseli, a little too strongly, “were to be fixed by definition, the subjects of the Farnese Gallery might be quoted as the most decided instances. The artist may admire the splendour, the exuberance, the concentration of powers, displayed by Annibale Caracci, but the man of sense must lament their misapplication in the Farnese Gallery.” Annibale availed himself of his residence in Rome, by studying the antique statues, the basso-relievs, and the compositions of Raphael. These models induced him to change his Bolognesian manner, which had much of Corregio in it, for one which was indeed more learned, but, both in design and in colouring, more dry and less natural. In comparing Annibale with the other Caraccis, it may be observed, that while he was perhaps inferior to Ludovico and Agostino in refined taste, sensibility, and judgment, he surpassed them both in the freedom, the warmth, the energy and originality of conception, by which true genius is characterised. In his paintings there is little of that delicacy which diffuses through the soul a silent pensive delight; but the grandeur of his designs, the liveliness of his expression, the vigour and firmness of his execution, burst in one powerful effect upon the mind, and hurry it away in a kind of impetuous admiration. He painted portraits and history; but it was in landscape that he chiefly excelled. The form of his trees is peculiarly grand; and though he does not appear to have understood completely the principles and doctrines of the chiaro oscuro, and his local colours are not always commendable, yet “no painter seems to have been more universal, more easy, more certain in every thing he did, nor more generally approved, than Annibale Caracci.” (a)

CARACCI, LUDOVICO, the cousin-german of Annibale and Agostino, was born at Bologna in 1555, and died in 1619. He studied under Prospero Fontana; but it was by contemplating the works of Titian, Tintoretto, and Paolo Veronese at Venice, and of Parmigianino and Corregio at Parma, that he refined his taste, and formed those elevated conceptions which characterise his paintings, and which have raised him to the distinguished eminence which he still holds among artists. He laid the foundation of that school which was distinguished by the title of the Academy of the Caraccis, and which became so highly celebrated. To this academy every student resorted who gave hopes of future eminence; and some of the noblest masters in the art had been the disciples of Ludovico. The advantages which they enjoyed in his academy were singularly attractive. The discrimination of Ludovico was not inferior to his other talents, and he directed the studies of his pupils to those departments of the art for which nature seemed peculiarly to have designed them. He had established at
a great expense, well-chosen models of men and women; and had collected at Rome a number of fine casts from the best figures, and some antique statues and curious baso-relievi. He took care to procure the most capital designs of the great masters; to purchase instructive books on all subjects relative to the art; and engaged the assistance of a very skilful anatomist, who taught the disciples whatever might be necessary to be known relative to the knitting of the bones, and the insertion of the muscles. His cousins, who were his pupils, were afterwards employed along with him in the management of this academy. The style of these great masters was nearly the same, varied only by the diversity of disposition and temper. Ludovico, with less fire and vigour than Agostino and Annibale, surpassed them in the more pleasing, though less commanding, qualities of grace, dignity, and sweetness. Mr Fuseli, who gives him the decided preference to both, has so well appreciated and described his manner, that we cannot forbear transcribing his own animated words. "Ludovico Caracci, far from subscribing to a master's dictates, or implicit imitation of former styles, was the sworn pupil of nature. To a modest but dignified design, to a simplicity eminently fitted for those subjects of religious gravity which his taste preferred, he joined that solemnity of hue, that sober twilight, that air of cloistered meditation, which has been so often recommended as the proper tone of historic colour. Too often content to raise the humbler graces of his subject, he seldom courted elegance, but always when he did, with enviable success. Even now, though they are nearly in a state of evanescence, the three nymphs in the garden scene of S. Michele in Bosco, seemed moulded by the hand, inspired by the breath of Love. This genial glory he communicates even to the open silvery tone of fresco. His masterpiece in oil is the altar-piece of St John the Baptist, formerly in the Cortos of Bologna, now in the Louvre, a work all painted by this solemn hue, whose lights seemed embrowned by a golden veil. But Ludovico sometimes indulged and succeeded in tones austere, unmixed, and hardy: such is the Flagellation of Christ in the same church, of which the tremendous depth of the flesh tints contrasts with the stern blue of the wide-expanded sky, and less conveys than dashes its terror on the astonished sense." CARACTACUS. See BRITAIN, p. 503.
CARALLUMA, a genus of plants of the class Pentandria, and order Digynia. See BOTANY, p. 180.

CARAMANIA, or CARAMANILI, as it is called by the Turks, is a province of Asiatic Turkey, which stretches along that part of the Mediterranean which lies to the north of the island of Cyprus, and extends a little to the west of Cape Volpe, near the Isle of Rhodes. This province formerly comprehended the ancient countries of Pamphylia, Lycia, Pisidia, Lycaonia, Isauria, Cilicia, part of Phrygia, Galatia, and Cappadocia. The part of the coast of Caramania, which once formed Pamphylia, is washed by very deep water, so that ships may approach very near it, without the risk of running aground. The coast is in general elevated and dry, and is broken by numerous intersections. The mountains behind the coast have a gloomy green appearance, and are covered with vast forests, which are either neglected or destroyed by the Turks. At the island of Castel Rosso, (the Rouge of Plinty), there is an excellent harbour open to navigators; but the depth of water within it is so great, that ships are under the necessity of anchoring in 60 or 80 fathoms. There is a fortified castle on the summit of the rock which forms this island. The part of the coast of Caramania, from Castel Rosso to the entrance of the Gulf of Macri, is not so high as the coast to the eastward, but it is equally perpendicular, and it consists of a white and arid rock, and is divided by large ravines. The admirable havens in the Gulf of Macri, are sufficient for containing large fleets: Four of the havens which are most retired, are frequented by a few vessels during the winter months, when the navigation of the Archipelago is dangerous. The crews were allowed to cut down the finest trees at no expence, and without any interruption from the inhabitants; and after rigging their vessels, they carried cargoes of wood to the ports where it brought the highest price. The immense variety of game and fish furnished them at the same time, with plenty of food, and with numerous sources of amusement.

"If the wind has ever so little strength," says Sonnini, "the sea is always very high in the strait formed by Caramania and the island of Rhodes. The waves rise there sometimes in a frightful manner; the currents, which, in a sea intersected by islands and projecting lands, vary and clash, are the cause of this extraordinary agitation, which is likewise increased by inconstant and irregular winds. Indeed, it frequently happens, that the wind is different in several parts of the same channel, and that, on one side, there reigns a flat calm, while, on the other, the winds blow with violence. Not only are the winds inconstant in these obstructed seas, but they are here felt by sudden and impetuous squalls, which are followed and preceded by dead calms; and these violent gusts are sometimes announced by infallible signs.

Above the high mountains, of which the coast of Caramania is for the most part formed, it is not uncommon, in clear weather, to see a very small black cloud, frequently no bigger in appearance than a bird. This globe of vapours is extremely agitated; at first very small, it spreads all on a sudden, contracts, appears, and disappears, at intervals, above the mountains, and changes its form every instant. How calm soever the atmosphere may be, a sudden and violent squall may be expected at the sight of these insulated clouds, which discharge the wind with so much rapidity and vehemence, that if a ship be not prepared for being overtaken by it, she runs a great risk of losing part of her sails, and even her masts and yards. On the 28th of October, we experienced one of these sudden squalls, after a calm which had kept the ship stationary abreast of Cape Crio, a large promontory of Caramania. During this calm, a numerous shoal of fishes, cleaving the water level with its surface, and even darting above it, passed close to us with great rapidity; and the agitation of these inhabitants of the depths of the sea, is always a certain presage of an approaching and violent agitation in the atmosphere and the waters. A small cloud, the precursor
of the storm, had made its appearance above the promontory; it expanded, and we were overtaken by a gale of wind, which compelled us to take in all our sails, and continue lying to during the whole night, tossed about by short and overgrown billows."

There are several lakes in Caramania which are well stored with fish, and furnish salt in abundance. A great deal of silk is also produced here. Atta'la, or Satila, situated upon a gulf of the same name, is the capital of the province. See Sonnini's Travels in Greece and Turkey, Eng. edit. 4to. 1801, p. 79—119; Chateaubriand's Travels in Greece, Palestine, &c. vol. ii. p. 227; and Fiers in Palestine and Caramania, from the original drawings of L. Mayer, with an Historical and Descriptive Account of the Country, &c. London, 1804. (x)

CARAPA. See Persoonia, Botany Index.

CARAVAN, from the Arabic Caravan, and the Persian kerwan, a trader, is the name given to a company of merchants or pilgrims, who travel through the deserts in a body, in order to be secure against the attacks of the Arabs and robbers with which they are infested.

In the articles Arabia, Asia, and Cairo, we have already given an account of some of the principal caravans of Asia; and we shall therefore confine our attention to present to those of the African continent.

A very extensive and lucrative commerce has from time immemorial been carried on between Timbuctoo, the great emporium of Central Africa, and the maritime states of Marocco, Tunis, Algiers, Tripoli, and Egypt, by means of akkabaahs, or accumulated caravans. These caravans consist of several hundred loaded camels, attended by the Arabs, who let them at a low rate to the merchants, and they generally cross the great desert of Sahara between the months of September and April inclusive. The line of their march is extremely irregular, as they are obliged to turn out of their direct route to fall in with the fertile and cultivated spots called Oases. * The caravans remain at each of these Oases about seven days; and after being supplied with water, and feeding and refreshing the camels, they proceed to another spot of the same kind.

Upon the arrival of the caravans at Akka, situated in Lower Suse, on the confines of the desert, the guides and camels are discharged, and others are hired to proceed to Fas, Marocco, Terodant, Tafilelt, and other places. Including the sojournings at the Oases, the caravans traverse the desert in about 130 days. Setting out from the city of Fas, and travelling 7 hours a day, at the rate of 3½ miles an hour, they arrive at Wedinoon, Tatta or Akka, in 18 days, where they remain. It is from the latter place that the grand accumulated caravan proceeds. Sixteen days are spent in the journey from Akka to Tagassa, and after remaining fifteen days to replenish their camels, they proceed to the Oasis and Well of Taudeny, which they reach in seven days. Here they stay 15 days, and in seven days they make the watering place called Arawan. After a stay of 15 days, they reach Timbuctoo on the sixth day. The time employed in this journey is therefore 129 days. 75 being spent in rest, and 54 in actual travelling. On some occasions this journey is completed in the short period of 82 days.

Another caravan sets off from Wedinoon and Sok Assa, and crossing the desert between the black mountains of Cape Bojador and Gualta, touches at West Tagossa, and after remaining there for some time to collect salt, it proceeds to Timbuctoo. This caravan employs five or six months in its journey, as it goes as far as the White Mountains near Cape Blanco, through the desert of Mogrifa Woled Abussebah, to a place called Agadeer, where it remains twenty days.

"The akkabaahs which cross the desert," says Mr. Jackson, "may be compared to our fleets of merchant vessels under convoy; the stata, or convoy of the desert, being two or more Arabs, belonging to the tribe through whose territory the caravan passes; thus in passing the territory of WolebAbussebath, they are accompanied by two Sebayees, a people of that country, who, on reaching the confines of the territory of Woleb Duleim, receive a remuneration, and return, delivering them to the protection of two chiefs of Woleb Duleim; these again conducting them to the confines of the territory of the Mogrifa Arabs, to whose care they deliver you, and so on, till they reach Timbuctoo. Any assault made against the akkabaah during this journey, is considered as an insult to the whole clan to which the (stata) convoy belongs, and for which they never fail to take ample revenge."

"Besides these grand accumulated caravans, there are others which cross the desert on any emergency, without a stata, or guard of soldiers; but this is a perilous expedition, and they are too often plundered near the northern confines of the desert, by two notorious tribes called Dikna and Emjot. In the year 1798, an akkabaah consisting of two thousand camels loaded with Soudanie produce, together with 700 slaves, was plundered and dispersed, and many were killed. These desperate attacks are conducted in the following manner: A whole clan picket their horses at the entrance of their tents, and send out scouts to give notice when an akkabaah is likely to pass; these being mounted on the heiree, or shrubba er'reeh, quickly communicate the intelligence, and the whole clan mount their horses, taking with them a sufficient number of (niag) female camels, to supply them with food, (they living altogether on the milk of that animal;) they place themselves somewhere in ambush near an Oasis, or watering place, from whence they issue on the arrival of the akkabaah, which they plunder of every thing, leaving the unfortunate merchants entirely destitute."

The manners and customs of the merchants, during these long and dangerous journeys, are extremely simple and natural. Prohibited by their religion from the use of intoxicating liquors, their only
CARAVAN.

438

nourishment consists of a few dates and a draft of water, and when their journey is but a few weeks, a little barley meal and cold water is their only food. Animated by the hopes of reaching their native country, they often sing during their journey, and when the camels are fatigued, or when they approach a habitation, their songs are sung in trio, all the camel drivers joining in the chorus. The camels march in time to the music, and seem for a while to forget their fatigue. The day's journey is generally terminated about four o'clock, and after pitching their tents, and saying their prayers, they prepare their supper; as soon as it is ready, they seat themselves round in a circle, and talk till they are overcome by sleep. At break of day they again proceed upon their journey.

In the course of these journeys, the hot winds called shumé are very seldom violent as to evaporate all the water carried in skins for the use of the passengers and drivers; and Mr. Jackson was informed by the Arabs and the people of Soudan, that on these occasions, 500 dollars have been given for a draft of water, and that 10 or 20 dollars are very frequently given when a partial evaporation has taken place. A caravan proceeding from Timbuctoo to Tafilet in the year 1805, was disappointed at not finding water at one of the Oasis, and the whole party, consisting of 2000 men and 1800 camels, perished of thirst.

The dangers arising from the drifting of the sand, are often very considerable. When the loose sand is drifted along the plains by the shume, the akkábahs are obliged suddenly to strike their tents, otherwise they would be all buried in the overwhelming torrent. On these occasions the desert has the appearance of a sea, as the drifting sand has a striking resemblance to the waves of the ocean. Hence the desert is emphatically called by the Arabs a sea without water.

The merchandise which is carried by these caravans are German linens, viz. plattilias, rouans, bréthannias, muslins of different qualities, particularly muls, Irish linens, cambrics, fine cloths of different colours, coral and amber beads, brass nails, pearls, raw silk from Bengal, coffee, bysson teas, refined sugar, and various manufactures of Fas and Tafilet, namely shawls and sashes of silk and gold, hayks + of silk, of cotton and silk mixed, and of cotton and wool, and Tafilet hayks. To these may be added woollen caps, which is the general covering for the head, turbans, Italian silks, cloves, nutmegs, ginger and pepper, cowries, Venetian beads, and a great quantity of tobacco and salt, which is the produce of Barbary and Bled-ejerrede.

The articles which the caravans receive in exchange for these goods, are chiefly the produce of Soudan. They consist principally of gold dust, twisted gold rings of Wangara, open at the extremity for the insertion into the cartilage of the nose; gold rings made at Jinnie; bars of gold, elephants teeth, gum of Soudan, grains of Sahara (or grains of paradise); odoriferous gums, called el B'hor's Soudan, employed for fumigation, and supposed to possess many virtues; and a great number of slaves from the slave-mongers of Wangara and Houssa, who bring them from the regions which border on the Mountains of the Moon. The Wangareen slaves are a gross stupid people, scarcely above the level of the brute creation; while those from Houssa are acute, industrious, and intelligent, and have an open and noble countenance. The latter are therefore sold at a much higher price. The average price of a slave is about one hundred ducats (8s. 6d. sterling each); but Mr. Jackson once saw a young girl of Houssa, of exquisite beauty, sold at Marocco for 400 ducats. Ambergria and ostrich feathers, collected on the confines of the desert, are added to the merchandise already mentioned. Mr. Jackson, to whom we are indebted for the preceding information, has given a map shewing the track across the desert, as followed by the caravans from Fas to Timbuctoo.

Besides these caravans, there are three which are employed in carrying slaves and other commodities from the interior of Africa to Cairo. The first of these sets out from Mborouk, the capital of Fezzan, the second from Sennaar, and the third from Fur. The caravan from Mborouk consists of between 100 and 300 travellers from the empires of Bornou and Cashina, from the kingdom of Caffaba, and from several of the negro states. It sets out almost every year in the end of October, or in the beginning of November, and generally finishes the journey in about 52 days. The following is a Table of its route to Cairo:

<table>
<thead>
<tr>
<th>Days</th>
<th>Events</th>
</tr>
</thead>
<tbody>
<tr>
<td>7th</td>
<td>Reach Temissa.</td>
</tr>
<tr>
<td>9th</td>
<td>Arrive at the lofty rock of Xanibba, where they get a supply of water.</td>

* At 20 leagues from land, in West Long. 11° 50', and North Lat. 50', Mr. Jackson collected from the deck of the ship a wine glass full of the sand carried by these violent winds.

+ A light and durable piece of cloth, about fourteen feet long and six feet wide. It is used as an outer garment by the northern Africans of that place. The Tafilet hayks are a light manufacture, well fitted for the climate of Soudan.

‡ The natives of Jinnie seem to excel Europeans in working gold. Mr. Jackson informs us, that he has seen trinkets, particularly the figure of an eagle, of such workmanship that it would have been difficult to imitate them either in England or France.

Caravan,

Caravan-
sery.

Days.

47th, Arrive at the convent of monks on the hill of Huaddy l'Ottôn.

52d, Reach Cairo.

The caravans from Sennaar and Dar Fûr are very irregular in their motions, arising from the revolutions which are constantly taking place in their unsettled governments. Sometimes two or three years elapse without any of them arriving at Cairo. The number of independent Arabs who infest the roads between these two places and Cairo is very great, and contribute to the irregularity of these caravans.

One of the finest descriptive pictures of the manners of a caravan that was perhaps ever drawn, without the aid of a pencil, is given by Chateaubriand, in his Travels into Greece and Palestine. "It was midnight, says he, when we arrived at the Kan of Me-nemen. I perceived at a distance a great number of scattered lights; it was a caravan making a halt. On a nearer approach, I distinguished camels, some lying, others standing; some with their loads, others relieved from their burdens. Horses and asses without bridles, were eating barley out of leather buckets; some of the men were still on horseback, and the women, veiled, had not alighted from their dromedaries. Turkish merchants were seated cross-legged on carpets, in groups round the fires, at which the slaves were busily employed in dressing pelts. Other travellers were smoking their pipes at the door of the kan, chewing opium, and listening to stories. Here were people burning coffee in iron pots; there hucksters went about from fire to fire, offering cakes, fruits, and poultry, for sale. Singers were amusing the crowd; imans were performing their ablutions, prostrating themselves, rising again, and invoking the prophet; and the camel-drivers lay snoring on the ground. The place was strewn with packages, bags of cotton, and coffs of rice. All these objects are distinct, now confused and enveloped in a half shade, exhibited a genuine scene of the Arabian Nights." See Chateaubriand's Travels in Greece, Palestine, Egypt, and Barbary, vol. i. p. 303, 304; Volney's Voyage en Syrie et en Egypte, vol. ii.; Russell's History of Aleppo; Pococke's Description of Egypt, vol. i. pp. 185-261; Maillet Description de l'Egypte, Paris, 1740; Rennel, Phil. Trans. vol. lxxx. p. 120; Jackson's Account of Marocco, p. 237; and Browne's Travels in Africa, chap. 18. See also the articles ARABIA, p. 257; ASIA, p. 551; BARBARY, p. 273; and CAIRO, p. 218, 219. (s)

CARAVANSELLA, or CARAVANSERAY, the name given in the East to the large inns or public buildings, for accommodating the merchants, pilgrims, and travellers, that accompany the caravans.

The caravanseras have generally been confounded with the khans; but the former, particularly about the time of their origin, were erected under the impulse of religious duty, in desert places, at a distance from large towns, to afford shelter and accommodation to travellers and caravans; while the khans which were generally built in towns, were used by foreign merchants, not only as a lodging-house, but as a magazine for their goods. The word caravansera, however, is the general name adopted in Asia for all these kinds of buildings. It is used not only in Turkey, but also in Persia and the Mogul country, while the word khan is more particularly used in Turkey.

But while the charity and hospitality of the Eastern princes have thus provided accommodation to travellers in those desert regions, where it is most required, they have limited their generosity to a mere shelter from the inclemency of the weather, and to a supply of water, which is often brought from a great distance. Neither beds, kitchen, nor provisions, are attached to these buildings; and the traveller must either carry along with him every thing that he wants, or purchase them after his arrival. The caravanseras, as well as the khans, are generally huge square buildings, being one or two stories high above the ground-floor. The interior façades, which form the spacious court or hall in the middle, resemble the cloisters of convents. The magazines are in the ground-floors, while the chambers for travellers are in the upper stories. A reservoir of water, in which the camels and other beasts of burden quench their thirst, is placed in the middle of the court.

In the city of Fas, in Marocco, there are no fewer than two hundred caravanseras, called Fondaques. These edifices are three stories high, and contain from 50 to 100 apartments, in each of which a supply of water, for ablution and other purposes, is conveyed by means of a water-cock. The traveller must carry bedding along with him, as they are provided only with a mat; and if he wants any refreshments, he must order them from a cook's shop, or buy them from a butcher, and dress them himself. A certain sum per day is paid for the use of the apartment.

The caravanseras of Constantinople, Isphahan, and Agra, are celebrated for their magnificence and accommodation. Those of Sheeraz and Casbin are said to have cost 60,000 crowns each; and that of Vrana or Urana, in Dalmatia, which is now in ruins, had a façade 150 feet long. It was built entirely of fine marble, with a compact grain, and susceptible of the finest polish; and the Abbé Fortis supposed that those blocks of marble had been taken from some Roman building. (w)

The permission to build a caravansera, has always been considered in Turkey as a mark of distinction. At one time, however, this privilege was bestowed only upon the mothers and sisters of the sultans, and upon the viziers and other nobles who had gained three victories over the Christians. For an account of several of the caravanseras in Persia, see Morier's Journey through Persia, Armenia, and Asia Minor, p. 81, 153, 154, 279; and Jackson's Account of Marocco, p. 131, and 256. (w)

CARBONIC ACID. See CHEMISTRY.

CARBURET. See CHEMISTRY.

CARCASS, is the name of a hollow body, containing combustible matter, and thrown from mor-
tars for the purpose of setting fire to houses. The case is sometimes made of ribs of iron, covered with pitched cloth, &c. and is sometimes an iron shell, with three or four openings, through which the fire issues. Carcasses are said to have been first used at the siege of Groll, in 1672, by the Bishop of Munster.

The following Table contains the result of a series of experiments, made with round case carcasses at an elevation of 45°.

CARCASSONE, anciently CARCASO, the capital of the department of the Aude, is situated upon the canal of Languedoc, and also upon the river Aude, which divides the town into two parts, called the Upper and the Lower Town, both of which are surrounded with a wall. The upper town, which is situated upon an eminence, is called the City; and, beside the cathedral, contains a castle, which is very strong, and commands the whole town. In this castle are kept the ancient records, which are written upon the bark of trees. The lower town, which is almost square, consists of streets intersecting each other at right angles, and leading to a large square in the centre, which is ornamented with a fountain of rockwork, surmounted by a figure of Neptune. The quays, which are adorned with rows of trees, form agreeable promenades.

From Carcassone, strangers generally go to Barbeyrac, on the road to Trebes, to see the Languedoc canal pass over an aqueduct bridge across the river Orbe.

In this town, the manufacture of drabs of all kinds is carried on to a very considerable extent. They are made of the wool of Beziers, Narbonne, and Spain, and are sold at Lyons, Bourdeaux, Thou- louse, and other towns of France. The quantity which is annually sent off amounts to about 16,000 pieces. The inhabitants of the town and the adjacent country are employed in carding, spinning, and preparing the wool; and such is the industry of the people, that a beggar is not to be seen in the country. The inhabitants of the six villages which compose the district of Grissescac, some leagues from Carcassone, are employed in fabricating copper goods. Population 15,500. E. Long. 2° 5', N. Lat. 43° 11'. See Histoire de Carcassonne, par Pere Bouges.
CARDS.

Cards, in the manufactures of cotton and wool, are instruments used for preparing the fibres of those substances for spinning them into thread; by straightening the fibres, and rendering them parallel to each other, so that each may have its full bearing and proper tension, when a number are twisted together to form a thread.

The card is a kind of brush made with wires instead of hair, stuck through a sheet of leather, the wires not being perpendicular to the plane of the leather, but all inclining one way at a certain angle.

From this description, such as are totally unacquainted with the subject may conceive, that cotton, being stuck upon one of these cards, or brushes, may be scraped with another card, in such a direction, that the inclination of the wire may tend to throw the cotton inwards, rather than suffer it to come out. The consequence of the repeated strokes of the empty card against the full one, must be a distribution of the cotton more evenly on the surface; and if one be then drawn in the opposite direction across the other, it will, by virtue of the inclination of its wires, take the whole of the cotton from that card whose inclination is in the contrary direction.

In this way the operation of carding was formerly performed by the hand, with sheets of card nailed upon thin boards, which were drawn and scraped against each other till the cotton or wool was evenly diffused over the surface, and freed from all the knotty or entangled parts. One of the cards being then turned, and applied in an inclined position, so as to scrape with one edge over the surface of the other card, in the direction of its teeth; the cotton was, by a particular manœuvre, stripped off, and coiled up into those short soft rolls, which were called Cardings, and were afterwards extended and twisted by the spinning wheel.

Such, in all probability, was the process employed, with little alteration, during the five last centuries, in the woollen manufacture of this kingdom, and applied, at subsequent periods, to the preparation of cotton. The use of cards was most likely derived from the Netherlands, at or before the time that our woollen manufactures were improved by the emigration of Flemish weavers to this country during the reign of Edward III.

Cards continued to be imported till the year 1468, when the tradesmen and manufacturers of London, and other parts of England, having made heavy complaints to parliament, of the obstruction to their own employment by the introduction of various foreign manufactured wares, an act was passed in the third year of Edward IV, prohibiting wool cards, among various other articles of iron, steel, copper, &c. from being imported into this kingdom.

The hand cards were succeeded by stock cards, and these again by cylinder cards, which were brought into extensive use by Sir Richard Arkwright in 1771, (See Cotton Manufacture.) Since this period, the consumption of cards for cotton mills has been immense. A very small carding machine will contain upwards of 150,000 card wires of the coarsest kind; and we have visited an establishment of cotton mills, where 150 of such carding machines were in constant work. Thirty or more machines are a very common number to find in one mill; and these are so numerous, as to make a very extensive trade in card manufacture.

Wool cards are of a coarser and stronger kind than those used for cotton, but are applied in the same manner, either on boards, for hand carding, or covered on cylinders for carding machines, as explained under the articles Cotton Manufacture and Woolen Manufacture. The card wires are the same for either of these purposes, except in size. The wire is bent into a staple, in the manner shewn at Fig. 1 of Plate CXI. and the legs of this staple are crip-

plied, or bent, in a second direction, as shewn by the figure Y, which shews a card wire ready for fixing the leather by, the two legs being stuck through two holes in the sheet of leather. This fastens the teeth firmly in their places; and then the bend in the legs, which is called the knee bend, gives the teeth their proper angle of inclination, as is shewn in the section of a sheet of cards at Z, Fig. 1. X is a view of the back of the leather, shewing the arrangement of the wires; which is such, that the adjacent wires do not fall behind each other, but, by filling up the intermediate spaces between each, renders the cards finer, the teeth being equally dispersed over the surface of the leather.

The cards used in the hand are called sheet cards; and the direction of the wire joining the two legs is parallel to the length of the sheet. Sheet cards of a greater length are also used for the top cards, or luga of the carding machine, and also for the great cylinders. Another kind are called fillet cards, being strips, or fillets of leather, and the wire stuck across them. It is this kind of fillet which is shewn at X, Fig. 1. It is only used in the machine cards, when the fillet is wrapped spirally round the small cylinders to cover all its surface.

The immense number of cards required in the cotton mills, causes the manufacture of cards to be very extensive; and several very curious machines have been invented for facilitating the processes, though they have not yet come into general use. In the present state of the trade, the principal seats of which are the countries about Glasgow and Leeds, the processes are divided into the preparation of the wires and the leather. The latter is pierced by machinery at the house of the manufacturer, who sends it out to the cottagers, together with the wire, which they cut and bend by three operations, (one performed by a machine); and the women and children insert them into the holes of the leather. The three operations of making the wires, are, 1st, Cutting to length, 40 or 50 being cut together; 2d, Doubling, which gives 3 k
them the form at y, Fig. 1.; and, 9d, Giving the
to bend Y, which is done by a little machine placed
close to the labourer's seat. We shall describe
these operations in order, as they follow each other.

Cutting. The workman clips off the wires from a coil,
or skine, making 30 or 40 turns; so that this num-
ber of wires are cut off at once by a pair of strong
shears fixed at the edge of the work bench, and mo-
ved by pressing the foot upon a treads. A weight
over a pulley is the re-action for opening them when the
pressure is relieved. By this means the workman has
both hands at liberty: in one he holds the end of the
skine, or bundle of wires, and applies the ends to a
gauge, which has an adjustable stop, to determine
the length of wire to be cut off from the end, when
the end of the gauge is held in contact with the
blade of the shears, and one treads cuts them off. By
this means 30 or 40 wires are cut at every stroke to
the intended length, for which the stop of the gauge
is previously adjusted.

Doubling or bending the wires, to the form of a
staple. The wires are held in a tool adapted to the
purpose, called a doubler, and bent by the pressure
of another tool, called the bender, which is formed like
a small reaping hook, but without any edge. The
doubler is a wooden handle, having a steel gauge
fixed in the end of it, to the stop of which the ends
of the pieces of wire are applied, and doubled into
the form of a staple, over a small flat bar of steel
(bridge) fixed in the doubler, perpendicular to the
length of the wire; and by means of the stop of the
gauge, the proper part of the wire is presented to
the bridge, so that the two ends or legs of the staple,
when formed, shall be exactly of the same length: The
bridge is, of course, the same breadth as the distance
between the two legs and points of the staple, which
is formed by bending or doubling the wire over it.
The workman, having adjusted the wires in the
doubler, presses the bender (held in the other hand)
against them; and thus, by one operation, bends
them to the form of the letter L, over one angle of
the bridge, and by repeating it over the other an-
gle doubles them, forming 30 or 40 staples together
very quickly.

Bending. The workman now removes the wires
from the bridge of the doubler by a small steel knife, or
spatula, introducing its point under the shank, and be-
tween the legs of all the staples at once, and thus lifts
them off from the bridge over which they were dou-
bled, and conveys them suspended on the blade of this
knife to a very curious little machine, which gives
them the knee bend. The workman hangs the stap-
les upon a small brass bar, or ruler, fixed in the
machine, and then withdrawing his knife leaves them,
and prepares to double another packet of wires. The
machine has an axis extending its whole length,
which is about eight inches: and this is turned with
a regular and equable motion, by the same wheel-
work as the common roasting jack; and the work-
man, from time to time, winds up the handle, to keep
it always in motion. The axis has ten small levers, or
claw, upon it, at different parts of its length; and
opposite to each is one of the rulers, with staples on
it always ready to be bent. Each claw does one at
once. The rulers being placed rather inclined, the
stakes always have a tendency to run down towards
the axis, but are prevented from falling off the end
of it by a knob or projection on the top of the ruler.

Over this knob one staple is lifted at every revolu-
tion of the axis, by a small detent, called the kicker,
which lies concealed in a groove in the upper surface
of the ruler, like a knife blade in its handle; but is
lifted up at every revolution of the axis, and then
raises one staple over the stop, and it slips down an
inclined plane, or continuation of the ruler, towards
the axis. At the bottom of this inclined ruler is a
sort of die, or recess, into which the legs of the wire
staple fall; and then the claw, or lever, upon the
axis coming past, gives the knee bend to the wire,
by forcing its point while it is held in the dies, and
bending it over a proper rest. The instant the claw
has passed by, the spring of the wire causes it to
leap out of its die, and make way for another, which
is kicked down at the next revolution. Thus every
turn of the spindle crooks ten staples; and the work-
man keeps it constantly supplied, so as to bend an
immense number per day. This machine is said to
have been invented about 1775, by a Quaker, whose
name we have forgotten.

This is the process of forming card wires, as at
present practised; but some more complete machines
have been invented by ingenious mechanics: One is
in use in the neighbourhood of Halifax, in York-
shire; and another, similar in its properties, is pre-
served in the repository of the Society for the En-
couragement of Arts, &c., London. It was invented
by Mr Joseph Beard of Cogeshall, in Essex, who
received a reward from the Society of a silver medal
and 40 guineas for it, in 1805. This machine dis-
splays so much ingenuity, that we requested and ob-
tained permission of the Society to have a drawing
made of it, which is given in Plate CXI. It has
not been published in the volumes of their Transac-
tions. The machine is double, having parts to make
two complete card wires at once. It receives two
wires at once, from two reels, on each of which a coil
of wire is placed. The wires pass between a pair of
rollers, by which they are drawn into the machine,
which cuts off a proper length from the ends, and
bends the pieces into the proper form, then drops them
into a drawer beneath, and proceeds with two others.
Our draughtsman has found it necessary, for simplic-
ty, to exhibit only one of the halves of the ma-
chine, which is by itself a complete machine; and in
this division some alterations were necessarily made
in the form of some few of the parts, which were in the
original common to both halves. This drawing is not,
therefore, to be considered as an exact representa-
tion of the machine in the Society's possession, though it
contains all the essential parts and movements. AA.
Fig. 2, is a main axis, which puts all the parts in
motion. It has a fly-wheel C fixed on the end of
it, and is turned round by a handle B; or it might
receive its motion from any machinery, by an endless
band, or strap and pulley, as it does not require any
attendance.

The wire a a is conducted from the reel before
mentioned to the machine, and first passes over a
rest or frame, b, which has a notch in each of its
sides to receive the wire, and to keep it down in

---

**Plate CXI.**

**Fig. 2.**

**Description of it.**

**Plate CXII.**

**Fig. 2.**
PLATE CXII.

The wire next passes through a guide, formed by a hole in a piece of iron $d$, fixed by screws to a vertical standard $G$, rising from the iron frame $F$, on which the whole mechanism is erected. By the guide $d$ the wire is presented to a pair of rollers or wheels $D$, by which it is drawn forwards. These rollers are exactly of the same size, and, being beneath each other, only one can be seen in the figure. The lower roller, which is hidden, is fixed upon an axis, which extends across the frame, its ends being supported by the joints of the centre screws $20, 20$. The axis is turned round by means of a toothed wheel $7$ upon the main axis, and acting in another exactly similar to it, fixed immediately beneath upon the axis of the lower roller, which is perpendicular to the main axis; but the teeth of the wheels being both inclined at an angle of $45^\circ$ to their respective axes, become parallel at the points of contact, and the wheels turn each other round, by a similar action, to the endless screw; from which, however, this mode of communication differs most materially, in the circumstance of the two wheels, or screws, (for they partake of the nature of both) being of equal dimensions and similar forms. This communication causes the lower roller to make a revolution for every one of the main axis. At the opposite end of the axis of the lower roller, a cog wheel is fixed, and operates upon another $E$ of exactly similar dimensions, and placed over it, so as to conceal the former. This wheel is fixed upon the axis (shewn by dotted lines) of the upper roller $D$, which is mounted upon the points of the centre screws, held in a frame marked $II$. This frame is attached to a standard $G$ of the frame by two centre screws, so that it will rise on the points of these as an axis, and thus permit the upper roller to rise and fall, to accommodate itself to the wire, and press it so fast upon the lower roller as to draw it forwards. The pressure is occasioned by a strong spring $K$ fixed on the frame $I$, and its end hooked beneath a projecting part (not shewn) of the standard $G$. The rollers $D$ deliver the wire into a steel tube, $ef$, (see also Fig. 3, where it is shewn separately,) the hole through which being but just large enough to admit the wire, strengthens it in the manner of dies, and, together with the rollers, completely takes out any crooks in the wire. The tube, (or pair of dies,) $ef$, is made in two halves, which are held together by the same clamp screw, which fastens them into the bracket $L$ that supports them. The end $f$ of the steel dies, which is enlarged, as shewn in Fig. 3, and has a smooth flat face, is the point where the wire is cut off, by means of a small knife $g$, fixed into an axis $M$, on which is a lever $5$, actuated at the proper interval by the lever or claw $4$, on the main axis $A$, into which it is screwed; and can therefore be readily adjusted in length, to operate more or less upon the lever $5$, by which it cuts off the wire at the point, where it emerges from the end $f$ of the dies $ef$. The length of wire which is advanced through the dies, before it is cut off, is measured by the end of the wire coming up to the flat head of a screw $10$, supported by a bracket $L$; but the instant the wire reaches this, the upper roller $D$ is lifted up, so as to relieve the pressure upon the wire. This is done by a cam $1$, which has a part of the frame $I$ projecting over it, and at the end of it is a tooth or knob, fastened by the square nut. This tooth is lifted by the cam $1$, which is a circle, having a deep notch cut in it, and thus relieves the wire when the circular part of the cam comes beneath it; and though the motion of the rollers continue, the wire remains stationary, but in turning the notch presents itself beneath the tooth of $I$. The spring $k$ now presses the upper roller upon the wire, which is then pushed forwards until the proper measure is advanced, when the upper roller will be again lifted up by the cam, as before mentioned. This movement is, therefore, devoted to measuring the wire; the rollers and dies $e$ to straightening it; and the shears, or cutter $g$, to cutting it off into the lengths measured by the other. We have now to explain the mechanism for doubling and bending. These parts are in the drawing shewn of their real size, to render them distinct, though all the other parts are only one half the full size. The wire, when advanced by the rollers, is introduced between two pieces of metal $q$ and $r$, s. These are shewn in all the figures. In Figs. 2 and 3, they are only represented by small squares; but Figs. 4 and 5, shew them to be the ends of levers $q$ and $r$, moveable on one common axis, but independent of each other. They are called the back and front blades of the pliers; their axis of motion is parallel to the main axis $A$; and is suspended between the points of centre screws, supported by the standards $G$. This forms the axis of the lever $r$, as shewn in Fig. 4, which only represents the moving parts. The axis of the lever $q$, marked 15, 15, swings between the points of centre screws attached to a part of the lever $r$, but exactly in a line with the two fixed centre screws on which $r$ itself moves. Thus both blades of the pliers move on the same central line, but independently; they have therefore a motion directly to and from the main axis, but no other. The two levers $q$ and $r$, have a small spring 19 (Figs. 4 and 5) between them, which always tends to separate them and open the pliers. The axis 15 of $q$ has a short tail or lever 18 rising from it, which stops against the point of an adjusting screw 16, (Fig. 5,) and determines the quantity of approach which the end of the blade $q$ (Figs. 2, 3, and 5,) shall make towards the main axis 17; is a spring of a semicircular form, always drawing the tail 18 towards the screw 16; and consequently urging the blade $q$ towards the main axis; the spring 19, also urges the front blade $r$, (Figs. 2, 3, and 5,) towards the axis, till the arm 11 screwed to it, rests upon the outside of the axis.—A cam 9 is fixed on the axis at this part; and when it comes round, acts upon 11, and by it forces the blade $r$, away from the main axis, till it comes in contact with the wire $a$, (Figs. 2 and 4, and shewn in Fig. 5 by a small black dot surrounded by a white circle,) and presses it against the blade $g$; thus holding it in the manner of a pair of pliers, or a finger and thumb, while the shears cut it off. All this time the blade $g$ may be considered as stationary; the spring 17, (Fig. 5,) which opposes its retreat from the main axis, being
so much stronger than 19, which opens the pliers; but as the cam 9 turns farther round, it continues to press upon 11, and the front blade with it, against the wire, and by this against the other blade q, so as to force the pliers back altogether on their common axis of motion, into the position Fig. 3.

Now the two ends of the wire being supported by the ends of two levers h and k, whilst the middle of it is thrust back by the pliers, doubles it, or gives it the form of a staple. The levers h and k, which are called the side benders, must be explained before this can be clearly comprehended. They have each a motion on their respective centre pins, or axis, 21, 22, fixed in a plate, screwed upon the framing F. These two levers have arms approaching each other, in a direct line from one centre to the other; and where they meet have a tooth i on the lever k, entering a notch in h, and operating in the manner of a cog, to cause any angular motion which is given to one lever to be communicated equally to the other. This causes the ends of h and k, where they operate upon the wire, to mutually advance and recede from each other, by equal quantities. The motion is given to the benders by a lever k', which is part of k, but has no connection with h, though it passes over it. To the end of k' a rod l is jointed, which passes over the axis, and has a stud, or tooth, fastened by the square nut, which is operated on by a cam upon the main axis, and, at the proper interval, draws k and k', and thus opens the benders k and h in the manner shewn in Fig. 2. When this cam passes by, the benders shut or approach each other by the force of a spring p. This operates on a lever m, which has a pin q rising from it, and pressing back a tooth of the lever k, giving them a tendency to shut. This they do the instant the cam has relieved the lever k', which remains till it rests against a screw r, determining the nearest distance they can approach to each other, as in Fig. 3, and the regulation of the cam, or the tooth of the wheel 4, which it acts upon, (by means of its square nut,) determines the greatest opening they can have, as in Figs. 2 and 4. The ends of the levers k and k', where they act upon the wire, have notches in them, through which the wire passes in the first instance before doubling. This is shewn in Figs. 2, 4, and 5: t and s are small plates of steel, screwed at the two sides of the front blade r of the pliers forming its faces; over these the wire is doubled by being thrust in between the side benders, which now close together, as shewn in Fig. 3, and also in Fig. 7. In this state, the two legs of the wire being doubled, (in the form of y Fig. 1,) pass, just beneath two shoulders, formed upon the steel blade s, Fig. 4, in the manner explained in Fig. 7. These shoulders will, of course, prevent the legs of the wires from rising, and they are bent into the state of y, (Fig. 1.) by a lever 8, fixed in the main axis, which passes by at the proper time, and raises the points a a (Fig. 3 and 7.) so high as to give them the proper quantity of the knee bend. This forms the wire, and when the cams pass by, the pliers and side benders open into the position of Fig. 2, when the card wire drops into a box beneath.

Considering the position of Fig. 3, as the point of commencement, we shall recapitulate the movements of this ingenious machine, to render its operations distinct, and shew the periods of the different parts of the process.

On turning the main axis in such a direction that the handle B (Fig. 2,) descends, the cams act in the following succession:

1. The notch of the cam 1 suffers the roller D to Describing the wire upon the wire, and thus holding it fast between the upper and lower rollers; which as they turn round,

2. Advance the end of the wire a a through the Measuring die f, before the notches in the end of the side benders h and k, and between the pliers q and l, r, s, until the end of it touches the screw 10. At this instant,

3. The cam lifts up the upper roller D, and the friction on the sides of the frame b prevents its further advance. This is the state in which Figs. 2, 4, and 5, represent the machines.

4. The cam 9 presses on 11, and forces the blade Holding r back, till the side t meets the wire; and removing it backwards, holds it fast against the front of q, and pinches the wire tight between the two jaws of the pliers; whilst,

5. The cam 4 depresses the lever 5, and by the Cutting cutter g, cuts off the wire instantly; leaving it held by its middle, between the pliers.

6. The cam 9, continuing its motion, drives back both parts of the pliers together, and the wire with them; its ends being supported by the ends of the side benders, it assumes the bend of the dotted lines in Fig. 2, (though the pliers are not there represented as thrown back).

7. A notch in the cam of the rod l now presents And by itself, and suffers the spring p to close the side benders h and k together, as shewn in Figs. 3 and 7, which completes the doubling into the form of y, Fig. 1.

8. The lever 8 rising, lifts the ends of the wire, Knee bend and the legs being kept down by the shoulder of s, gives the knee bend. The manner of this is shewn by the dotted lines in Fig. 3, though neither the pliers or lever 8 are there in the proper situation to effect this part of the process.

9. All the cams except one relieve their respective movements at once, and the finished wire drops out of the pliers. Thus the cam 4 has, in the interim of the other operations, passed by and suffered the blade q to return by the action of its spiral spring 6; the cam of the rod l, and lever k', opens the side benders; the cam 9 passes by, and permits the return of the pliers, by the spring 17, (Fig. 5,) but when the tail 18, of the blade q, meets its stop screw 16, q returns no farther, but the front blade r continues to advance towards the axis, by its spring 19, as fast as the cam 9 suffers it. This opens the pliers, and the wire falls out.

The notch of the cam 1 now comes round, and suffers the roller D to descend on the wire, and advance another portion, which is treated in the same manner as the first. These operations succeed each other with such rapidity, when the machine is in action, that the handle may be turned at the rate of 150 times per minute, without in the least injuring its operation; and the power required to turn it is so
small, that one person might turn a dozen, or if they were turned by a mill he could attend a greater number, as they very seldom do wrong, or make a false wire.

The machine is capable of making wires of any size, by the following adjustments:

1. The length of the notch in the cam 1, regulates the length of the wire which shall be cut off, because it is only as long as this notch is presented to the lifting tooth of the frame 1, that the rollers act upon the wire. The screw 10 is adjusted to stop the wire when sufficiently advanced; but this is only a precaution, to prevent any accidental protrusion after the cam 1 has lifted the upper roller. The cam 1, as before stated, is a circle; and to have the means of adjusting the length of the notch in it, the cam is made of two equal circles, or wheels, fitted on the main axis, and applied to each other, side by side, so as to make one. The back of the frame 1, which rests upon their circumference, is as broad as both circles together. Each has a notch cut in it much wider than the notch in the cam is ever intended to be.

Now if these circles were twisted round on the axis, so that the notch in one circle is applied opposite to the complete part of the other, the cam would act as a complete circle, and the tooth of 1 would never drop into the notch of either, because the circumference of the other circle holds it up at the time. On the other hand, by placing the two notches opposite to each other, the rollers would be suffered to act upon the wire longer than is ever intended. Therefore between these two extremes, the limits of the notch may always be determined by trial, that the proper length of wire shall be protruded, one circle making the beginning, and the other the end of the notch in the cam. Both are fastened on the axis by clamp screws.

2. The centre screws, on which the whole of the pliers r r (Fig. 4,) are suspended, admit of adjusting them, so that their blades shall seize the wire by the middle, and make the ends of the staple equal when doubled.

3. The steel faces t and s, of the blade r of the pliers, can be removed, and any other substituted. This regulates the distance between the legs and points of the card wire, or the length of its shank.

4. The screw m determines the degree of closure of the side benders shall have, and the square nut on the rod h, (which attaches to it the piece on which the cam operates,) determines the distance to which they will open. This is of consequence, for the wire, if bent too sharply at once into the dotted position, (Fig. 4) might be cut or broken, instead of bent fairly.

5. The screw which fixes the lever 8 into the main axis, admits the lever to be set farther out, and then it will give a greater degree of knee bend, or if nearer the axis will bend less. This is also influenced by the quantity of motion the cam 9 gives to the pliers, which can be adjusted by sliding the curved piece 11 up or down the lever r, for which purpose its screws are fitted in grooves. This causes a more or less protuberant part of the curve 11, to meet the cam g. The screw 16, as before stated, adjusts the blade g of the pliers.

The wires being thus crooked, either by hand or by machinery, are to be stuck through the leather, in which holes are pricked for their reception. This was formerly executed by the tedious process of pricking with a double awl, but now it is done by machines; one kind adapted to the sheet cards, and the other for filleting. The former consists of a square wooden frame, like a table without the top, and in this a square frame or carriage slides horizontally, and has cross bars, provided with jaws to fasten, and screws to stretch the sheet of leather with a proper degree of tension. A cord is fastened to one end of the carriage, and passing over a pulley, has a weight attached to it, which always urges the carriage one way. It has a rack fastened to one side of it, the teeth of which are engaged by the worm of an endless screw, formed at the end of a long axis, placed parallel to the direction of the motion of the carriage, which is also parallel to the rack. The endless screw is prevented from running round, as it would do, by the weight drawing the carriage by a cylindrical brass wheel, the circumference of which has several circles traced upon it, each divided into a different number of divisions, and marked by small holes. A spring with a tooth, or pin at the end, applies to these divisions, in the same manner as the dividing plate of a wheel-cutting engine. Now, by lifting the spring tooth out of any division, the weight operating upon the carriage draws it forwards, the teeth of the rack turning the endless screw about till another division comes to the tooth which drops into it, and holds it fast till the workman again relieves the spring catch. By this means the carriage and the leather is moved an equal quantity at each time, to measure the distance at which the rows of holes shall be pricked; and this measure can be altered at pleasure, by using a different circle of divisions. The holes are pierced by a double row of prickers, as long as the sheet of leather. They are small steel points fixed into a piece of iron, which is screwed to a strong frame, moving on two centre screws, forming an axis for it immediately over the leather, and in a direction across that of the motion of the carriage. On this axis the frame rises and falls in the manner of a book lid, when moved by a long handle (lever) which is fastened to it. The row of points being fixed parallel to the axis, forms a double row of holes, when the lever is pressed down, in a direction across the motion of the leather. A proper bed is prepared beneath the leather, just where the points act, to support the sheet while it is pierced. This machine is used as follows: A sheet of leather is prepared by rubbing the grain side with soap, and sizing over the flesh side. It is then fixed to the two Operation cross bars of the carriage, by the jaws which bite its edge fast; and by the two screws first mentioned, the sheet is strained very tight. All this time the lever and pricker frame is turned up out of the way; and the end of the lever being suspended from the ceiling, but the leather being fixed, the workman adjusts the carriage to the proper point of commencement, and then strikes down the end of the lever, pricking one double row of holes across the whole length of the sheet; he then lifts up the lever, and, taking the spring catch of the dividing cylinder in
CARDS.

The other hand, lifts its point out of a division, suffering the carriage to move till the next division comes to the catch; then he strikes down the lever, and pricks another double row, and at the same time that he lifts it up again he suffers another division to pass by; and in this manner the operation proceeds with great rapidity, till the whole sheet is finished. The pricker, it should be observed, is provided with a double row of points, and pierces two rows at once, that the points of one may fall opposite the spaces of the next row; a condition which it would be difficult to effect by other means than piercing two at once.

The fillet cards are pricked by a different machine. In this the pricker frame is moved by a crank, on a spindle parallel to its axis of motion, and turned with a band and fly wheel, to give it a rapid motion. The fillet of leather is wrapped round a roller fixed in the frame of the machine, and provided with a pulley and cord, to which a weight is suspended, acting to wind the leather upon the roller; and therefore when the fillet is forcibly drawn off the roller, this weight acts to keep the leather to its proper degree of tension. The fillet is drawn forwards by a pair of rollers, between which it passes, and they are pressed together by a spring, with a sufficient power to hold the leather fast between them. They are turned round by a detent at the end of the main spindle, which moves the wheel one tooth at every revolution; and by turning the rollers, advances the leather a proper quantity to receive another double row of pricks, which it does from the pricker frame when it is moved by the crank before mentioned. The pricker frame, except in size, is the same as the machine before mentioned.

The wires are put into the leather by women, who first enter them into the holes, and then push them home by a thimble. Some can put in two wires at once; but this requires a degree of dexterity which very few can attain. The filling the leathers is a very serious portion of the whole labour of card making, and has therefore attracted the attention of mechanics to perform it by machinery. We have seen a model of a very ingenious machine, invented by Mr James Fryer of Rastrick, near Huddersfield, Yorkshire, which pricked the leathers, and at the same time put in the wires, previously doubled in the usual way; but the knee bend was given to them by the machine after being stuck through the leather. This machine has not yet been brought into practical use.

We have received information of a very surprising card wire machine used in America, invented by Mr Amos Whittamore. It completes the whole operation at once, cutting and doubling the wires, pricking the leather, and sticking them in, and then giving the knee bend to them afterwards. It does one wire at a time; but acts with such rapidity, as to complete four per second; so that the whole labour by this machine is less than any one operation in the common way. The following extract of a letter from the proprietor of these works, William Whittamore of West Cambridge, to the collector of Boston, dated 24th of November 1809, was published in the American minister's report on the manufactures of the United States, and gives some account of this manufacture.

"The machines with which we now manufacture all kinds of wool and cotton cards that have been called for, were invented by Amos Whittamore in 1797; he then obtained the exclusive privilege of using the said machines by letters patent, for fourteen years. Amos Whittamore and myself were jointly concerned in the first machines that were built, and are still the sole proprietors of the patent. Congress at their last winter session, extended the patent fourteen years, by a special act. We have fifty-five of those patent machines, thirty-seven of which are now in use. These machines, with the other apparatus necessary to carry on the business to its present extent, have cost us about forty thousand dollars."

"We have now employed in the factory upwards of forty hands. We manufacture weekly one hundred and eighty dozen pair of hand cards, and two hundred square feet of cards for the woollen and cotton factories, which together amount to about two thousand dollars. Had it been in our power the year past to have supplied ourselves with card wire, the amount of cards manufactured in our factory would have exceeded three thousand dollars. Fifty thousand dollars at least, is necessary for a capital to carry on the business to this extent, exclusive of buildings and machinery. We have been obliged to make great sacrifices to obtain money, to enable us to carry on the business, so as to be able to answer the demand for cards. Our monied institutions have afforded but little support to domestic manufactures. The wire is the only article necessary to the manufacture of cards; but what our own country produces, and that might be manufactured here as good, and nearly as cheap, as in England. Of this we have so far satisfied ourselves, (by experiment), that nothing but want of capital has prevented us from setting up that business. The iron made on Lake Champlain is found to be as good for wire, if not superior, to any ever imported. The wire to supply our factory one year, will, in England, cost about fifteen thousand dollars, and the expenses of importing, about ten per cent, (it being free of duty). Perhaps about the same quantity is used annually in the other card manufactories in the United States. There is no doubt in my mind, from the observations made since I have been in the manufacturing business, that had the same support been afforded manufacturers generally, that has been made to trade and commerce, our manufactories at this time would have been carried on much more extensively, and would have generally afforded a profit to those concerned. Since the obstructions to our foreign trade, the manufactures of our country have increased astonishingly. The demand for wool and cotton cards, during the present season, has been twice as great as it has been during any preceding year. We hear that Mr Joseph Dyer has, in conjunction with the inventor, recently taken out a patent in England for this invention, which will most certainly supersede all the other machines that have been contrived for this purpose."

(J. P.)
CARDAMINE, a genus of plants of the class Tetradyomia, and order Siliquosae. See Botany, p. 263.

CARDAMOM. See Materic Medica.

CARDAN, Jerome, a celebrated Italian mathematician and medical writer, was born at Pavia on the 24th of September 1501, and appears to have been the natural son of a celebrated advocate and physician at Milan. When he was only four years old, he was sent from Pavia to Milan, where he was instructed by his father in mathematics, astronomy, and judicial astrology; and in his eighth year, when he was afflicted with a dangerous illness, his father devoted him to St. Jerome. In the year 1521, he went to study medicine and philosophy at the University of Pavia, and two years afterwards he was able to give lessons on mathematics. In 1524, he went to Padua, where he received in the same year the degree of master of arts; and in the year following, he was honoured with his medical degree. He married about the end of the year 1531, and, contrary to his expectations, he had several children. Having refused a medical chair in the university of Pavia, he was, in 1533, appointed to the professorship of mathematics at Milan, and at the same time he commenced the practice of the medical profession. In 1539, he was a member of a college of physicians in that city; and though he was thus brought into notice, his time seems to have been more occupied in writing books than in attending patients. His work De Malo recentiorum Medicorum melendii uus, Venet. 1536, and his Contradicenium Medicorum Libri duo, Lyons, 1548, in which he censures the practice of his contemporaries, and points out the inconsistencies and contradictions of which the best writers have been guilty in their account of diseases, seem to prove that he was not on very good terms with the other physicians in Milan. In the year 1543, he gave public lectures in medicine at Milan, and in the following year he repeated them at Pavia; but as he could not procure payment of his salary, he discontinued them at the end of a year, and returned to Milan.

Upon the recommendation of Vesalius in 1547, the King of Denmark offered Cardan a professorship in the university of Copenhagen, with a free table, and a salary of 800 crowns a year; but Cardan declined this offer, on account of the severity of the climate, and the religion of the country. Archbishop Hamilton, the primate of Scotland, and the regent's brother, having been severely afflicted for ten years with an asthma, applied for relief to the physicians of the French king and of the emperor of Germany, but as he received no benefit from their prescriptions, he sent for Cardan in the year 1552. At the end of 75 days, Cardan left the archbishop in a state of convalescence, and gave him such prescriptions, that he was completely cured at the end of two years. Larrey, in his history of England, informs us, that when Cardan was taking leave of the primates, he remarked that though he had nearly cured him of his malady, yet he could not change his destiny, and prevent him from being hanged. After receiving the most liberal remuneration for his services, Cardan returned to Milan at the end of ten months by the way of London, the Low Countries, and Germany; and during his stay at London, he is said to have calculated the nativity of Edward VI. Having resumed his former employments of practising medicine and teaching mathematics, he continued at Milan till the end of October 1559, when he went to Pavia to fill the professorship of medicine; and in the year following, he accepted a similar office at Bologna. In this situation he continued till the year 1570, when he was thrown into prison for some offence with which we are not acquainted. At the end of some months, however, he was permitted to confine himself in his own house, and as soon as he obtained his liberty, which was in September 1571, he repaired to Rome. Here he lived for some time without any public employment; but he was soon chosen a member of the college of physicians, and received a pension from the pope, which was continued till the day of his death, which happened on the 28th September, 1575.

Cardan was perhaps one of the most singular characters that has appeared in any age or country. In the account which he published of his own life, he has, with great ingenuity, given a full detail of his good and bad qualities, though it is probable that he has suppressed many facts which were by no means favourable to his moral reputation. He gravely informs his readers, that he had frequently determined to put himself to death; that he often wandered all night in the streets; that he took the greatest delight in bringing forward subjects that were disagreeable to the company; that he introduced every topic, whether it was conrected or not with the subject of conversation; that he ruined his family and his reputation by playing for whole days at games of chance; and that he staked even his furniture and his wife's jewels.

At a time when astrology was in the zenith of its glory, it was natural that Cardan should follow the example of the most distinguished of his contemporaries; but though we find in the character of the times a sufficient apology for his devotion to judicial astrology, yet we seek in vain for any palliation of that empiricism and imposture which he seems to have systematically pursued during the whole of his life. He who could seriously believe that he had the power of foretelling future events both in his dreams, and from particular marks upon his nails, must have been utterly devoid either of reason or intelligence; but he who could commit such pretensions to writing, and try to impose upon posterity the same delusions which he had practised upon his contemporaries, must have possessed a mind destitute of every honourable feeling, and so deeply in love with falsehood as to deceive when nothing could be gained by

* * * Cum Sol et malefica ambe et Venus et Mercurius essent in signis humanis, ideo non declinavi a forma humana, sed cum Jupiter esset in ascendente, et Venus totius figura dominata non ful oblussus nisi in genitalibus, ut a xxi anno ad xxxi, non possimus concubire cum mulieribus, et serpues desiderem sortem meam culque alteri propter invidium. Cardanus. De Vita Propria, cap. ii. p. 8.
of the deceit. Cardan, indeed, seems to have been the most determined impostor of his times. He ascribed the extravagance of his opinions, and the eccentricities of his conduct, to the influence of the celestial bodies. He had the audacity to calculate the nativity of our Saviour; and having foretold the time of his own decease, he is said to have starved himself to death, in order to verify the prediction.

The irregularities of conduct into which Cardan was continually hurryed, by the violence and caprice of his temper, became the source of great misery and distress; and the vices and misfortunes of his children, filled up the measure of his suffering. His eldest son married a woman who possessed neither character nor fortune; and having killed her by poison, he was condemned to death, and executed in the prison at midnight. This distressing event produced a deep impression upon the mind of Cardan, who endeavoured to justify the murder on the ground of the wife’s infidelity, and who maintained that the vengeance of heaven had followed the judges who pronounced sentence upon his son. His other son was also an abandoned character, and his father was under the necessity of throwing him into prison, and of cutting off one of his ears, and disinheritting him. The payment of his daughter’s dowry, and the circumstance of her having no children, were the only distresses which she occasioned.

From such a degrading picture, it is pleasing to turn to those marks of genius and talents by which Cardan has perpetuated his name. As a philosopher, he is entitled to no praise, and as a medical writer he is chiefly famed for his industry and fidelity in the collection of facts. The philosophical speculations which he has published in his works De subtilitate and De Varitale rerum, are the mere ravings of an unfettered imagination; and if arguments were wanting to prove that Cardan laboured under a partial insanity, we should appeal to these works, as well as to the whole of his conduct.

As a mathematician, however, the merits of Cardan are beyond all praise. In the year 1539, he had completed nine books on arithmetic, algebra, and geometry, under the title of Liber Arith magnae; and when it was nearly printed, having heard accidentally of Tartalea’s discoveries in cubic equations, he was extremely anxious to obtain these discoveries for insertion in his work. Cardan first applied to Tartalea through the medium of a bookseller, and, along with the most flattering compliments, he sent him a number of questions to resolve. Tartalea, however, refused to disclose his rules, which Cardan again attempted to obtain from him by personal correspondence. Finding every effort unsuccessful, Cardan at last endeavoured to gain by cunning what he could not acquire by the most urgent supplication. He wrote to Tartalea, that he had recommended him to his particular friend and patron the Marquis dal Vasto, who was very anxious to see him; and he invited him to spend a few days with him at Milan, accompanying the invitation, however, with a distinct notification, that such a visit might be useful to Tartalea, and that it would be dangerous to offend the Marquis by a refusal. More intimidated by the threat than allured by the invitation, Tartalea set out for Milan; but as the Marquis had gone to Vigevano before his arrival, he was induced to spend three days with Cardan till the Marquis should return. Cardan employed every artifice to obtain from his guest the secret for which he so ardently longed. “I shall swear to you,” says he, “on the holy evangelists, and by the honour of a gentleman, not only never to publish your inventions, if you reveal them to me; but I also promise to you, and pledge my faith as a true Christian, to note them down in cyphers, so that after my death no other person may be able to understand them.” To these protestations Tartalea replied, “If I refuse to give credit to these assurances, I should deservedly be accounted utterly void of belief; but as I intend to ride to Vigevano to see his excellency the Marquis, as I have been here now these three days, and am weary of waiting so long; whenever I return, therefore, I promise to shew you the whole.” Cardan, however, having renewed his entreaties to obtain the rule before the departure of his friend, Tartalea replied, “I am content; but you must know, that to be able on all occasions to remember such operations, I have brought the rule into rhyme; for if I had not used that precaution, I should often have forgot it; and though my rhymes are not very good, I do not value that, as it is sufficient that they serve to bring the rule to mind as often as I repeat them. I shall here write the rule with my own hand, that you may be sure I give you the discovery exactly.” These verses contained the rule for the three cases

\[x^3 + bx = c\]

\[x^3 = bx + c\]

\[x^3 + c = bx\]

Tartalea reminded Cardan, at parting, of his obligation to secrecy; and during a subsequent correspondence, in which the latter proposes some difficulties in the solution of cubic equations, Tartalea displays the greatest suspicion that Cardan would betray the secret, and never fails to remind him of the vow which he had made.

Notwithstanding all these promises so solemnly made, and so frequently repeated, Cardan published in the year 1545, his tenth book, which contained the whole doctrine of cubic equations, and of course the substance of the rules which he had received from Tartalea. He acknowledges that Tartalea gave him the rule, but without the demonstration, and he asserts, (see cap. xi.), that by the help of the rule alone he discovered the geometrical investigation. Tartalea complained bitterly of this violation of his promise; and Cardan defended himself on the ground, that he greatly extended the method of Tartalea, and was therefore entitled to publish his own improvements. A controversial correspondence was carried on between the two mathematicians with the greatest acrimony, till it was terminated by the death of Tartalea in 1557.

Though Tartalea is certainly entitled to the high honour of originality, yet Cardan has the merit of having prosecuted the subject of cubic equations with singular assiduity and success. His tenth book contains rules for all the forms and varieties of cubic equations, with their geometrical demonstrations;
and in every part of it he shows himself eminently skilled in the various branches of algebra. Dr. Hutton has given a very full and interesting analysis of Cardan's work, and a list of his analytical improvements, to which we must refer our readers for further information on this subject.

The writings of Cardan, which are extremely numerous, were collected into ten volumes folio, and published at Lyons in 1663. Many of them are hasty productions, which were printed only to relieve his pecuniary wants.

The following is a complete list of the different works of our author.

CARDIFF, or CAERDYFF, the county town of Glamorganshire, in South Wales, was first built in 1080. It derives its name from the river Taff, which runs along the west side of it, having a bridge of five arches, and falls into the Severn about three miles below the town. It is pleasantly situated on a fertile flat. Its streets are spacious, and its houses well constructed. It consists of two parishes, St Mary's and St John's. There is, however, only one church for both; St John's church having been; with many other edifices, destroyed by inundations of the river in 1607. The high tower of St Mary's church, which was erected in the reign of Edward III. is of light appearance and elegant workmanship, having open corners and lantern pinnacles. There were anciently four religious houses in Cardif: a Benedictine priory, and black, grey, and white friars. There is nothing left of all these except a few remains of the whitefriars, and the ruins of the blackfriars, which now afford shelter to some poor fishermen. Formerly the town was encompassed with walls, which were flanked with watch-towers 1280 paces in circumference, and had gates at the four cardinal points. Of these some traces are still visible. The castle, which is the chief object of attention to a traveller, was built in 1090, by the conqueror Fitzhamon, a Norman, after he had taken possession of the country of Morgannoc; and is remarkable in history, principally as having been the scene of the long imprisonment, cruel treatment, and death of Robert, Duke of Normandy, brother to Henry I., and as having sustained a siege by the parliamentary forces, who took it from the Welsh loyalists in 1645. It stands on the north side of the town wall; is a large stately edifice; was originally of
great strength; and is said to have covered no less than eight acres of ground. Though a great part of
the ruin has been barbarously pulled down, for
the purpose of erecting houses in the town, the
present possessor, the Marquis of Bute, has been care-
ful to repair and modernise what remains of it. The
entrance into it is bold, having two portcullises and
massy gates. In the inside of the wall, around its
whole extent, there is a high terrace; and on the
keep, which stands in the centre of the inclosed area,
there is a tower, which is of an octagonal form, and
very handsome.

Vessels of 200 tons can come up to the town; but
the principal harbour, called Penarth, or the Bear's
Head, is three miles below it, and adds greatly to
the consequence of Cardiff itself, as well as affords
shelter to those ships which are detained in the Bris-
tol Channel by westerly winds. The inhabitants of
the town and neighbourhood send great quantities of
corn, butter, and poultry, to the Bristol market.
Nearly 9000 tons of cast and wrought iron are an-
nually exported to London and other places; and the
conveyance of this ponderous article has been great-
ly facilitated, by a canal cut from Penarth Point to
Cyfartha iron-works, carried with much ingenuity
through a mountainous country to the extent of 25
miles, and subsequently improved by a branch which
goes off to other works at Aberdare. No less than
30,000 boxes of tin-plates, which are manufactured
at a place called Melyn Griffin, about four miles dis-
tant, are annually sent off for Bristol; and the scrobes
of iron-plate, from which the tin is made, are con-
verted into bolt-iron for ship-building, and form another
considerable article of exportation in the trade of
Cardiff.

According to the return made in 1801, it contains
397 houses, and 1870 inhabitants; and of these, 218
are stated to be engaged in trade and manufacture.
By the return of 1811, its population amounted to
2457. It is an ancient corporation, governed by the
constable of the castle, two bailiffs, twelve aldermen,
twelve capital burgesses, &c.; and along with Cow-
bridge, Swansea, Longher, Aberavon, Kenfig, Neath,
and Lantrissent, sends one member to parliament.
Here a court of record is held every fortnight; and
the assizes for the county meet in April and August.
There are two weekly markets, on Wednesdays and
Saturdays, which are well supplied: Those held in
the second Wednesdays in March, April, and May,
are very large. And there are fairs for horses, cattle,
&c. on June 19, Sept. 19, and Nov. 30. See Evans' Tour in South Wales; and Barber's Tour in
South Wales. (*)

CARDIGAN, called by the Welsh Aber-
tyvi, is the county town of Cardiganshire, in South Wales. It is situated on a steep bank, and about two miles
from the mouth of the river Tivy, over which there is
a stone bridge of five arches, that leads into Pem-
broke shire. The river is navigable here for vessels of
150 tons, and there is a tolerably good key for load-
ing and unloading; though a dangerous bar, which
lies at the mouth of the river, must ever prevent the
town from becoming a great commercial place. At
the commencement of the war, Cardigan had a con-
siderable export trade to Ireland and other places,
in lead and corn, of which last article it annually
shipped off from 50,000 to 100,000 bushels; but at
present, the commerce in which it chiefly engages,
and on which it chiefly depends, is furnished by the
iron-works in its vicinity. In 1801, it contained 415
houses, and 1911 inhabitants, of whom not more than
200 were employed in trade and manufactures.
In 1811, the population was 2129. It is governed
by a mayor, a recorder, twelve aldermen, and thir-
teen common councilmen; and, in conjunction with
the outlying boroughs of Aberystwith, Lampeter,
and Adbar, sends one member to parliament—the
number of voters amounting to about 1200. Though
the houses and shops are on a small scale, yet, upon
the whole, the aspect of the town is pleasing. At
the same time, considering that it is the capital of the
county, it has an air of poverty in it. The principal
public buildings are, the church, which is a stately
edifice; the town hall, where the assizes are held, which
has a good appearance; and the county gaol, which
was erected in 1797; and is sufficiently commodious.
Cardigan was anciyntly surrounded by a wall; and
near the bridge are the ruins of a castle, which seems
to have been a spacious structure. It is said to have
been built by Gilbert de Clare in the time of Hen-
ry II.; and Powell affirms, that it was built for the
purpose of defending the borders. In 1164, it was
besieged, taken, and razed to the ground by Rhys
Gryffydd.——Cardigan has a market for ordinary pur-
poses on Wednesday and Saturday; and four fairs
annually, viz. on February 13, and April 5, for
horses, peddlars' ware, &c. and on September 8, and
December 19, for black cattle, &c. See Malkin's
Scenery, Antiquities, &c. of South Wales, vol. ii.;
Evans' Tour through South Wales; and Lipscomb's
Tour, &c. (r)

CARDIGANSHIRE, in Welsh Swidh Aber-
tyvi, or Sir Abber Teivi, a county in South Wales.
It anciently formed one of the six parts into which
the kingdom of Wales, called Disneowers, was divided,
and contained four cantrefs and ten comots: (See End evie's Cambria Triumphant, p. 214.) It is
bounded on the north by Merionethshire, on the
west by that part of St George's Channel called Car-
digan Bay, on the south by the counties of Caermar-
then and Pembroke, and on the east by those of
Radnor and Brecknock. The western side of it has
suffered great depredations from the sea. Accord-
ing to tradition, an extensive tract of land has been
swep t away; and, instead of many flourishing towns,
there now remain only a few miserable villages.
Some have supposed, that the whole of Cardigan
Bay was formerly a spacious plain, on which the
sea made gradual encroachments, till its progress was
stopped by the elevated ground which now encircles
the shore; and the appearance which the scene exhib-
its, together with the common opinion that prevails
among the people, renders this supposition extreme-
ly probable.

This county may be divided into two districts, the
lower and the upper. On the more elevated grounds
of the lower district, the soil is in general a light
sandy loam, varying in depth from four inches to a
foot, and having for its substratum a slaty kind of
rock. In the valleys it is very deep, and, with a few
exceptions, very dry. The manures made use of are
dung, lime, and marl. Tolerable crops are raised
of wheat, barley, peas, black oats, and potatoes. Turnips also are cultivated to some extent, and rich fields of clover and natural grass are occasionally to be seen. But the mode of farming is, on the whole, injudicious and slovenly; and, consequently, the produce is in very few cases so abundant as might be expected from the goodness of the climate, and the quality of the ground. It is a singular fact, that there is a good deal of land on the sea coast from which crops of barley have been annually taken for at least sixty years past, without any diminution either in the quantity or quality of the produce. The manure employed is sea-weed; and the grain is accounted so excellent, that it is sent to the adjacent counties for seed-corn. The farmers all keep cows for the purpose of breeding; and also of making butter and skimmed milk cheese,—the former of which is chiefly for exportation, and the latter solely for home consumption. The black cattle are of the Pembroke shire breed; they work, travel, and fatten well; and used to be favourites of the English drovers, who bought them readily, and at good prices. There are not many sheep in this district. These are kept by the few who sow turnips. Their number is diminishing, because a spirit for inclosing prevails, and they are reckoned enemies to the growth of young hedges. This is surely unwise, as the soil is so well adapted to them, and as the evil which they occasion might be easily prevented.

The upper district, comprehending chiefly the northern and eastern parts of the county, is very mountainous. A great proportion of it is bleak and barren; but much of this is owing to want of judicious enterprise and agricultural skill, as well as to natural sterility and unfavourable situation. In the valleys and dips, which are narrow, and of no great extent, the soil is chiefly of a stiff retentive clay; in the declivities it has an admixture of light loam; and on the high grounds it is uniformly thin and excessively poor, yielding little except ling, heath, and moss. The farmers here depend more on their stock than on cultivation. They scarcely raise a sufficient quantity of corn for their own consumption; and pay their rents principally by the profits derived from the sale of cattle and horses bred by themselves, and of sheep, which they have in pretty numerous flocks. The breed of black cattle is much the same with that of Pembroke shire and Caermarthenshire. They are small, but well-made and hardy, and answer much better for the butcher than the dairy. Formerly all England to the south of the Trent was supplied with black cattle from this quarter; and it is still looked to by dealers and drovers as a kind of nursery for these animals. The native unmixxed breed of sheep are very small, long legged, narrow on the chine, of various colours, some with horns, and many without them. There are also a good many pigs reared. These, indeed, always form a part of the farmer's stock, though they are not found to be a very profitable concern. In the south east of this division there are some pieces of ground inclosed, and well cultivated; and there is a larger portion of good pasture and meadow here than is generally to be found in the neighbourhood. The kinds of grain produced in the upper district are the same as those produced in the lower, with the addition of rye, which is raised here in considerable quantities. The waste lands in Cardiganshire are very extensive. Including those tracts which are but partially cultivated, they may be estimated as amounting to nearly the half of the county. A large proportion of them, however, if not fit for the plough, might be planted with great advantage. Indeed, improvements of this kind have been already set on foot, and are advancing with a rapid progress. The climate is mild and temperate, varying a little according to the elevation of the ground, the distance from the sea, and the state of cultivation; not so cold as in the midland counties, nor so humid as in the western coasts of England; and, upon the whole, favourable both to health and husbandry. Cardiganshire used to be considered as so barren and unproductive, that it was proverbially called by the people of the neighbouring countries, the Devil's Grandmother's Joisture. But it is gradually falsifying that reproachful appellation; and though it can never, perhaps, vie in fertility with regions that have been more favoured by nature, it promises soon to hold a respectable place among those districts which are distinguished by agricultural improvements. The principal ground of hope rests in the institution of an Agricultural Society, consisting of the most intelligent gentlemen and farmers in that quarter, which has already done a great deal of good, and from which a great deal more is to be expected; because, according to Mr. Malkin, it is formed "on a better plan, and founded on more rational principles than that of any county in South Wales."

The principal rivers in this county are the Tivy, the Rydol, and the Ystwith. The Tivy, which forms the greatest part of its southern limit, rises out of one of the many small lakes which are collected in the hollows on the eastern side. It runs over a very rocky and irregular channel till it reaches Ystrad Fflwr, when it assumes a more settled course, and, passing by Landbeder, at the border of Caermarthenshire, becomes from thence the boundary between the two counties, till it falls into the Irish sea, about two miles below Cardigan. The Rydol rises on the south-west side of Plynlimmon, and, after running south and south-west, discharges itself into the Irish sea near Aberystwith. The Ystwith has its mouth, as the name of the town denotes, at the same place with the Rydol, though it takes its rise from among the hills in the eastern district. Beside these, there are some streams of smaller consequence; and, as might be expected from the nature of the country, a vast number of rivulets. Indeed, the authors of the Agricultural Survey tell us, that, "exclusive of springs upon the hills, there is no valley without a river or a brook, and scarcely a glen, or what we call a dingle, without a stream sufficient to turn a mill." These must be considered as great advantages, both for watering the soil, where irrigation may be useful, and for driving corn mills and other kinds of machinery. At the same time, they are frequently productive of much injury. Though, in dry weather, these rivulets are very inconsiderable, yet, after storms, or continued rains, they become formidable torrents,—rush with terrible impetuosity through the deep narrow chasms that are formed by the hills,
are precipitated sometimes in the form of tremendous cascades—bear away before them every thing that lies in their way—and even tear up the fertile soil of the valleys, substituting in its place nothing but barren gravel and stones.

There is a great want of fuel in this county. Coals are scarcely to be had, except at a high price, being all brought from a great distance by sea. Of wood there is but little, and in many places that little is much neglected; though in other quarters, particularly in the neighbourhood of Hafod, considerable tracts of land have lately been laid out in plantations, which promise to be both profitable to the proprietors, and useful to the country. Various kinds of trees have been planted, but those which seem to thrive best are the larch and the beech. The most prevalent species of fuel is peat. There are many extensive tracts producing it, such as the plain between Tregaron, and Strata Florida or Stratflour, and that part of the coast beyond Aberystwith which borders on the Dee. These are capable of great improvement, by draining and other means; but as the inhabitants depend so much upon it, such improvements might occasion greater harm than good to a numerous class of the people, and therefore is not likely to be soon accomplished.

The mountains, especially those in the north part of the county, contain lead and other minerals in great abundance: but these are not now an object of attention, either because there is not a sufficient spirit of enterprise, or because the expense and difficulty of working them would more than counterbalance the probable profits. Formerly, however, they were in great repute, and found to be extremely productive. In Queen Elizabeth's time, a company of Germans made a great deal by the mines of lead and silver, the ore of which often gave seventy or eighty ounces of silver in the ton of metal. In the reign of James the First, Sir Hugh Middleton, for some years, out of a single mine, cleared at the rate of £2000 per month, one ton of lead yielding a hundred ounces of silver, and in this way accumulated that large fortune which he afterwards employed in bringing the New River water into London. A Mr Bushel also, who succeeded him, made such immense sums, that, according to one author, he presented Charles I. during the civil wars, with a regiment of horse, clothed his whole army, and lent him, besides, £40,000. The mines wrought by these gentlemen were so much exhausted, as to become ever after of inferior importance. But the mineral prosperity of the north of Cardiganshire did not decrease. In 1690, other mines of great value were discovered on the estate of Gogerthan, belonging to Sir Carbery Price. They were so rich as to obtain the appellation of the Welsh Potosi, and have been celebrated, both in the prose records of the principality, and in the poetical strains of Yalden and Sargent. Afterwards the mind adventurers were at considerable expense in carrying on the works, and had proportionate success in the profits which they derived from them; but happening to disagree among themselves, their undertakings declined in prosperity and in value, and have never since been revived with advantage; though a gentleman well versed in the

subject has given it as his opinion, that with money sufficient for carrying on the works in a proper manner, it was quite possible to make them produce a clear annual profit of £12,000. The lead mines of Cwm Ystwith are situated on the sides of two mountains, to the right of the river Ystwith, in one of which the lead is obtained with ease near the surface, but in the other the earth must be penetrated to no less an extent than 300 yards. In Cardiganshire there are also rich veins of copper, which may be digged without great difficulty, but which cannot be carried with advantage through the different processes, for want of coal, of which there is not one particle to be found in the whole county.

The antiquities to be met with in Cardiganshire, are neither very numerous nor important. Near Neuadd, in the neighbourhood of Cardigan, there are the remains apparently of some barbarous monument, consisting of nineteen stones. There is another monumental stone in the parish of Llan Glodmor, which is of prodigious size, being half a yard thick, and about six-and-sixteeneen feet in circumference. Not far from this, is what the Welsh call Lheuy gowres, which means the stone of a gigantic woman. This stone is remarkably large, and supported by four great pillars, about the height of five or six feet. In the village church of Llan Dhewi Brevi, is preserved the horn of an ox, no less than 17 inches in circumference at the root, and as heavy as stone, being, it is probable, in a state of preservation. It is said to have been kept there ever since the time of St David, who lived in the beginning of the 6th century. At a house in the vicinity, is a place called Kaer Kestil, or the Field of Castles, where a great number of stones has been occasionally found by digging, bearing inscriptions, some of which have been preserved, though most of them are lost. One of them, according to Camden's interpretation, is, Cali Artius manibus (vel memorie) Ennius Primus. Stratflour, or Yetred Fler, abbey, is situated about six miles from Llanbeder, on the bank of the river, and was in former times a place of great note, many of the Welsh princes having been buried in it, and the records of their acts and successions having been kept in it for a long series of years. At Llanfihangel, a parish not many miles from Aberystwith, is a stone monument, 4 feet long and 3 broad, which should seem, from its name, Gineyl Taleisin, to point out the grave of Taleisin ben Bierth, a celebrated poet, who flourished about the year 540. Some; however, suppose that, along with many others of a similar kind, it is an old sepulchral monument, erected in heathen times. Among the antiquities of Cardiganshire, may also be reckoned the castles of Cardigan and Aberystwith, which were anciently large edifices, though the ruins of them which remain are inconsiderable.

There is no district in South Wales, which abounds so much in picturesque and romantic views. Before the traveller can reach them, indeed, it is often necessary to pass over some very bleak and dreary ground. But he is amply repaid for this, by the interesting scenery which he is sure to meet with. It is on a pretty large scale, and in very fine style, exhibiting the grand and the beautiful, both singly and in com-
bination. A very particular and excellent description of its more striking parts, is to be found in the work of Mr. Malkin, referred to at the end of this article.

Though the people understand English better than they appear to do, the language of Cardiganshire is almost wholly Welsh. As the judges are English, the intervention of an interpreter becomes necessary; this circumstance occasions great inconvenience, and some very absurd and unfair decisions. The inhabitants, however, do not suffer much from this cause in a religious point of view; because the church services are almost universally performed in Welsh, so that none but the gentle part of the congregation are prevented from deriving benefit. The dialect which is spoken in this county, comes nearer than that in any other to the modern literary or written dialect.

The inhabitants of this part of Wales are peculiarly simple in their manners; they get but small wages for their labour; their mode of living is extremely coarse; their mud-walled cottages, (for they have no good stone for building, and no lime,) are ugly without, and squallid within; their internal intercourse, and their communication with other places, are very rare; they are seldom known to emigrate from the narrow spot of their nativity; and, like most other people in their circumstances, they are much given to hospitality.

The Bay of Cardigan, which bounds the west side of this county, abounds in various kinds of fish. There are cod, whiting, herrings, &c. In catching these, a great number of people find employment in the proper seasons. The monk-fish, otherwise called the angel-fish, is also found here in plenty, and sometimes so large as to weigh 160 pounds. It is said that blue sharks, of a monstrous size, have been sometimes seen; but from the description given of the fish, this is probably a mistake. In the river Tivy, very fine salmon are caught; and in the various streams which water this county, all the common fresh water fish are to be met with.

The only manufactures of any consequence in this county, are the iron and tin works, which were established in the neighbourhood of Cardigan, about 50 years ago, and which are still carried on to a considerable extent. From the want of good harbours, the maritime trade of Cardiganshire is comparatively trifling. The chief exports are iron, tin, black cattle, pigs, salt butter, barley, and oats. At the large fairs, of which there are several, a good deal of business is transacted in the staple commodities of the county. Rhosvair, in particular, a place near the source of the Tivy, is celebrated for its fairs of sheep and black cattle. A great proportion of the wool is spun and manufactured by the inhabitants for their own use.

The rest, more especially the coarser part of it, is mostly sent to the English market.

Cardiganshire is, at an average, about 40 miles in length, and 20 in breadth. It contains 7,260 square miles, or 1,641,610 acres, of which about 145,000 are in pasture, about 100,000 in a course of tillage, and the rest in waste, plantations, &c. It is divided into four hundreds, viz. Geneurglyn, Llar, Moysdlyn, Penarth, and Troedyrogow; has five market-towns, viz. Aberystwith, Cardigan, Llanbadarn-fawr, Llanbeder, and Tregaron; contains 77 parishes, and sends one member to parliament. It lies in the province of Canterbury, and diocese of St. David’s, and is included in the North Wales circuit. In 1801, the number of houses in it was 9040, and of inhabitants 42,956; of these, 20,408 were males, and 22,548 females; 2896 were employed in trade and manufactures, and 16,511 in agricultural pursuits. In 1811, the population was 50,260. In 1806, it paid £175,213 of property-tax; and, in 1805, it paid one part of the rate-tax, and £10,167 of poor’s rate. See the Description of England and Wales, vol. i. p. 282; A Tour in Wales, &c. in the Summer of 1805, in Phillips’ Collection, vol. iv.; Agricultural Survey of Cardiganshire; and Malkin’s Scenery, Antiquities, &c. of South Wales, vol. ii. (r)

CARDINAL is more particularly applied to an ecclesiastic in the church of Rome, who is a member of the conclave, and who is invested with the power of electing the pope.

The origin of this order is involved in a considerable degree of obscurity; but there can be no doubt that it derived its existence from the oligarchical nature of the form of church government adopted by the see of Rome, and the desire which all who have sat in the chair of St. Peter have shewn to render the city of Rome the centre of all ecclesiastical power, and to which those who looked forward to the acquisition of dignities or preferment in the Catholic church, were alone to direct their attention. The aggrandisement of papal jurisdiction was a favourite object of pursuit with all the bishops of Rome; and by means skilfully contrived, and as skilfully executed, they succeeded most effectually in accomplishing their purpose.

Some difference of opinion has existed respecting the origin of the name cardinal; and yet it is strange that, upon a subject which appears to be so plain, ingenious men should call forth all their learning and acuteness in tracing the etymology of a word which appears to be so obvious, and accords so well with the analogy of the language. Among the Latins, the word cardinals signifies principal. Thus, quatuor viti cardinalnes, the four cardinal or chief winds; princeps cardinals, a sovereign prince; missa cardinals, the great mass; and, altare cardinale, the great altar of a church. The name was even applied to those who held the chief civil offices in the state under the Emperor Theodosius.

The cardinals, who with the pope constitute the conclave, or sacred college, are composed of three distinct orders, viz. deacons, presbyters, and bishop. It may be proper to observe, that in towns there were three sorts of churches. The one was called Tituli, or parish churches, in which the people assembled for the general purposes of public worship, to hear the liturgies read, and to receive the sacrament. The second was called Diaconies, or deconories, which were public hospitals for the benefit of the poor, and to these were annexed chapels. The third were oratories, in which it was not permitted either to administer baptism or the sacrament. Private mass was performed in them by chaplains or presbyters appointed for the express purpose, who had the title of local or stationary; and in order to distinguish the parish priests from those who offici-
ated in the oratories, they assumed the name of cardinals, or cardinal titles, because their functions implied the privilege of administering the sacraments, from which the priests of the oratories were precluded. Though this appellation was exceedingly general, yet in a short time it was confined to those at Rome who assisted the Pope at the celebration of the mass, or attended him when any public procession took place.

The number of cardinals has been exceedingly fluctuating. Like all institutions that have existed for a long series of years, their number was originally inconsiderable. The deacon cardinals at first only amounted to seven, and were gradually augmented to fourteen and eighteen. They were afterwards reduced to fourteen. The priest cardinals are to the number of fifty, which, with the six cardinal bishops of Ostia, Poro, Sabina, Palestrina, Frascati, and Albano, make generally the number of seventy. It was a favourite object with the church of Rome to render the whole of its rites and ceremonies, and even the different orders or ranks which composed the whole, as sacred as possible. As they could derive little sanction from any precedent in the New Testament, they therefore had recourse to the Old; and, by a singular conceit, a resemblance was supposed to exist between the pope and Moses, and the cardinals and the seventy elders of the people. Till the year 1125, their number was only fifty-two or fifty-three. The council of Constance reduced them to twenty-four. But as the see of Rome could never brook controul, Sixtus IV., totally disregarding the enactment of the council, restored the former number of cardinals, and Leo raised them to sixty-five.

When the pope purposes to create any cardinals, he causes their names to be read in the consistory, after he has informed those who are present frater habetis, that is, you have for brothers, &c. If those who are elected are not at a great distance, they are immediately sent for, and they receive red caps from his holiness. The cap is sent to those who are absent by a person of distinction, but they must receive the hat from his own hands; and when they are introduced for this purpose, they are received with great pomp and ceremony. Their dress, like that of all the different orders in the Romish communion, is prescribed, and defined with great accuracy. It consists of a rochet, over which is a short purple mantle; and, upon extraordinary occasions, the mozzetta, and a papal cap over it. The colour of their garment is either red or violet, according to circumstances. The regular cardinals wear no silk, nor any other colour, excepting that of their order. The red hat and cap are common to them all.

Whatever may have been the original occasion of the institution of this singular order, or by what means soever they acquired that ascendency over all the ecclesiastics of the same communion, it must appear evident, that in arranging the various ecclesiastical and political measures which were deemed most expedient to be adopted, the pope himself was altogether inadequate. His claim to supremacy, as well as that of the city of Rome to be considered as the metropolitan city of the Christian world, naturally gave a precedence, or rather a most substantial influence to those of the hierarchy who were near to the pope's person, and whose interest so powerfully co-operated with that of his holiness. In the course of time it became an object of the highest ambition to enterprising men to obtain a cardinal's hat. This was sometimes the reward of literary merit, or of having rendered essential services to the papal see; but, in general, the chapter consisted of opulent ecclesiastics, who, in consequence of their own private fortune, and the affluence and high rank of their family, or the political influence which they possessed at the different courts of Europe, rendered them persons upon whom it was expedient to confer honours. The cardinals can be viewed in no other light than that of the pope's privy council. All measures of state, or whatever regarded the real or supposed interests of the Catholic church, were first the subjects of consideration in the conclave, and the sanction of their authority was necessary to the validity of any measure which related to the interests of the church. Besides the influence that they necessarily possessed as the advisers, and even the leaders, of papal politics in the city of Rome, they were frequently employed in negotiations in foreign countries; and as a proof of the immense power that was vested in the Pope, they were designated legates a latere. They were thus inferior to the Pope, but in rank superior to any one else. Whatever may have been the manner in which the patriarch of Rome was at first elected, it is certain, that for many ages the cardinals have claimed this privilege as their unalienable right. They have even gone farther, and succeeded in establishing it as a settled point in ecclesiastical policy, that the head of the Romish church must be elected from their body.

So eagerly did the Pope enter into this right, that Stephen ordered the body of his predecessor to be dug up, because he had only attained to the rank of Bishop when he was elevated to the papal chair. It was Urban VIII. who expressly commanded, that the cardinals should be addressed by the title of eminence. This decree was promulgated in 1630; previous to that period they were called most illustres. They have long been esteemed as possessing a rank next to the pope. See Du Cange, Omphrins, Du Darent, Moveri, Ciacomus, and Mosheim. (n)

CARDINAL Notes, in music, are, according to Ambrose Warren, those with long finger-keys on the organ, otherwise prime notes, viz. A, B, C, D, E, F, and G. The remaining five notes he calls adjuncts, or supplemental notes. (g)

CARDIOSPERMUM. a genus of plants of the class Octandria, and order Trigynia. See Botany, p. 204.

CARDOPATUM. See Brotêra.

CARDS, Playing. As neither the manufacture of cards, nor the history of card playing, are subjects of any interest or importance, we shall merely refer our readers to those sources from which they may obtain information on these points.

In the 8th volume of the Archæologia, Daines Barrington, Mr Bowler, and Mr Gough, have written essays on the antiquity of card playing.

An account of the art of making cards by M. Duhamel, and approved of by the Academy of Sciences,
CAR

will be found in the *Mem. Acad. Par.* 1762. p. 169. The existing laws respecting cards will be found in the *Act 43 Geo. III.*

**CARDOUS**, a genus of plants of the class Synge-
nessia, and order Polygamiæqualis. See Botany, p. 293.

**CAREX**, a genus of plants of the class Monocotyle,
and order Triandria. See Botany, p. 320.

**CARGILLIA**, a genus of plants of the class Poly-

**CARIA** was an ancient kingdom in Asia Minor; the limits of which are defined so differently by different authors, that we should be tempted to reject their authority altogether, were it not more congenial to the spirit of legitimate criticism to reconcile their discrepancy, by supposing that they describe this region as it was extended or contracted at different periods. We, perhaps, approximate as near as possible to the truth, when we say, that it was bounded on the east by Phrygia and Lydia; on the south by the Mediterranean Sea; on the west by the Ægean sea; and on the north by Ionia and the river Me-
ander, which separated it from Lydia. Surrounded
by the sea on two sides, its inhabitants were drawn to maritime affairs more than to agriculture; and hence its valleys, though numerous and well sheltered, were not so fruitful as the hand of industry might have rendered them; but its mountains were covered with flocks, the wool of which, from its superior quality, formed an article of commerce with the neighbouring states. The principal cities of this dis-

tribute, on the south, were Calinda, Caminus, Physcus; on the west, Cnidos, Ceramus, Halicarnassa, My-
dus, Miletus; and in the interior, Antiochia, La-
dicea, Trapazopolis, Aphrodiasis, Apollonia, Alba-
nda, Stratonic, Tendeba, Pedasa, and Alinda.

Nothing is more difficult than to trace the name and the inhabitants of an ancient dynasty to their source, and in the present case we are involved in the deepest obscurity. Whether the Carins, as they assert, were aborigines, or, according to the assertion of others, Pelasgians or Cretans, is unknown; but the country rises on the page of history at a very early period under the name of Phœnicia,—a name originating in the dominion which the Phenicians exercised over it. Car, who has descended to us as the brother of Lydus and Mysus, two princes who gave names to Lydia and Mysia, accompanied by a band of his countrymen, emigrated from Macedonia, the ancient name of Lydia, over which his father reigned; and settling in this region, called it Caria, a name derived from his own. This account, given us by Herodotus, receives some confirmation from a temple built at Mylasa, dedicated to Jupiter the Carian, and in which, from the most remote antiquity, the Carins, the Lydians, and the Mysians, assembled together, as if descended from the same source, to worship their common god. Governed by the wisdom and defended by the bravery of Car and his descend-
ants, the inhabitants of this country rose to power and to eminence, wrested the island of Rhodes from the Phenicians; and, emboldened by this first suc-
cess, embarked their daring veterans, and subjugated the other islands of the neighbouring seas. To re-
conclde the contradictory accounts which Thucydides and Herodotus give of their history after this period, we must suppose, with the former, that Minos II. forced them, at first, to abandon these islands; and, with the latter, that he afterwards allowed them to return to their possessions, upon receiving from them a number of ships to increase his navy. But when Greece advanced in power and enterprise, she landed various bands of bold adventurers on the coasts of Caria, and drove the inhabitants to the mountains and barren parts of the country. The hardships and dangers, however, to which the natives were thus ac-
customed, gradually formed them for the most daring exploits; and incited them, not only to recover the territory which they had lost, but likewise to push their conquests and their commerce by sea. It was
about this period, that, having acquired by their skill and courage high military renown, they began as mercenaries to assist the neighbouring nations that were engaged in war; and their assistance was amply sought and liberally rewarded. When, therefore, eleven of the twelve kings, who had divided Egypt
among themselves, joined to expel Psmettichus from his division; that wise and magnanimous prince en-
gaged the Carins with some other mercenaries to es-
pouse his cause; and it was chiefly by their means that on the field he extinguished the hopes of his ri-
vals, and united under his authority the kingdom of Egypt. About this period the independence of the Carins was threatened by Alyattes king of Lydia, who invaded their territories with a mighty army; but their address or bravery either averted or braved his superior power during his whole reign. The hap-
ier destiny of Croesus, however, accomplished what his father attempted; and in his victorious career, he rendered Caria dependent upon his throne, though it appears still to have been governed by its own kings. The friendship which the Carins had formed with the Egyptians in the days of Psmettichus continued during the three successive reigns; and when Apries, the last of his race who wielded the sceptre, en-
deavoured to subdue his subjects who, under the com-
mand of Amasis, opposed his tyranny, the Carins defended the authority and shared in the disgrace of that monarch on the plains of Memphis. They after-
towards entered into an alliance with the usurper, which was confirmed with Psmmetnitus his son; and
the bravest of his forces fell on the field of battle when that monarch yielded to the superior fortune of Cambyse and his Persians. The remainder of their troops returned to their own country, which was now almost reduced to a province of Lydia; but the ven-
gence of the Persians still pursued them, till in the
wreck of the neighbouring kingdoms, they swelled the triumph of Cyrus. But though subject to Persia, they were still governed by native princes; and when Xerxes formed the inglorious design of extinguishing the liberty of Greece, Artemisia I. who then ruled in Caria, augmented his fleet by joining him with her own, which she commanded in person. When that
monarch held a council of war to decide on the prop-
erty of engaging the enemy's fleet at the Straits of Salamis, this princess was the only person who had the wisdom and the courage to oppose the king,
who was bent on the engagement: but when the attack was made, and the destruction of his fleet blasted the hopes of Xerxes, the same spirit which induced her to dissuade him from the dangerous enterprise, induced her also to maintain the combat with the most determined bravery. Her squadron was the last which retired from the conflict, and the reward of 10,000 drachmas which the Athenians offered to the person who should take her captive, as well as the declaration of Xerxes, that the men fled like women, and the women fought like men, consecrated her fame to future ages.

In this state of degradation, Caria groaned till about 444 years, B.C., when Lydamis, either by the friendship or the permission of Persia, ascended the throne. The page of history has preserved little more than his name, and the names of several of his successors, from oblivion; and after a long and an inglorious interval, we find the sceptre in the hand of Mausolus. This prince, who changed the seat of government from Mylasæ to Halicarnassus, not only united and strengthened his native dominions, but took the advantage of the death of Artaxerxes to shake off the Persian yoke, and establish the independence of his country. He then gained signal advantages over the Ionians, Lydians, and Lycians, and assisted the inhabitants of Cos and Rhodes to break the fetters of Athenian slavery. But the glory of delivering them from a foreign yoke was for ever obscured, when by corrupting their nobles he subjected them to his own; but at his death, they not only asserted their independence, but carried their arms into Caria. Artemisia II. the widow and sister of the late king, who had assumed the government, commanded the inhabitants of Halicarnassus to receive the Rhodians with the greatest demonstrations of friendship, in order to cut them off by stratagem; and when they were allured from their ships into the city, before ever they were aware, they were surrounded and slain. Artemisia having seized, by surprise, their fleet, set sail for Rhodes, entered the port amid the gratulations of the unsuspecting multitude, took possession of the capital, and slew all who had promoted the expedition into Caria. The Rhodians applied to the Athenians for assistance; and the Athenians, fired by the eloquence of Demosthenes, enabled them to expel their oppressors.

At the death of Artemisia, which happened soon after, her brother Idrieus ascended the throne, acknowledged his dependence on Persia, and, in obedience to Ochus, fitted out a powerful fleet, which, under the command of Phocean, made a descent upon the isle of Cyprus to subject it to the Persians, from whom it had revolted. But, though the siege of Salamis was begun, nothing was performed to arrest our attention. At the death of Idrieus, Adda, his widow and sister, who had gained the affections of the Carians, seized the government, but was soon driven from her capital by Pexodorus, whom Darius had made viceroy over that kingdom. To Pexodorus, Orontabatus succeeded; and Adda was forced to shut herself up in the city of Alinda, which she fortified, and held in defiance of her enemies. But when Alexander marched to subvert the throne of Persia, he was welcomed and assisted by Adda; and when that prince had levelled with the ground the walls of Halicarnassus, which alone dared to check his victorious career, he established her authority over all Caria. Her reign was, however, short; and in her was extinguished the royal race, and the independence of her country. At the death of Alexander, Caria composed a small part of the territories that owned the authority of Cassander; it has since shared in the revolutions which have agitated Asia Minor, without the hope of vindicating its freedom; and there is no probability that it will ever again claim the honours of an independent state. (t. k.)

**CARIBBEE ISLANDS.** is the name given to a semicircular range of islands lying between Anguilla and Tobago, between the parallels of 11° and 19° of north latitude, and including both these islands. The principal islands, beginning from the north, are Anguilla, St. Martin's, St. Bartholomew, Barbuda, Saba, St. Eustachia, St. Christopher's, Antigua, Montserrat, Guadaloupe, Martinique, St. Lucia, Barbados, St. Vincent, Grenada, and Tobago. A full account of these islands will be found in this work under their respective names. (o)

**CARICA,** a genus of plants of the class Dicocia, and order Decandria. See BOTANY, p. 337.

**CARILLONS, or Bariolons,** in music, is the name of small instruments furnished with bells, properly tuned, that are acted on by finger keys, like those of the piano-forte, and used for accompanying certain songs, where the ringing of church bells are to be imitated, and where dampers are not used, for preventing the continuance of the sound. In Holland and some parts of the Netherlands, the steeples of the churches are furnished with a large series of bells, tuned accurately to the tones and half-tones of the scale, and with strong wires that are connected at one end with hammers that strike the bells, and at the others with keys, and pedals for the lower notes of the scale, on which persons called Carilloneurs perform music in parts, by striking the keys rather forcibly with their hands and feet. (y)

**CARINI,** a town of Sicily, situated in the fertile valley of Muzora, and from some ruins supposed to be built on the site of the ancient Hyccara. The town, which is nearly built, is encircled by high rocks, and the adjacent country is highly cultivated, and produces grain of all kinds, olives, fruits, and manna. Swinburne makes the population 4000, and Denon 7000. See Swinburne's Travels, vol. ii. (o)

**CARINTHIA,** a duchy of Germany, in the circle of Austria; bounded towards the east by Styria, towards the north by the same duchy and the archbishopric of Salzburg, to the west by Tyrol, and to the south by the Venetian territories and by Carniola. It is situated between 46° 20' and 47° 6' N. Lat., and between 12° 32' and 14° 50' E. Long. Its greatest length, from east to west, is about 118 miles, and its greatest breadth about 50. The aspect of this country is in general woody and mountainous. The Noric Alps pass through this province, whose tops of granite, rounded into immense domes, are covered with perpetual snow and ice. St Ulrich, St. Helena, St Verit, St Laurence, the mountains of Lobel which separate Carnithia from Carniola, and those mountains which lie in the direction of Tyrol,
Carinthia is described as one of the loftiest mountains that occur in this quarter. So much of the whole extent of the duchy is occupied by such elevated grounds, that though the vallies which run between them are abundantly fertile, the produce, upon the whole, is not ordinarily equal to the consumption. In compensation, however, for this defect, the means of a lucrative commerce are found in the productions with which this province more abounds, and which are more of a nature to be expected in a country so situated and distinguished by such characteristic features.

Carinthia abounds in valuable mineral productions. Its mountains yield very good iron. The principal mines of this description are at Huttenberg, Moosir, Loelling, Waldenstein, Sainte Gertrude, and St. Leonard. It has also copper mines at Fragant and at Lamberiberg. Carinthia has been much noted for its lead, of which the principal mines are at Villach, at Sittarnzab, and at Reibling. It has silver mines at Steinfeld and at Meiselden, and one of gold at Groskischheim. Of its iron mines, those near Friesach, on the north, and in the tract among the springs of the Lyser, are particularly famous. The iron of Friesach is perfectly equal in quality to that of Styria, which has gained such high reputation, and which we know to have been very long in possession of it, as we find it greatly extolled by Pliny and others of the ancients, and learn, that it was commonly used by the Romans in the manufacture of their swords. The lead of Carinthia is excellent, and it is an article of great consequence for this country. In that department, the mines of Villach are particularly remarkable, both for the abundance and the superior quality of their produce. The lead obtained here is commonly known in Europe by the name of the yellow lead of Villach. This substance occurs also in some of the contiguous districts, but is not equal in goodness. Lead mines have been wrought in Carinthia from a very remote era; that near Steibling has been wrought for 1100 years. The produce of this duchy, in the most considerable of its metals, has been thus stated: Of iron it is said to yield annually to the amount of 165,000 quintals, of copper 936 quintals, and of lead 37,000 quintals valued at 330,000 florins. The other mineral productions of most consequence in Carinthia, are calamine, bismuth, beautiful blue granite, marble, and alabaster, nitre, and boral earth. Of calamine there are found here several sorts, in all to the amount of 3400 quintals annually. In some places there occur likewise alum, vitriol, cobalt, sulphur, and other minerals of inferior importance.

The principal vegetable produce of Carinthia consists in its woods, pastures, and a few cultivated crops. Turpentine, the produce of the pine tribe, is procured from this quarter in abundance, as also birch juice. The vallies and lower parts of the hills furnish excellent pasture, which is further improved in the spots that admit of such melioration, by the culture of lucerne and of clover. The crops which in all countries in this quarter of the globe chiefly contribute to the subsistence of mankind, viz. wheat, rye, oats, and barley, are in greater or less quantity raised here, as well as generally in every district of the empire. The produce of wine is scanty, and the wine itself is of an inferior quality; but a wholesome beverage is found in the beers, or ales of two sorts, which are commonly brewed in the country. A great deal of cider is made here, which implies an abundance of the fruit from which that liquor is prepared. Besides apples, various other sorts of fruit trees are cultivated in this province, and to a considerable extent. A little flax is raised also, chiefly in the environs of Saxonburg; and, among the numerous medicinal and aromatic plants that cover the sides of the Noric Alps, there is one that is called in German Speik, (Spica Celica,) which is much esteemed by the Turks and other Eastern people as a perfume; and which, therefore, being collected and dried, forms a considerable article of commerce with the Levant.

The pasture grounds of Carinthia maintain great herds of cattle. The numbers of horned animals of different descriptions found in it in 1780, have been estimated at 47,836. The north-western parts of the duchy have been chiefly noted for this sort of stock. The common breed generally throughout the province is good and strong, though not of the largest size. Dairies are usual here of a similar description with those of Switzerland. The number of horses in the country, at the period alluded to, was stated at 21,490. Sheep are not numerous, nor does the pasture in this quarter seem, in general, to be well adapted to the maintenance of that species of stock. Swine are raised in considerable numbers in the eastern parts of Carinthia; and in the forests there are found wild-goats, as also bears, red, brown, and white.

The climate of Carinthia is such, as does not prevent the vines and corn of Turkey, though natives of a region so much more southerly, from arriving at perfect maturity. The air is somewhat cold, but it is pure, tolerably equal, and wholesome. The prevailing winds are the west and the north-west. The range of the thermometer in the vallies and low-lying grounds is from 35° to 40°. This extent of variation is not considered to be so dangerous to health as the occasional stagnations of the air amongst the hills. The winter season lasts here for the space of three, sometimes four months. The spring is mild and kindly, rarely very wet. The summer is pretty warm, but attended with much stormy weather. The most agreeable season is the autumn, reckoning from its commencement till the end of the vintage. The harvest is usually begun, perhaps even far advanced, by the middle of July.

The duchy of Carinthia abounds in lakes, brooks, and rivers. The largest of its lakes, known by the name of Wordsee, is eight miles long. Its principal river is the Drave, which, issuing out of the Tyrol, traverses the whole of this province in a di-
Carinthia.

Carinthia is divided into the Lower and the Upper Carinthias. In the former division, the principal towns are Klagenfurth, St Veit, Friesach, Villach, St Andrée, Wolfberg, and Gurk. Those of Upper Carinthia are Villach and Gumnd. The states are constituted here as in Austria, their assemblies being held at Klagenfurth, which is considered as the capital of the whole province. This is the seat also of the ordinary administration for one part of the duchy; that for the other is at Villach. The military establishment of Carinthia is under a governor or land-captain. A regiment of foot is usually quartered here; and to the military state of the house of Austria it has been accustomed to contribute annually to the amount of 637,695 florins.

Christianity was introduced into this duchy in the 7th century. The system of religious belief and practice generally acknowledged over the whole of it, is that of the Roman Catholic Church; which properly, indeed, is the only one that is tolerated, though there are also found in the country many Protestants and adherents to the Lutheran doctrines. There are here two bishoprics, nine chapters, and nineteen convents. The bishops are those of Gurk and Lavant, who are subject to the archbishop of Salzburg; in which dignity, as well as in the bishop of Bamberg, there is also vested a considerable portion of the territory of this country.

In regard to the spirit of industry, and of manufacturing and commercial enterprise, the people of Carinthia, compared with the inhabitants of the other provinces of the empire, hold a sort of middle state, having their minds less-directed towards such objects than the inhabitants of Bohemia, Moravia, and Austrian Silesia; but in a proportional degree more so than those of Hungary, the two Gallicias, Transylvania, and Istria. As to the matters which in this department have principally excited their attention, this, of course, fell to be-regulated in a great measure by the nature of their produce. The mines are the great source of the riches of Carinthia; and its principal manufactures, accordingly, are those of steel and iron. In 1789, Carinthia is reckoned to have had 149 wire-drawing mills, 82 forges for nails, and 267 ordinary forges. Here the renowned steel denominated Brescia is made. The manufacture of arms at Fertlach occupies 500 persons. There is also at Friesach, in this district, a great manufactory of silver lace. From the lead that is furnished here in such quantity and perfection, a great deal of coarse is prepared. Goats' and chamois skins are also a considerable object of attention, and the workmen in those branches are in high reputation. One of the principal branches of the commerce of Carinthia, is that which consists in the transport of those vast numbers of cattle that are sent from that country into the states of Venice. It exports, at the same time, various other articles, either in the form of raw produce, or of manufactured goods. These are chiefly its iron, steel, lead, copper, calamine, flax, linen, hides of animals, horses, grain, and cloth.

Its imports are wines, spirituous liquors, sugar, cotton, coffee, drugs, corn, cloths, and salt. This country is stated to sell, in common years, to the amount of 1,470,373 florins, and it buys to the amount of 895,172 florins; thus obtaining a balance in its favour to the amount of 575,201 florins. In a more general view, the whole extent of the income of the duchy has been considered to amount to 2,550,897 florins; its annual expenditure to 2,342,564 florins; thus leaving to it disposable funds the amount of 208,333 florins. Of the whole aggregate of the returns which this duchy obtains annually from articles exported, more than a half is commonly derived from the produce of its mines. The trade of the duchy, in general, is maintained and regulated by its chamber of commerce.

The amount of the sums which the province of Carinthia has contributed to the general funds of the state, has for several distinct years been reckoned to stand thus: Busching estimates the contribution for 1770, at 2,386,884 florins. Schlezer states its contribution for the year 1780, to have been 1,250,000 florins. In 1903, according to the manual of Francfort, Carinthia contributed to the general funds of the state 2,500,000 florins; or, according to Ockhart, 2,600,000. The annual return from this province to the Montanianum, or that particular revenue which the emperor derives from all the mines in his dominions, is 48,351 florins.

With respect to the situation of its towns, the appearance of its buildings, or other circumstances chiefly of a local nature, Carinthia offers little to attract particular attention. Klagenfurth, though it cannot be called handsome, is yet a large and pleasing town, and contains several considerable edifices, as well as spacious squares. This is the residence of the princes of Porzia and Rosenberg, and a great number of counts and inferior nobility. The streets are spacious, intersecting each other at right angles; and the public monuments, statues, and fountains, which are of generally large dimensions, though they convey no very favourable idea of the state of the arts in the country, yet serve to give to the place an appearance of dignity and importance. The city is surrounded by walls and a ditch, but these are not in any respect of such a nature as to constitute it a place of strength. St Veit is a pretty town, with handsome houses, and a spacious market-place. There is here a fine fountain, the water of which falls into a basin of good form, hewn out of a single block of white marble, and which, according to Busching, is five fathoms in circumference. This is said to be a Roman antiquity. About half-way between these towns is a swampy tract, called the Saaler-moss, which has been considered by some to be the site of the ancient Tiburnia. Busching says, that on this plain there are still to be seen the ruins of an ancient town; but Kuttner, when travelling in that quarter, could not, it seems, discover the traces of any such ruins, nor even learn by tradition any thing of their existence.

Wens are a prevalent disorder in Carinthia, as well as in the adjoining province of Styria. When these have attained a certain size, they may generally be considered as indicative of a state of idiocy. Hence it is, that cretins, or idiots, are not uncommon in
CARLISLE, a city of great antiquity, in the north of England, and the capital of the county of Cumberland, is delightfully situated in a fertile vale, on the south side of the river Eden, which falls into the Solway Frith, five miles below; having the Pettrell on the east, and Caldwel on the west, both of which empty themselves into this river, the former about a mile above the city, and the latter about half a mile below it. It was till very lately surrounded by ancient walls, most part of which have been removed, in order to afford materials for the construction of the new court-houses, and to enlarge the town. Various opinions have been entertained by antiquarians respecting the etymology of the word Carlisle. It was called by the Romans and Britons, Luguballium, and Luygallia, or Luguballia. The most probable notion is, that it is derived from the Celtic, Caer, a city; and Lucl, signifying the town or city of Lucl.

The history of Carlisle, prior to the time of the Romans, is involved in much obscurity; nor have we any well authenticated account of the size or form of the place in distant antiquity. Leland, an author, whose accuracy and veracity can hardly be disputed, observes, "The hole site of the town, is sore chaungid. For whereas the strectes were, and great edifices, now be vancant and garden plothes. The cite of Caerucl stondeth in the forest of Ynglewood. The cite ys yn compace scant a myle, and ys walled with a right fayre and stronge wal, et lapide quadrato subrasto. In diggyng to make new buildyngs yn the town, of tymes hath bene, and now alate founde diverse foundations of the old cite, as paimentes of strectes, so hold and maidid, that when yt was strongly touched yt went almost to mowlder." After the departure of the Romans, it declined till the 7th century, when Egfrid, king of Northumberland, rebuilt it, and encompassed it with a strong wall of stone. From the time of this prince to the arrival of the Danish invaders, it is supposed to have been much augmented in importance and power. When, however, those barbarous ravagers had possessed themselves of the northern part of this island, it appears to have undergone a destruction so complete, that it continued a heap of ruins till the time of the Norman conquest, when one of William's subjects is said to have built some parts of the city. But it was not till the reign of King William Rufus, that the ecclesiastical buildings were erected, and the city fortified. Henry I erected Carlisle into a bishop's see, and appointed Adelulph, his confessor, the first bishop; and likewise completed the monastery. Stephen, about the beginning of his reign, gave this country to David, king of Scotland, to procure his aid against Henry II. After the death of David, which happened not long after, Stephen took Carlisle from the Scots, and granted to the city the first char-
Carlisle lies on the river Eden, which was afterwards consumed by an accidental fire. In the 29th of Henry VIII. Carlisle was besieged by an army of 8000 men, and being repulsed by the garrison, were afterwards intercepted by the Duke of Norfolk, who ordered the leaders with 70 others to be immediately executed on the city walls. In 1644 this city was surrendered to the parliament forces under General Leslie, after a siege of nearly eight months. In 1745, Carlisle was taken possession of by the rebel army, commanded by Charles Edward Stuart, and afterwards retaken by the king's forces, under the Duke of Cumberland. During these unhappy times, Carlisle was a place of considerable military importance, and kept up the appearance of a formidable place; sentinels were stationed at every gate, on the walls, at the castle, &c. and the gates were shut and locked every night with much military parade; and, as a signal when to shut the garrison gates, a gun was fired in twilight, when a white horse could not be seen at the distance of a mile from the fortifications.

So late as the beginning of the last century, the dwellings of the inhabitants were mere hovels, constructed principally of wood, laths, and mud; the gables fronted the streets, the doors were generally in the centre, and many of the houses had porches projecting two or three yards into the streets. The front door was arched or Gothic, to correspond with the gable, and the diminutive windows were of the same order. The doors were of oak, remarkably strong and clumsy, put together with wooden pins, a part of which projected a considerable way from the door, and sometimes placed in figures romantically irregular. The streets were badly paved, and had ditches or kennels on each side, which being the reservoirs of all kinds of filth, rendered the air impure, and consequently the city very unwholesome. But as the prospect of future warfare vanished, trade and manufactures began to increase, and an equal augmentation of wealth, spirit, and taste for improvement, took place; so that Carlisle, at the present day, in the openness of its streets, neatness and elegance of its buildings, and respectability of its inhabitants, is excelled by few towns of equal size in Great Britain. Carlisle affords several commodious inns, and maintains an intercourse with other parts of the island by several regular mail and stage coaches, waggons, &c. There is a stone bridge over the Caldew on the west side, leading into the city, and one on the north side over the river Eden, one of two and the other of eight arches; all of which are extremely narrow and ill constructed. Parliament have very recently granted the sum of £10,000 to the county, for the purpose of building a new bridge over the Eden; and we understand that the magistrates have ordered it to be immediately begun.

From the market-place, the principal streets, called English-street, Castle-street, Scotch-street, and Fisher-street, diverge as from a centre. At the head of the latter, is the ancient Guild hall, a mean edifice; built of brick, and appropriated to the meetings of the eight free trades, viz. merchants, butchers, tanners, weavers, tailors, skinners, smiths, and case-makers.

Carlisle contains a few public buildings deserving of particular notice. The Cathedral church of St Mary's, is a venerable structure, partly of Gothic and partly of Saxon architecture; where is performed the parochial and cathedral service, and in a part of it the chancellor of the diocese holds the consistory court. The choir and aisles of this building are of beautiful Gothic architecture, with clustered columns and pointed arches. In the aisles, on each side, are many singular legendary paintings, of the history of St Augustine, St Cuthbert, and the Romish St Anthony. In the Abbey, contiguous to the church, and in which the church properly stands, are several ancient buildings, the deanery, fraternity, &c., which has been lately considerably improved by the dean and chapter. St Cuthbert's, the other parish church, is a modern edifice, plain, and without ornament. Besides these two churches, there is, in Carlisle, a Quaker's meeting-house, a Presbyterian chapel, two Methodist chapels, an Anabaptist chapel, and a Catholic chapel.

The castle is situated on a gentle eminence, at the north west extremity of the city. The donjon, or great tower, whose walls are 12 feet in thickness, constructed agreeably to the old mode of defence, was formerly strengthened by a draw-bridge over a wide ditch; there is also a half-moon battery mounted with cannon, and a large platform also mounted under cover of the outer wall. A well of vast depth, within the tower, supplied the garrison with water. In the outer castle is a fine grass plot, a garden, a governor's house, and an armory lately erected, capable of containing 10,000 stand of arms. Here the dreary dungeon is shown the curious visitor, where Mary queen of Scots, whose beauty, misconduct, and misfortunes are alike famous in history, was confined, after her defeat at Langside. During her imprisonment, the royal captive used to walk in front of the castle, which yet retains the name of the Lady's Walk; and tradition says, that with her hand she planted some ash trees, whose spreading branches till lately shaded this consecrated walk.

That the castle of Carlisle has been a Roman fortification, there can hardly exist a doubt; but having always, in times of commotion and tumult, been the assailable point, it has undergone so many alterations and repairs, that there is scarcely a fragment of the original building to be discovered. The old centre tower, or keep, appears, from the stile of the architecture, to have been constructed in the reign of Edward I.; and at some parts of the base of the external buttresses of the north wall, where the modern casing of stone added to it in the reign of Henry VIII. is broken down by the decay of the embankment below, a part of the original may easily be observed. The stones of this wall being different from any in the other parts of the building, and corresponding exactly with the materials that compose the remains of the great Roman wall which crossed the northern counties of England, it is not unreasonable to suppose the castle nearly of the same date, and, consequently, erected by the Roman emperor Adrian. The base of this still extends to the bottom of the hill on which the castle stands, and has been erected as a bulwark to defend and secure the fabric against the floods of Eden, which river ap-
there to have formerly run under the castle walls. The various alterations and additions that have been made to the castle at different periods, can easily be traced to the reign of Elizabeth, when it underwent a thorough repair; and from thence to the time of Oliver Cromwell, when the keep was converted into a battery, and long guns, in order more effectually to command the town, mounted on the roof.

In 1807, an act of parliament was obtained for erecting court houses, &c. on the site of the citadel adjoining the English gate. The work was immediately begun, on a very extensive plan, and is now nearly completed. The citadel was a very large building, consisting of a strong square tower, connected to two large bastions, and was built by order of Henry VIII.

The county goal is a mean edifice, built of stone, and situated at the head of English Street. No furniture belongs to the prison, but what is found by the unfortunate persons confined there, who are allowed merely straw for their beds. The city prison is placed above the Scotch gates.

The town hall, or Moot Hall, and council chamber, stands in the centre of the city, where is held the courts of assize, the quarter sessions, the mayor's court; and there two members of parliament are elected for the city. The council chamber is ornamented with a cupola and clock.

Carlisle contains few charitable institutions. A dispensary was established in 1782, where the medical gentlemen are in the habit of giving their advice and attendance gratuitously. The apothecary, whose duty is to prepare and deliver the medicines prescribed by the physicians, has a salary of about £60 per annum. There are two workhouses for the maintenance of the indigent poor, a school of industry, where thirty girls are taught sewing, writing, reading, &c. and two schools supported by subscription, one on Lancaster's and the other on Bell's plan, besides Sunday schools.

The corporation consists of a recorder, twelve aldermen, twenty-four common councilmen, and two bailiffs. One of the aldermen is annually elected mayor, and the other annual placemen are chosen out of the common council. The subordinate officers are three sergeants at mace, five beadle, or town scavengers. The sergeants act as bailiffs in processes before the mayor's court; and to them is committed the execution of summons and writs of arrest for debt issued for it. The sergeants and beadle wear the corporation livery, which is brown turned up with red; and their places are generally for life. The office of the latter is to keep the streets clean, and to put into execution the punishment awarded to offenders within the mayor's jurisdiction. The liberties of the corporation extend a few yards without the site of the city walls, and are ascertained by what is called the Free-bridge-stone.

The printing or stamping of cotton was first established in the year 1761, which was followed by weaving, and afterwards spinning; all of which branches have been carried on to a very great extent. Carlisle was formerly celebrated for its manufacture of fish hooks and whips, though not much so at present.

There are four public breweries, and three iron and brass foundries. It also possesses five flourishing banks, two of which issue notes on their own account. The importations to Sandfield, commonly called Port-Carlisle, consist principally of iron, tar, deals, slates, salt, sugar, rum, &c.; and the exportations consist of grain, oak bark, flour, timber, lead, alabaster, &c.

The air of Carlisle is particularly salubrious. The population of the city and suburbs, accurately taken at four different periods, was as follows:

<table>

In the year 1802, the enumeration, according to act of parliament, was 1420 houses, and 10,875 inhabitants; of these 5133 were males, 5742 females. Owing chiefly to the establishment of cotton mills, and the spirit of trade, the population has of late years been rapidly increasing. The following are the population returns for 1811:

The market day, every Saturday, is abundantly supplied with provisions of all sorts, and is considered by the farmers as one of the best corn markets in England.

Immense strata of siliceous sandstone, usually denominated freestone, occur in the neighbourhood, from whence the stones employed in building are principally obtained. Gypsum, or alabaster, is also found here. Several Roman coins and antiquities have, at various times, been found in and about Carlisle. Distance from London 301 miles; from Edinburgh 96; from Dublin 200. For further information on the subject of this article, see Hutchinson's History of Cumberland. Burns and Nicholson's History of Cumberland. Camden's Britannia. Hook's Archæologia. Horsley's Britannia Romana. Leland's Itinerary. Pennant's Tour from Downing to Alston Moor. Jollie's Cumberland Guide and Directory. (f.s.)

CARLISLE, New, the principal town in the county of Cumberland in Pennsylvania, is pleasantly situated in a plain near the southern bank of Conewgwinet creek, a water of the Susquehanna. The houses, which are built of stone and brick, are tolerably good. The town is regularly built, the streets intersecting each other at right angles; and the principal public buildings are Dickinson's college, a court house and gaol, and four places for public worship, which belong to the Presbyterians, Germans, Episcopalians, and Roman Catholics. The college was founded by John Dickinson, Esq. the
CARLOW, or CATHHERLOGH, a county of Ireland, in the province of Leinster, bounded on the north by Kildare, on the north-west by Queen’s County, on the north-east by Wicklow, on the south-east by Wexford, and on the west and south-west by Kilkenny. The part of the county which lies to the west of the river Barrow, is covered with high and rough-hills, and in the south-eastern part that is contiguous to Wexford, there is another mountainous district, stretching from the rocky mount called Leinster to another eminence called Blackstairs. The level part of the county is rich and fertile, the soil is of a calcareous nature, and in many places the cultivation has extended considerably up the sides of the mountains. Leases which formerly ran for thirty-one years and three lives, have been of late granted for twenty-one years and one life; and the fee has been more transferred here than in any other part of the country. The average rents in this county are 5s. per acre. The following is a statement of the quantity of cultivated and uncultivated land.

Carlow is reckoned one of the first dairy counties in Ireland. The dairy consists of from 20 to 50 cows, and, during the season, produce 1½ cwt. of butter per cow. Barley of the best quality is raised in Carlow, and a larger quantity, is sown than in any other part of the kingdom. It is carried by the canal from Carlow to Dublin; and in the north it is consumed by the illicit distilleries.

Iron ore, a considerable quantity of oxide of manganese, limestone, marle, and a great variety of clays, are found in the county; but its mineralogy has not yet been carefully examined.

The principal river in Carlow is the river Barrow, which traverses the county from north to south, and forms its western boundary for many miles. This river is navigable, and its navigation has of late been greatly improved. The river Slaney also crosses the eastern part of the county, and, though small in size, it contributes to the beauty of the surrounding districts.

Carlow is about 33 English miles long from north to south, and 29 miles broad at its greatest breadth. It contains 220,098 English acres, or 334 square miles, and is divided into 50 parishes. The principal towns are Carlow, Leighlinbridge, Tullow, Pale- town, and Rutland, Hacketstown, Clongan, and, Gousbridge. The number of houses is 87,363, which, at the rate of five to each house, gives a population of 438,115. See Transactions of the Dublin Society; Young’s Tour in Ireland; Beaumont’s Memoir of a Map of Ireland; and Wakefield’s Statistical and Political Account of Ireland, London, 1812. (J)

CARLOW, CATHERLOGH, or CATHHERLOGH, a word which signifies the fortress in the lake, is the capital of the county of Carlow, and is situated on the east side of the river Barrow, in the north-west part of the county. The town, which is regularly built, is superior in riches to most towns in Ireland, and has some good public buildings. There are here some ruins of a fine abbey, which was built in A.D. 634. The town was formerly walled, and defended by a castle, which has a turret situated upon an eminence which overhangs the Barrow. Considerable quantities of coal and coarse woollen cloth are exported; and its trade is facilitated by the improved navigation of the Barrow, which communicates with Waterford river, and with the grand canal. Coarse implements, such as reaping hooks, scythes, or shears, are manufactured here. There is a large seminary in Carlow for the education of Roman Catholic priests. The part of the town called Graingo, on the Queen County’s side of the bridge, contains, in 1806, 1240, inhabitants, and Carlow 3335, in all, 6375 inhabi- tants, and 1109 houses. West Long, 59° 58’, North Lat. 55° 50’. See Beaumont’s Book of Roads; and, Wakefield’s Statistical and Political Account of Ireland, London, 1812. (J)

CARLSBAD, or WARY, a town of Bohemia, in the circle of Saatz, situated on the river Eger, and celebrated for its hot springs, which were discovered, in 1370, by Charles IV, while he was hunting. This town, which is now much frequented as a watering place, contains several public buildings, such as the church, the Hotel de Ville, the new theatre, the hall of Bohemia, and that of Saxony. The part of the town called the Wiese, or the Meadow, is the most healthy and agreeable quarter of the town. It consists of a long range of houses, before which is an esplanade adorned with fine cypress trees, and which stretches even to the banks of the river Toepel. The lower story of the houses is occupied by shops and work houses. Carlsbad is most frequented in the months of June and July. The principal manufactur- es of the place, are works of tin and Damascus steel; and the arms fabricated here are known over the whole of Europe. The principal spring, called the Sprudel, discharges, with great velocity, about 332 cubic feet of water hourly, through a curious natural vault, or incrustation of stalactite, and has a temperature of 165° Fahrenheit. An esplanade and a fine saloon, built by M. de Saldern, the Russian mi- nister, serves as a promenade to those who drink the
The waters of Carlsbad are used in a great variety of disorders, but particularly in dyspeptic complaints, obstructions of the abdominal viscera, diseases of the urinary passages and kidneys, and in the uterine system in females. About five pints, divided into fourteen cups, are drunk at an average by each individual every day. Several hundred pounds of sulphate of soda are annually prepared from the water. The regular population of Carlsbad is about 3000; and in the years 1799 and 1800, about 3000 strangers came to take the benefit of the baths. E. Long, 142° 52', N. Lat. 50° 14' 58''. See D. Becker, Abhandlung über das Carlsbad, 1789; 3 vols. 8vo.; Beschreibung von Carlsbad, Prag.; Carlsbad und die umliegende Gegend von Hubert von Harver, Prag. 1801, 8vo.; and Klaproth, Recherches chimiques sur les eaux de Carlsbad, Berlin, 1770, 8vo.

CARLSCRONA, a sea-port town of Sweden, in the province of Blekingen, South Gothland. It derives its name from Charles XI. by whom it was founded in the year 1680, as a station for his ships of war. He removed them from Stockholm to this place, which was greatly preferable, both on account of the convenience of its situation, and the safety of its harbour. And it has continued ever since to be the grand, or rather the only, depot of the Swedish fleet.

The principal part of the town stands on a small rocky island, which communicates with the main land by a strong dike and two wooden bridges. The mole, too, which lies close to the basin where the fleet is moored, is covered with houses; and there are several little islands immediately adjoining, on which the more wealthy inhabitants have their country-seats and gardens. These suburbs are fortified Carlscrona.

The Neubrunnen, or New Spring, is not so warm as the former. It has, however, been in great request for some years, and several changes have been proposed on the basin which receives it. Here is the Muhlenbad and the Theresebrunnen, with a house built by the Empress Maria Theresa, the lower story of which contains very fine baths, and apartments for the bathers. The Schlossbrunnen, or Spring of the Castle, has been more recently discovered. It contains more fixed air than the rest, and has a temperature from 120° to 125° Fahrenheit. The Kalte Sauensing is another excellent spring, which issues out of a rock of granite behind the brasiery, but has no basin. It is covered with a stratum of fixed air, about five inches thick.

According to the experiments of Klaproth, one hundred cubic inches of the Carlsbad water contains:

The harbour of Carlscrona is very large and commodious, being capable of holding 100 vessels. It has depth of water sufficient for ships of the largest size carrying their lower tier guns; and it is perfectly protected, both by nature and art, from any hostile attack by sea. Before it are many shallows, and nearly 100 inconconsiderable islands, which render the navigation quite impracticable to strangers. Ships of war, indeed, can only enter the harbour in one way, i.e. between the islands of Aspo and Turko, and these are furnished with batteries which completely command the passage. Formerly there was another way, but it has been shut up by sinking some frigates. There is still another entrance, but it admits of no vessels except those of light burden.

The new docks at Carlscrona give to this town its chief interest and importance. Originally ships, on undergoing repair, were laid on their sides in the open harbour. But in 1714, according to a plan of Folhem, whose mechanical skill is celebrated in Sweden, a dock of considerable dimensions began to be formed, by hollowing out the solid rock. This, however, though it was not finished till the year 1754, was found to be too small for men of war; and therefore it was afterwards enlarged to the capacity of receiving vessels of the first rate. In length it is 100 Swedish feet, in depth 33, and in breadth 46. When full, it contains 300,000 cubic feet of water, and is emptied by means of chain pumps, which require the labour of 90 men constantly employed for ten hours, and relieved every half hour. A dock so capacious, hewed out of the solid rock, was unquestionably a bold and grand undertaking; but it is far surpassed by the new docks which, in the language of Cours, "have been begun upon a stupendous plan, worthy of the ancient Romans." According to the proposed plan, accommodation is to be provided for twenty ships of the line, which are to be kept dry, and under cover. As these ships were to run directly from the sea into the docks, it became necessary to erect vast works, by which the violence of the waves might be prevented from doing them injury. For this purpose, it was requisite to have a solid foundation for the walls and dams, and also for the places in which the vessels were to stand, and to provide these with gates of large extent, and great strength. The ground, in its natural state, was not favourable for the purposes to which it was to be applied, some parts of it being very low, and other parts of it very high. The latter, therefore, consisting of granite rocks, were removed by means of gunpowder introduced through hollow tubes; and the former were filled up with massive flat stones, cemented with puzulana brought from Naples, and carefully reduced to a smooth surface. The form of the new docks is semicircular.
CAR

From the centre to the circumference it is divided into four divisions, each division having separate receptacles for five vessels—a distinct gate, 48 feet in breadth, and nearly thirty in height—and a detached edifice over it, with a copper roof. The walls, like the bottom, are of hewn granite, about 40 feet thick, and filled up in the middle with earth; and the roof is supported by rows of granite pillars, which give it a very magnificent appearance. There is one common entrance for the five ships, which each of the principal divisions contains. The docks and buildings connected with them, are separated from the town by a lofty stone wall, remarkable for having been erected by the Russian prisoners captured by Charles XII. As this wall, which was intended to provide against the communication of fire, is found to be of no use, Admiral Chapman has ordered the upper part of it to be taken down, and the materials thus procured to be employed for raising more necessary structures. The progress which has been made in this vast undertaking, has not equalled the hopes and views that were entertained at the outset. It was begun in 1757; and L. 25,000 were annually expended. The work, however, as soon as its novelty had ceased to interest, was much neglected. It was afterwards warmly patronized by Gustavus III.; but it was again allowed to languish. The annual expenditure was reduced to L. 6000. Instead of finishing a dock every year, as was proposed and expected, nine or ten years were wasted in executing the first, after it had fairly commenced; and even now, of all the four divisions of which the plan consists, only one has been completed since the year 1761; and in this, not more than three out of the five docks are ready for use. Of the other divisions little more has been done than to exclude the water.

The ships at Carlscrona are built chiefly by English workmen. The provinces of Blekingen and Scone not affording a continued supply of oak, this sort of timber is partly imported from Germany. But masts, deals, pitch, tar, and the greatest part of the flax used in the navy, are procured from the Swedish territories. Ropes and sails are manufactured from Riga hemp. Cannon is cast, and gunpowder made with Swedish saltpetre. Carlscrona is the place of residence for the governor of Blekingen, and is the tenth in order of those towns which vote in the diet. It is one of the four places in Sweden in which the Jews were permitted, by a decree of the state, to erect synagogues for their peculiar worship. Of the population of Carlscrona different statements are given by different writers. Catteau, in his General View, &c. makes it only 9000; but in his Travels in Sweden he makes it about 15,000. Coxe says that it is about 18,000; Reichard, between 12,000 and 15,000; Tornquist, from 15,000 to 18,000; and Kuttner 12,000. But the most correct information on this subject is to be found in a work entitled Diirberg's Beschrijving om Sverike, vol. i. p. 188; in which the population of the principal towns in Sweden is given from the best authorities. Diirberg makes the number of inhabitants in Carlscrona, in the year 1800, to be 13,800. E. Long. 15° 26' 15", N. Lat. 56° 20'. See Coxe's Travels in Poland, Russia, and Sweden, &c. vol. iv.; Catteau, Voyage en Allemagne et en Suede, &c. tom. ii.; Kuttner's Travels through Denmark, Sweden, &c. in 1798 and 1799; Diirberg's work, quoted above; and MalteBrun's Annales des Voyages, &c. tom. iii. p. 352. (r)

CARLSRUHE, or CARLSROUHE (signifying peace or repose of Charles), is a town in Germany. It is situated in the circle of Suabia, and marquisate (now electorate) of Baden, was founded in 1715 by the Margrave Charles William, and is now the residence of his successors, who have here a fine palace and delightful gardens. The plan on which the town is built is very regular; and it is also very singular, being in the form of a fan. There is a single street, about an English mile in length, running in a direction parallel to the front of the palace, and at a considerable distance from it. From this, all the other streets, amounting to thirty-two, go off at right angles, and are so arranged as to have their view terminating, at one end, in the front of the palace, while the other penetrates the forest by which the town is surrounded; and the houses are constructed with as much regard to uniformity as the streets, being all of equal size and height. The coup d'ceil from the top of the palace is said to be extremely beautiful and magnificent. Of churches, there are four; two for Protestants, and two for Roman Catholics. There is also a Jewish synagogue. The literary establishments of Carlsruhe are chiefly these—the Gymnasium Illustre; seminaries for educating village curates and schoolmasters; an institution for the deaf and dumb; and a type-foundry. There are here some collections of natural and artificial curiosities, which deserve notice. They consist of the library belonging to the Margrave; his physical cabinet; his cabinets of medals, of models, and of natural history; in which last, the collection of tulips is uncommonly fine. Besides these, there is a botanical garden; Gmelin's cabinet of natural history; Boeckmann's physical cabinet; and Becker's collection of prints. There is a charming promenade in the garden behind the palace, where there is a greenhouse that is reckoned the largest and finest in Germany. Many attempts have been made by the Margrave to introduce manufactures and industry into Carlsruhe, and he has had considerable success. He has induced several watchmakers from Geneva to settle in it, by granting them peculiar privileges; and many of the inhabitants, instructed by English mechanics who reside there, are engaged in steel manufactures, similar to those which are carried on in Birmingham and Sheffield. Meyer's work for grinding and polishing is deemed remarkably curious. The population is estimated at 10,000. See Reichard's Guide des Voyageurs en Europe, tom. ii. p. 57.; Stolberg's Travels; and Brieûe über Carlsruhe von Brunn. (s)

CARSTEDT, a town in Sweden, lying in the province of Woermeland, West-Gothland. It is situated on an extensive island, called Tingwalla, which is 12 miles in circumference, and is formed by the river Clara, dividing into branches, and afterwards uniting and falling into the Wenner Lake. It was built by Charles IX. in the year 1584. All the houses, excepting the cathedral and the school, are constructed of painted wood. The streets are broad
and straight; there is a number of spacious buildings; and, upon the whole, it is a pretty place, having the agreeable features of cleanliness and cheerfulness to recommend it to the stranger's eye. It is the see of a Bishop, who has here an episcopal palace: has the 38th vote in the order of the diet; and, according to Diirberg, contains 1800 inhabitants. There is a mineral spring in its neighbourhood. It has manufactories of linen and woollen; imports sugar, tea, and spices; and trades in iron and wood across the Wupper. East Long. 15° 18', North Lat. 51° 21'. See Coxe's *Travels in the North of Europe*, vol. iv.; and Kütter's *Travels through Denmark, Sweden*, &c. in 1798 and 1799. (r)

CARMAGNOLA, a town of France, in the department of the Po, and formerly in the marquisate of Saluzzo, is situated at a small distance from the right bank of the River Po. In the year 1691, the French fortified this town with walls and ditches, and enlarged the citadel. The Fauxbourgs, which were too large, were demolished; and it was thus rendered one of the strongest places on the frontiers of Piedmont. The same number of Fauxbourgs were afterwards rebuilt at the distance of 500 paces from the town, and as large as the former. Carmagnola is situated in a fertile country, abounding in grain, flax, and silk; and its market is much frequented not only by the Piedmontese, but by the inhabitants of Dauphiny, Nice, and the country of Genoa. There is only one parish within the walls of Carmagnola, and four in the Fauxbourgs. The population of the town and Fauxbourgs amounts to 12,000. East Long. 7° 45', North Lat. 44° 50'. See Tynna's *Almanach du Commerce*, pour 1811, p. 779; Denina *Tableau Historique, Statistique, et morale de la Haute Italie*, p. 17, Paris, 1805. (w)

CARMATHIANS, or KARMATHIANS. See the article *Arabia*, vol. ii. p. 304, col. 2.

CARMEL, a celebrated mountain in Palestine. Though spoken of in general as a single mountain, it is in fact rather a mountainous region, the whole of which is known by the name of Carmel, while to one of the hills more elevated than the rest, that name is commonly applied by way of eminence. It has the plain of Sharon on the south; overlooks the bay of Acre on the north; and is bounded on the west by the Mediterranean, forming one of the most remarkable promontories that are to be seen on the shores of that extensive sea. John Phocas, a Greek monk, who visited Mount Carmel in the twelfth century, describes it as having the form of a ridge, extending from the bay which winds by Ptolemis and Caiphas, to the Galilean territory. Josephus says, *Ambigu. I. iii. c. 3.* that Carmel was a mountain of Galilee. In another place, *Antig. lib. v. c. 1.* he states that Issachar, in length, lay for its limits Mount Carmel and the river; and that the tribe of Zebulon's lot included the land which belonged to Carmel and the sea. Theodoret *Comm. ad. c. 32. Jesuic* places Carmel in Samaria. Hieronymus *in Comment. ad Jes. 29.* describes it as situated on the confines of Phoenicia and Palestine, and overlooking Ptolemias. In a passage of the 4th vol. of Hudson's *Minor Geographers*, it is represented as lying immediately to the north of Dora. It belonged to the tribe of Asher and Manasseh, according to the division made by Joshua of the Holy Land. (See Josh. xix. 26. Keland. *Palest. Illustr. tom. ii. p. 599, and Calmet's Dictionary.* St Jerome informs us, that this tribe having remained in captivity with the other tribes, Carmel returned into the possession of the Phcenicians, its original masters. It is, according to Volney, about two thousand feet in height. It has the shape of a flattened cone. Its sides are steep and rugged. Its soil is neither deep nor rich. And among the naked rocks, stunted plants, and wild forests which it presents to the eye, there are few traces of that fertility which every reader of scripture naturally associates with the idea of Mount Carmel. Yet even Volney himself acknowledges, that he found among the brambles, wild vines and olive trees, which proved that the hand of industry had once been employed on this ungrateful spot. Of its ancient productiveness there can be no doubt; the etymology and ordinary application of its name being sufficient evidence of the fact. Carmel is not only expressly mentioned in the sacred writings as superior to other districts in that respect; but every place possessed of the same kind of excellence, obtained from it the same appellation, in the language both of the prophets and the people. Some accordingly suppose that Carmel was primarily the name of the mountain, and that on account of its natural or superinduced fertility, the name came to be transferred to all places that were distinguished by a similar character; while others think, that as the original signification of the word Carmel is a fertile place, the mountain in question got that appellation from its peculiar and acknowledged fertility. We shall not attempt to determine which of these opinions is the most correct—Ben David himself declines the task on account of its difficulty—but each of them implies a testimony to the ancient fruitfulness of Carmel. And it is curious, that the words of which that name is compounded, as well as the name itself, refer not only to the general quality ascribed to Mount Carmel, but even to the particular kinds of produce in which that quality appeared. Thus מַרְבַל signifies to cut off, to prune, מַרְבּל or מַרְבּל to fill, מַרְבּל a vine, and מַרְבּל a full ear of corn, a fruitful field or country, a place planted with fruit-trees. The word Carmel also signifies purple or crimson; because at the foot of the mountain, on the south side, a certain shell-fish was caught which was of great use in dying that colour. See Song of *Solom. vii. 5.* and also Bochart de *Animal. Sac. Scrip.*

Mount Carmel is celebrated in scripture as the abode of Elijah and Elisha. It was here that Elijah opposed so successfully the false prophets of Baal; (1 Kings xviii.) and there is a certain part of the mountain facing the west, and about eight miles from the point of the promontory, which the Arabs call Mansur, and the Europeans the Place of Sacrifice, in commemoration of that miraculous event. Here also, near the same place, is shown a cave, in which it is alleged the prophet had his residence, and in which, according to Phocas, "that wonderful man, after he had spent an angelic life, was translated into heaven." There is a small spot, too, which tradition represents to have been his garden. Mariti observes,
Carmel.

that the prophet seems to have inhabited successively every part of Mount Carmel; for almost all the fields, groves, and mountains, are still called by his name. On the summit of the mountain there is a chapel dedicated to Elijah, which commands a most extensive and delightful prospect. It is certain that Mount Carmel very early began to be an object of great veneration among both Jews and Christians, and that those parts of it which were particularly hallowed by his presence, have been always regarded by them with the most pious emotions. Chateaubriand gives an animated account of the impression made upon his own feelings and on those of the pilgrims who accompanied him, by the first view which they got of it. (See his Travels, p. 358.) And we are told that even the Mahometans, forgetting their principles and their prejudices, participate occasionally in the reverence which is felt for Mount Carmel, and invoke the images of the Virgin and Elijah, which are worshipped there in the Carmelite church.

Carmel is mentioned in profane history. Suetonius tells us, that Vespasian, when he went into Syria to subdue the Jews who had revolted, ascended this mountain to offer a sacrifice to the deity of the place, and to consult the oracle as to his future fortunes. Tacitus, (Hist. i. ii. c. 78.) in relating this fact, states, that the name of this deity was the same with that of the mountain; that there was no image or statue of him, and no temple erected for his worship; and that there was only one altar, on which sacrifices were devoutly offered to him. Jamblichus, however, in his life of Pythagoras, speaks of a temple there, to which that philosopher frequently resorted, for the purposes of solitary meditation. In the writings of Scylax, who, according to Gronovius, flourished in the reign of Darius Hystaspes, and whose geographical notices have been much restored by the labours of the learned Vossius, we read of Carmel as "the mountain and temple of Jupiter"—"Καρμελεις ἱερὸς καὶ θυσιαῖος Διὸς." There is a book written by Mendoza a Spaniard, and translated into Latin by Papenbrochius, which treats particularly of the god Carmel, and contains many things in proof or illustration of this point.

The order of the Carmelites has its name from this mountain, and, if we may believe some of themselves, takes its origin from the prophets Elijah and Elisha. Phocas, already quoted, gives an account of their origin as rational as any other. In 1185, when he was at Carmel, he tells us, that there still existed the remains of a large monastery, which time and violence had reduced to ruins; and that a few years before, one Berthold, an aged Calabrian priest, instructed, as he said, by a revelation from the prophet, erected a small temple or chapel, and having collected about ten brothers, took up his abode in that holy place. He was in this situation when Phocas was there. These Carmelites, in 1205, got a very rigid rule from Albert the patriarch of Jerusalem; which, in 1226, was confirmed by Pope Honorius III. and afterwards mitigated by Innocent IV. In 1229, they left the Holy Land under Alan, the 5th general of the order. Some of them were sent into Cyprus in 1238; some went to Sicily; and some were brought by St. Lewis into France. They came into England in the year 1240, and erected a great number of monasteries. In the 16th century, they divided into two branches, viz. Carmelites of the ancient observance, and Carmelites of the strict observance, or bare-footed Carmelites, which separation was confirmed in 1557 by Sextus V., and completed in 1593 by Clement VIII. The Carmelite order has always been eminent for its missions, and for the great number of saints with which it has furnished the Roman calendar. Its members received from several of the popes the title of Brothers of the Blessed Virgin.

On the mountain, the Carmelites have still a convent, which is almost wholly indebted to nature for its construction and accommodations. It has a small chapel, containing two altars, one of which is consecrated to the Virgin Mary, and the other to Elijah. Two priests and two Carmelite laics are here almost constantly at prayer. There are several cells and apartments destined for the use of travellers, and for the French inhabitants of Acre, who come hither sometimes for the benefit of the air. They are under the protection of the consulsip of Acre, and depend upon the charity of the Mahometans, who esteem them for their exemplary life. The ruins of the monastery formerly mentioned, which are as thick as the walls of a fortress, and have every appearance of solidity, hang over the cells of these Carmelites, who, afraid of being buried under them, an accident not unlikely to happen, have taken a great part of them down. Some of the grottos have been converted by the Mahometans into a mosque, under the title of El-haden, the green, in which a dervise, who with his family lives in a neighbouring hut, regularly performs divine service. Between this place and the convent of the Carmelites, along the whole declivity, there is a great number of cisterns, some of them very spacious, intended to hold the rain water which is collected during winter for the use of the monks. Most of them are now insufficient for that purpose, but there are some excellent springs at a little distance, which supply their place in the summer time or dry season. From one of these flowed a stream which passed along a canal cut out of the rock, and after turning a mill lost itself in the sea. Both canal and mill are now destroyed, and the stream is applied to no useful purpose. From the foot of the mountain proceeds the lake Cendevia, out of which flows the Belus, a river mentioned by Pliny, Tacitus, and Flavian, as famous for having its sand richly intermixed with glassy particles. This sand is taken away by foreign vessels as ballast; and from it were manufactured those fine plates of glass with which Venice long supplied the European market. The brook Kishon, which issues from Mount Tabor, waters the bottom of Carmel, and falls into the sea towards the northern side of the mountain, and not the southern, as some have erroneously alleged.

On Mount Carmel there are the remains of many magnificent buildings, which are calculated to give a grand idea of what they once were. Mariti tells us, that he saw the vestiges of many convents, and some most beautiful columns of oriental granite. According to Pliny, (Nat. Hist. i. c. 19), there was once a town here anciently called Ecbatana, and more re-
Carmel

Carnatic

Car

CARNATIC is a narrow stripe of country on the eastern side of the peninsula of India, which anciently comprised all that part of it that lies south of the Gondega and Tungabhadra rivers, from the coast of Coromandel eastward, to the Ghaut mountains westward; and was divided into Balla-Ghaat and Payen-Ghaat, or the Upper and Lower Ghauts, (that is passes through mountains), the former being the western part, and the latter the eastern part, or the Carnatic, according to its present definition.

From the intercourse, however, which has subsisted between Europeans and the inhabitants of the Carnatic, in the way of mercantile speculation, and the numerous wars by which that fine country has been infested, we are as well acquainted with this part of Indostan as any other district of our immense possessions in India.

The Carnatic, in general, is even and dry, and presents a sameness of appearance, of which those who have only had an opportunity of traversing regions that are mountainous, can scarcely form any adequate idea. In the hot season, the dreariness of the prospect forcibly strikes every traveller. He has nothing to amuse or to withdraw his attention from the labours which necessarily accompany the fatigue of his journey, but a naked, brown, dusty plain, and now and then small villages, and a ridge of detached hills. The sameness of the appearance of the whole district of country, seems to have impressed every one who has had the curiosity to visit it.

In the rainy season, however, a most remarkable change takes place, and the inhabitants of those tropical regions, so fertile, that the produce of the earth seems to be almost spontaneous, are subjected to greater and more sudden transitions, in regard to climate, than those who live in countries where more labour is requisite for the cultivation of the soil. Those alterations are indispensably necessary for promoting vegetation, and the natives consequently look forward to the change with the utmost eagerness and anxiety.

An immense ridge of mountains, extending 13 degrees of latitude, that is, from Cape Comorin to Sural, produces the most important effects in regard to the nature of the seasons, not in the Carnatic only, but throughout the whole peninsula. Although the altitude of these mountains is unknown, yet it is sufficiently great to prevent the great body of clouds from passing over them; and, accordingly, the alternate N. E. and S. W. winds (called the monsoons) occasion a rainy season on one side of the mountains only; that is, on the windward side. It would appear, nevertheless, that a sufficient number of clouds pass over to occasion a rainy season, at a considerable distance to leeward, where those clouds descend, as we may suppose them to do; although at the time they passed over the Gaits they must necessarily have been too high, and of course too light, to condense and fall in rain there. The ridge of the Gaits shelter a particular tract only, beyond which, the light and elevated clouds that pass over it descend in rain. Madras is within the limit of the sheltered tract, though at least 300 miles to leeward of the Gaits. (See Rennell's Memoir.)

Though an immense number of rivers intersect India in every direction, yet the Carnatic, properly so called, is worse supplied with such as are navigable than almost any country of equal extent. This no doubt operates as a powerful barrier towards promoting the facilities to commerce, and consequently to the progress of manufactures, which it would otherwise have enjoyed. Little or no internal navigation can be carried on, and the difficulty of transporting goods from one place to another, must be severely felt. All the rivers on the coast of Coromandel are subject to very sudden and unforeseen alterations, which are occasioned by the rains that fall on the mountains. In the space of twenty-four hours, it often happens, that from being fordable, they become almost impassable even by boats, on account of the rapidity of the current. Considerable inconvenience to the inhabitants is the certain effect of the suddenness of so great an increase, but this is greatly counterbalanced by the genial influence which these overflows have upon the soil, from which they must derive their subsistence. In,
a tropical country, the heat is so excessive, that the ground is quite parched; and had not nature made the wise provision of periodical rains, common to every region of the same latitudes, vegetation could never take place; it must soon have become altogether uninhabitable, because incapable of affording sustenance to man or beast.

There are only three rivers in the Carnatic, properly so called, which it is necessary to mention in this place. The Palar runs past the cities of Vellore, Arcot, Conjeeveram, and Sadras. At the last mentioned place, it is extremely broad, and discharges itself into the sea. About the middle of October, when the winter commences, and the rain pours down in torrents, it is sometimes half a mile broad, and flows with the utmost violence and impetuosity. The second, named the Chonenbar, falls into the sea on the south of Pondicherry, after having united, not far from that city, with the Gngaee. The third is called the Pannar, or the Golden River. It has its source in the Gauas, not far from Darampur in Mysore, runs past Tricalore, and on the north of Cuddalore throws itself into the sea.

Navigation. — It is a singular circumstance, that the coast of the Carnatic forms nearly a straight line, and that it has no port for shipping. It is also commended with a high and dangerous surf or wave, that breaks upon it, and induces the necessity of using the boats of the country to land in. These are called massa lool, and are of a singular construction, being formed without ribs or keel, with flat bottoms, and having their planks sewed together, iron being totally excluded throughout the whole fabric. By this construction they are rendered flexible enough to elude the effects of the violent shocks which they receive, by the dashing of the waves, or surf on the beach, which either overtops or breaks to pieces a boat of European construction. The sides of these boats are raised remarkably high, and sewed together with the fibres of the cocoa-nut tree, and caulked with the same material. They are remarkably light, and are managed with great dexterity by the natives; they are usually attended by two cattamarana or rafts, paddled by one man each; the intention of which is, that should the boat be overset by the violence of the surf, the persons in it may be preserved. No port for large vessels occurs between Trincomalee, on the east side of Ceylon and the Ganges, which is an extent of 15 degrees.

The coast of Coromandel has, at a distance, the appearance of a green theatre, when the season is favourable. The sea-shore is covered with white sand; and a multitude of beautiful shells are occasionally to be seen. The land is covered to a considerable distance, with a great variety of trees, and particularly that called by the Europeans the real Indian palm, or the cocoa-nut tree. The natives call it teng, and make much use of it in embellishing their gardens. A great number of these are planted on the coast, interspersed with hamlets and villages, and afford a most delightful prospect to the spectator.

The maritime cities and towns of the Carnatic are Cuddalore, Pondicherry, Portonovo, Sadras, St Thomas, Madras, and Pullicat, and a few others of lesser note. Cuddalore is naturally a very strong situation, a circumstance of great importance formerly, when war was so frequently carried on in India, and would certainly have been more commodious for the British settlement than Madras, at the time that the French were in possession of Pondicherry. The Dutch formerly possessed the towns of Portonovo, Sadras, and Pullicat; but the value of the British arms has wrested these from them, and rendered us independent of the rivalship of any European power on the eastern coast of India. St Thomas is from three to four miles to the southward of Madras, and here there was formerly a considerable Portuguese settlement. Madras, or Fort St George, is close on the margin of the sea, and is the principal settlement of the British East India Company on the east side of the peninsula.

The nominal capital of the Carnatic is Arcot, the residence, or rather which was formerly the constant residence of the nabob of that name. From the dependent state of its old possessor, and the obligations under which he lies to the British government, it has lost much of that splendour and luxury of a court, by which it had been so long distinguished. All the towns throughout the whole Carnatic, are exceedingly exposed to the attacks of an enemy's horse, from the level nature of the country. This has rendered it an object of indispensable necessity to erect forts, and to improve the situation of the place, and in general to remedy the disadvantages of so dry, open, and unprotected a territory. Accordingly the fortress at Madras, called Fort St George, is of very great strength; including within it a regular, well built city. Upon any sudden incursion of the enemy, (as in 1780,) the inhabitants of the country flock to these fortified places, and carry along with them their families, and what little property they can conveniently collect. The instances of the most excessive cruelty that have occurred in the Carnatic wars, have not been confined to its Mahomedan conquerors; for so late as 1761, Pondicherry, the finest city in India, together with its citadel, was razed to the ground. From the complete subjugation of the native princes, and the ascendency of the British arms, it is not considered at present as of any importance to keep in constant repair any forts in the Carnatic, excepting those that are on the sea-coast, or command some of the great roads leading into it. Thus the fortress of Arcot is in bad repair, although the nabob maintains a garrison of his own troops in it; whereas that of Vellore, being a post of great importance, and the most direct route from the country of Mysore, is justly deemed impregnable to an Indian army. It consists of three strong forts, on as many hills. That part of the Carnatic which more peculiarly belongs to the East India Company, is called Jaghore, a term which generally means, a grant of land from a sovereign to a subject revokable at pleasure, but in most instances for a life rent, neither of which apply to that under consideration. It contains 2440 square miles, and, according to Rennell, its revenue is reckoned at about £150,000 per annum.

* Vellore was chosen for the residence of the family of the late Tippoo Saib.
This tract of country extends from Madras to the
Pullicate lake northward; and to Alamparú, south-
wards; and westward, beyond Conjeeveram; that is
about 108 miles along shore, and 47 inland, in the
widest part.

The inhabitants of the Carnatic, particularly upon
the sea coast, consist of an immense variety of different
tribes of men. This has arisen, no doubt, from the
marketable nature of the commodities which it has
produced in every age, and the consequent opportu-
nity that was afforded to adventurers to acquire
wealth, one of the leading pursuits of the generality
of mankind. The population of the whole district
has never been accurately ascertained. The city of
Madras itself is extremely populous, and the strange
medioly of which it consists, is well calculated to con-
vey a just idea, though upon a large scale, of the
variety of inhabitants in the rest. None are permit-
ted to reside in Fort St George but the English,
and it is called the White town; but the outer dis-
trict is inhabited by Europeans, Armenians, Benga-
lese, Chinese, Peguans, Arabsians, Jews, and black
and white Indians, of all classes and religious sects,
&c.; it is called the Black town.

It would be improper to enter here into a long
detail respecting the different races of men, their dress,
customs, manners, peculiar institutions, or religion,
as a full exposition of those different particulars will
be given under the article India. It may be neces-
sary to observe, however, that throughout the whole
of India, a very great similarity exists in all these
respects. They have very generally been arranged
under Hindoos, Mahomedans, and Christians. Their
religion conveying a pretty accurate idea of the tribes
which compose those different orders. The comple-
xions of the people on the coast of Coromandel
are considerably darker than those to the northward;
and the native Hindoos are generally darker than the
Mussulman, who originally came from Tartary and
Persia. They all wear white cotton dresses, and make
almost in the same manner. To distinguish
the Hindoos, therefore, you must look very closely
at their forehead or breast, because they have certain
marks which they consider as sacred, and by which
it may be discovered to what sect they belong, and
what Deity they worship.

It is well known, that the Hindoos are divided in
to classes. Four of these are esteemed pure, that is,
the Brahmanas, the Kshatriyas, the Vaishyas, and the
Sudra. Every other member of the community,
who is not connected with one or other of these, is
reckoned impure. The divisions of the first class,
however, in the Carnatic, are different from what
they are in Bengal. They are divided into three
sects, and though they admit the divine authority of
the same purans or religious books, they interpret
them differently, and have each their followers. They
consider the second class as having been quite extinct
for many centuries. Another very singular difference
also exists in this country, no Brahman officiates in
any of the temples of the inferior gods, whose altars
are stained with blood.

The food of the natives of India is well known to
be very similar throughout the whole continent. A
vegetable diet and milk constitute the whole of it.

In so extensive a tract of country, it must naturally
be expected that a difference of taste will exist. The
tari, or fermented juice, and the jagory, or impissated
juice of the palmira tree, (Borassus Flabelliformis)
are more esteemed in the Carnatic than those of the
wild date, to which the Bengalese give the decided
preference. They pretend to be very moderate in
the use of the tari, but consume great quantities of
the jagory. It sells in the country for about nine
shillings and five pence per hundred weight. The
people who make jagory from palm trees, follow no
other profession. The cast is called Shanar, but the
individual in the Tamul language is Shanam. He
ascends the palmira tree morning and evening, in order
to collect the exuded juice, and through the day he
and his family boil it down into jagory. The tree
produces at all seasons, and one man can take care of
200 trees, from which he can extract about 482
pounds of jagory.

A great variety of languages are spoken in the Carnatic. The Tamul, the Hindostanee, the Persi,
and the Arabic, &c. Many of the names of remark-
able places and objects (e.g. the word Ghaut,) are
of Arabic extraction, or at least are to be found
in that language. Whether these words were bor-
rowed in the same manner, as we in modern times
borrow the names of arts, sciences, &c. from the
Greek, or from what other cause it proceeded, it
would be presumptuous to affirm positively. Simi-
larly of sound, even when accompanied with identity
of meaning, is an exceedingly uncertain foundation
upon which to assert a priority of claim upon the
one side or the other. The early literature of the na-
tives of India, as well as their knowledge of the more
abstruse sciences, have been frequently the subject of
panegyric. The inhabitants of the Carnatic have
laid claim to a considerable share of the fame which
they conceive their ancestry to have acquired in the
cultivation of learning, and in the opinion of compe-
tent judges have made good their title. It would be
idle to launch into the regions of uncertainty, upon
a subject which the hand of time has now consigned
to impenetrable darkness. One thing, however,
seems to be placed beyond the shadow of doubt,
that, at a period how remote soever, the sovereigns
of the Carnatic must have been possessed of great
wealth and power, and the country in general must
have made extraordinary advances in population,
industry, and in the arts, before they could have left so
magnificent monuments of their architectural profu-
sion and skill. The number, variety, extent, and ele-
gance of their pagodas and other public buildings,
cannot be exceeded, and scarcely equaled in nations
that have attained to a very high degree of civiliza-
tion. The duration of those remains of ancient gran-
deur has been accounted for, or at least attempted to
be accounted for, from the nature of the cement em-
ployed in building in India, (it is composed of a mix-
ture of oil and viscous substances,) and from the na-
ture of the climate.

It is perhaps impossible for an European to judge
of the true genius of Indian poetry, or to enter, with
the spirit of an Asiatic, into the productions of their
bards. The superiority of the knowledge of the
language, aided by many fabulous traditions which
the natives consider as canonical, render them much more inclined to perjury, with enthusiasm, the works of their favourite authors. Their painting, it must be confessed, bears little or no resemblance to nature; and of their music perhaps no high encomium can be pronounced. Dr Buchanan remarks, "that the music of the Nabut, or state band of the nabob of Arcot, is much superior to any thing he had ever heard among the natives, and is not much harsher than our clarionet."

The first and the most important of all arts is that of agriculture, and civilization have made but very inconsiderable progress where it is not cultivated. Mankind have a powerful stimulus to employ every exertion, in order to increase the means of subsistence. The degree of exertion, however, which is actually made, depends upon many adventitious circumstances, such as the climate, the soil, the spontaneous productions of the earth, &c. The progress of agriculture in the Carnatic has been very small, like that of every other country in India. It may be said to have been stationary for ages. The soil in many places is fine, and, when the proper quantity of rain falls, requires very little labour to produce a most abundant crop. In others the soil is very indifferent. Rocks, or large detached masses of granite, are very common in many fields, even in those districts that are considered as the most fertile. In other places, again, there are immense beds of granite, or of that rock decomposed into harsh coarse sand. Many of the hills are composed of the same substance, which alone renders cultivation totally impracticable. From the intemperance of the heat of the climate, even the best and most favourable soils require a very great quantity of water, in order to promote vegetation. Nature most commonly supplies abundance of this necessary manure in the rainy seasons, and in that case two crops are produced. If this be withheld, scarcity, and, even famine, is the certain consequence. The natives, however, have attempted to provide what is, in a small degree, a substitute for this invaluable blessing. Throughout the whole of India, what is called tanks, or reservoirs of water, have been formed. In Bengal, this is generally effected by digging; but in the Carnatic, where the situation is more favourable, they shut up, with an artificial bank, an opening between two natural ridges of ground. Some of these tanks extend from seven to eight miles in length, and three in breadth; and are said to be sufficient to supply with water the lands of thirty-two villages for eighteen months, should the rains fail. In the villages thus watered by Saymbrinbacum tank, there are 5000 persons employed in agriculture. But the bounty of Nature renders this seldom necessary. The water which is collected is generally employed in the dry season, and let out in small streams, without the aid of machinery, as wanted for cultivation. The genial nature of the soil and climate, assisted by moisture, is all that is requisite to produce the most luxuriant crop. When the water of a tank is exhausted before the rice of the fields watered by it is ripe, the crop must either perish, or they must use the yadam, or, as the English call it, the pacota. One acre and nearly one-fifth, require the constant labour of four men to supply it with water for the cultivation of rice. The same number of men are able to water three times the same quantity of garden ground, because a smaller supply is required. When there is a necessity for watering by machinery, a deduction from the rent is generally allowed. The machines are exceedingly rude, and discover very little enterprise or knowledge of the mechanical powers in those who have for ages employed them.

The instruments of husbandry are of the same rude construction; and were it not for the excellence of the soil and climate, they never could dress the ground so as to render it capable of producing what could indemnify the labour bestowed upon it, or even support the labourer himself. It is not the want of an inventive genius, to which we ought to ascribe the small progress that they have made in improving the instruments employed by them. There are few inventions in the arts that have not been dictated by necessity, and have, either in imagination or in reality, been considered as contributing to that love of ease which is so natural to man. Every implement of husbandry they make use of would be totally useless in a different region of the earth. The spade, hoe, harrow, and plough, are equally bad, and scarcely deserve the names. The great additional labour which thus devolves upon the husbandman is inconceivable; but custom and ancient usage reconcile them to any thing.

In the Carnatic, the greater part of the Brahmans engage in secular professions. Besides being officers of the revenue, and employed in administering justice, &c. they rent a great deal of land, but they never put their hand to the plough. Two unfortunate and miserable races of men are doomed to discharge this laborious duty. These are the Sudra and Panchum Bundum. The latter are by far the most hardy and laborious people of the country; and Hyder discovered his sagacity when he shewed them such particular marks of his preference, as to settle them in many parts of his dominions as farmers, and interdicted his subjects from calling them by any other name than that of cultivators. There are a few Mussulman who cultivate their farms by means of slaves, but they are not numerous in this part of Hindostan. Some of the Sudra cast, who have acquired a little property by their industry, have also purchased slaves, whom they employ in agriculture; but in general their lands are cultivated with their own hands.

The staple grain of the country is rice. It forms the favourite beverage of the Hindoos, whose religion forbids them the use of animal food; and their agriculture is chiefly directed to its production. They bestow also considerable care on the cultivation of maize, the sugar-cane, and cocoanut tree. The wheat that is raised, whether from the climate or injudicious treatment, or from both, scarcely deserves to be mentioned. The cotton-tree, however, is widely diffused, and in no part of India does it thrive better than on the dry coast of Coromandel.

The narrow policy of the proprietors of the ground has produced very injurious effects in many parts of India. Thus, when the tenant is unable to pay his rent, it is usual in Bengal to prevent the crops from
being cut down. In the Carnatic, however, the
custom is to collect the grain in stacks, or heaps,
after it has been threshed out in the field. To guard
against embezzlement, several pieces of clay, stamp-
ed with a seal, are then put on the surface of the
heap; and, to prevent injury from the weather, it is
thatched. The grain continues in these heaps till
the cultivator is able to satisfy the renter, either by
advancing money, or by dividing the produce. In
every village a particular officer, called talliari, keeps
watch at night, and is answerable for all that may
be stolen. See Buchanan's Travels.

There are no markets in the Carnatic, similar to
the fairs or haunts of Bengal. The shopkeepers pur-
chase what they have occasion for from the farmers
and manufacturers, and retail the articles thus proc-
cured in the bazars, or towns. Milk, a favourite be-
verage, is sold in all its different preparations by wo-
men on the road side.

The animals in the Carnatic are nearly the same as
are to be found in the other countries of Hindoostan.
It would exceed our limits even to attempt an enu-
meration of them. These shall be noticed under the
article INDIA.

The roads through the Carnatic are in general
tolerably good. That from Pondicherry to Madras
is excellent. In many places it is bordered by bushy
trees, under the shade of which the traveller is pro-
tected from the scorching heat of the sun. Every
two or three miles there are choultries or taverns, in
which comfortable accommodation may in general
be obtained. Of these, however, there are two sorts;
one for the convenience of travellers, and another
for the reception of those images that may happen
to be carried in procession. If not occupied by
their idols, persons of all descriptions are admitted
into them. These charitable foundations bear a great
resemblance to institutions in the Romish church,
and to the caravanseras in Turkey and Persia. The
accounts given by different authors of the hospita-
ality of the natives of the Carnatic, is very various.
They run into extremes; and perhaps a whole
people have been characterised only from the compara-
tively few individuals with which they may have each
happened to have had intercourse.

The manufactures of the Carnatic are chiefly those
of cotton, which is wrought into an immense va-
riety of different articles. From the earliest times,
the Hindoos have excelled in this species of manu-
facture, and for ages supplied the whole of Europe,
a great part of Asia, and the shores of Africa upon
the Mediterranean and the Red Sea, with cotton
goods, whether for the purposes of dress, or of house-
hold furniture, &c. Madras and Pondicherry have
always taken the lead of all the other towns and ci-
ties on the coast in regard to commerce. The for-
egn trade was formerly partitioned principally among
the Portuguese, the Dutch, the Danes, the French,
and English. The latter, however, have at present
a monopoly of the whole trade with India. What
is called the country trade, is carried on in ships,
the property of merchants who reside on the spot.

There is a very great difference in the value of the
coin used in the Carnatic, as well as in other parts of
Hindoostan. The East India Company have, however,
co-operated with the natives in bringing the weight
and measures to a much greater degree of accuracy;
and in the Jaghire they are permanently fixed. See
Renel, Bartolomeo, Buchanan, Sonnerat, and
Hodges; see also the articles India, Madras, and
Pondicherry. (ii)

CARNEADES. See the article Academics.
CARNICOBAR, the northernmost of that cluster
of islands in the bay of Bengal, called the Nicobars.
It is about 40 miles in circumference, of a circular
figure, and elevated little more than six feet above
the level of the sea. So much does it abound in
wood, that at a distance it appears to contain nothing
else, though there are several spots upon it well clear-
ed, and very delightful. The trees are chiefly the
barringtonia, cocoa nut, tournefortia, borassus, and
arcca; the aletris fragrans, and various other shrubs,
are to be met with: nuts of different kinds, pine-
apples, plaintains, limes, &c. are produced in great
plenty: there are also wild ginger, excellent yams,
and a root which the natives call cachu, and which is
obviously a species of arum. All these grow abun-
dantly, and with very little care, the climate being
genial, and the soil rich. Lord Valentia, however,
when he visited the island in 1802, could get no
yams, and did not see a single pine-apple. The tim-
ber, which is plentiful, affords excellent materials
for building and repairing ships, and some of it is of
very large dimensions. No grain of any sort is pro-
duced on the island. There are great numbers of
pigeons, poultry, and pigs. The latter are of the
species called sus babyrussa. It is probable that
now there are also goats, as Lord Valentia left a male
and female of that useful animal, of which the na-
tives promised to take great care. The other qua-
drups are dogs, rats, and a large animal of the
lizard kind, called by the natives tolonguei. Serpents
are numerous, and their bite is frequently fatal to
the inhabitants.

The houses, or huts, in this island, are generally
erected upon the beach, which is sand, intermixed
with coral rock; and form villages, each consisting of
fifteen or twenty of them, and every house containing
a family of about twenty persons. They are of a
round shape, elevated upon long wooden pillars, cov-
ered with thatch, and having no windows, so that
they very much resemble bee-hives. The entrance
to them is by a trap door below, and the inhabitants
mount by means of a ladder which is drawn up at
night. For the admission of light and air, the floor-
ing is made of thin slips of bamboo, laid at certain
distances. The inside is finished off with neatness,
and usually decorated with nets, fishing lances, and
other implements of that kind. The inhabitants sleep
in little hammocks made of matted grass, or the rind
of trees; the males on one side, and the females on
the other. To prevent the rats, and especially the
snakes, from getting in, the pillars on which the
houses stand, are covered with a very smooth sort of
leaf; and still farther to increase security, there is a
flat broad piece of wood made to project from each
pillar, near the top of it, which it is impossible for
the noxious animals to pass.

The inhabitants of Carnicobar, though of small
stature, are well made, very muscular, uncommonly
active, and in general healthy. Their complexion is of a copper colour, and their features have a resemblance to those of the Malays, excepting that their noses are not so flat. They have large mouths, and irregular teeth, which the practice of chewing betel renders black and disgusting. The men have their hair cut short, while the women have their heads shaved quite bare. Both sexes get their ears pierced when very young, and contra, by squeezing large pieces of wood into the holes, and suspending heavy weights from them, to render them hideously wide, and very disgusting to the eye. From the accounts which have been given of them, it would appear that their countenance is far from being handsome or elegant. The women, in particular, Mr Hamilton says, are extremely ugly. Lord Valentia, however, tells us, that their features, though the very reverse of beautiful, have a pleasing expression. Though fond of European apparel when they can get it, their native dress has all the simplicity of savage life in a warm climate. The men wear nothing but a narrow strip of cloth wrapped close and tight about the middle. The women have only a short petticoat made of rushes, or dry grass, reaching half way down the thigh, and hanging round them like the thatching of a house. They speak a mixture of broken English and barbarous Portuguese, which Lord Valentia tells us prevented him from having any difficulty in communicating with them. But their original tongue is that of Pegu, from which the Nicobar islands were peopled; though their frequent intercourse with strangers has made them in a great measure renounce or forget it. They have this peculiarity in their utterance, which is the principal feature that they have retained of their native language, that they pronounce their words with a sort of stop or catch in the throat, at every syllable.

In eating and drinking, they go to great excess. Their favourite food is pork, which, with them, is remarkably fat, and of which they devour immense quantities at their village feasts. They like to sit at table with Europeans; and they eat every thing that is set before them with the most voracious and indiscriminating appetite. As might be expected, they are by no means nice in the cooking of their victuals. Their pork gets nothing more than a hasty grill over a quick fire, and is swallowed by them almost raw. Their method of roasting a fowl, is by running a wooden spit through it, and holding it over a brisk fire till all the feathers are burnt off, when it is quite prepared to their taste. They also make use of small shell fish, of which they have great plenty, and which they kill by means of lances, with wonderful dexterity. Their drink consists of cocoa-nut milk, and a liquor called sorsa. The sorsa is a juice which exudes from the cocoa-nut tree, after cutting off the young sprouts or flowers, and, being allowed to ferment, acquires an intoxicating quality. This they suck slowly through a small straw, which method of taking it increases its power of inebriation. They are also very fond of arrack, which they obtain in presents or by barter. They will continue drinking bumpers of it till they are completely drunk. Besides feasting, in which they take great pleasure, their chief amusement is dancing. After eating, the young men and women, fancifully dressed with leaves, engage in this exercise; while the old people sit around them, smoking tobacco and drinking sours. The only musical instrument which they have on such occasions, is made of a hollow bamboo, about 2½ feet long, and 3 inches in diameter, along the outside of which, from end to end, a single string, made of the threads of a split cane, is stretched, with a hollow groove immediately under it, to prevent it from touching. The instrument is played on like a guitar. It has of course but few notes. The performer, however, improves its effect by accompanying it with his voice; and the whole is said to be tolerably agreeable, as the dancers all the while sing tunes, which are not destitute of harmony, and to which they move in exact time.

The Carnicobarians have no notion of a God; or rather their god is the devil, in whose existence they firmly believe, and to whom they pay a most servile worship. They have assigned him the best habitation in the place, in the front of which they have suspended offerings of various kinds. On the approach of a storm, or of any similar calamity in which they recognise the immediate agency of the evil spirit, they perform many superstitious ceremonies, such as marching round the boundaries of their respective villages, and fixing up at different intervals small sticks split at the top, into which they inserted a piece of cocoa nut, a wisp of tobacco, and the leaf of a certain plant. It is difficult to determine whether these are intended to propitiate the object of their fear, or to frighten him away. It appears, however, that in every village a high pole is erected with strings of ground-rattans hanging from it, and that, in their opinion, this pole has virtue sufficient to keep him at a distance. Indeed, they seem to place much confidence in charms of this sort; for Lord Valentia tells us, that near the shore he saw a range of small cleft sticks, with a piece of flesh stuck in each, which served as a talisman to keep off death that had visited them most destructively in the form of the small-pox. In the moral character of the Carnicobarians, there are some respectable qualities, which place them far above many tribes in the same stage of society. In their intercourse with strangers who visit them, they are at first shy and suspicious, probably from the experience or the tradition of some acts of treachery; and this suspicion they shew by appearing every one of them with some weapon in his hand, which he never quits for a moment; but as soon as they see that there is no ground for jealousy, their apprehensions are easily dispelled, and they appear frank and good natured, civil and inoffensive. Their aversion to dishonesty is remarkable. Theft or robbery very seldom occurs among them; is so rare, indeed, that a man when he goes from home never thinks of using the ordinary precautions for securing his property, having no fear of any depredations being committed by his neighbour. Nor is it alleged, so far as we know, that their conduct in this respect is in any degree different in the intercourse and dealings which they have with those strangers, by whom they are frequently visited. It is to be observed, too, that their ideas of property are sufficiently strict; for though they are very willing to impart to one another,
They are united, indeed, by a mutual and constant interchange of good offices; and neither feel, nor even show, any of that deference which characterizes the more refined stages of civilization. No authority is claimed by one over another, and no peculiar honour is paid to any class of individuals except to the old, who, merely on account of their age, are treated with a little more respect than others. We are not informed in what light they regard the virtue of chastity. But Mr. Hamilton tells us, that polygamy is not known among them; and that they punish adultery with so much severity, as to render that crime of rare occurrence. The punishment consists in cutting off a piece of the foreskin proportioned to the enormity of the offence, or to the frequency with which it has been committed.

The inhabitants of Carnicobar enjoy good health, and meet with few accidents; and their skill in medicine and surgery is not greater than their need of it. Their mode of curing the sting of a scorpion, or centipede, is this: They take the under jaw of a small fish, having two rows of teeth as sharp as needles; these are forcibly struck with a piece of wood by way of hammer, into the swelling, till it bleed freely, and the diseased part is then bound up with certain leaves till the cure is completed. Mr. Hamilton mentions an instance of this mode of treatment which he witnessed, being attended with perfect success in the course of twenty-four hours. When a man dies, all his moveables, as has been already stated, are buried with him; his death is mourned by the whole village, and his wife, according to custom, must either consent to have a joint of one of her fingers amputated, or submit to have a deep notch cut in one of the pillars of her hut. Mr. Hamilton gives the following account of the funeral of an old woman, at which he was present. "When we went into the house, which had belonged to the deceased, we found it full of her female relations; some of them were employed in wrapping up the corpse in leaves and cloth, and others tearing in pieces all the cloth which had belonged to her. In another house hard by, the men of the village, with a great many others from the neighbouring towns, were sitting drinking soura and smoking tobacco. In the mean time, two stout young fellows were busy digging a grave in the sand near the house. When the women had done with the corpse, they set up a most hideous howl, upon which the people began to assemble round the grave, and four men went up into the house to bring down the body; in doing this, they were much interrupted by a young man, son to the deceased, who endeavoured with all his might to prevent them, but finding it in vain, he clung round the body, and was carried to the grave along with it; there, after a violent struggle, he was turned away and conducted back to the house. The corpse was now put into the grave, and the lashing which bound the legs and arms cut. All the live stock which had been the property of the deceased, consisting of about half a dozen hogs, and many fowls, was killed and flung in above it. A man then approached with a bunch of leaves stuck upon the end of a pole, which he swept two or three times gently along the corpse, and then the grave was filled up. During the ceremony the women continued to make the most horrible vocal concert imaginable; the men said nothing. A few days afterwards, a kind of monument was erected over the grave, with a pole upon it, to which long strips of cloth of different colours were hung." Lord Valentia saw, around the village which he visited, tall pieces of bamboo stuck into the ground, each of which, he was told, marked the spot where a person had been interred. The Carnicobarians carry on some trade. Their cocoa-nuts are reckoned the finest in that part of India, and there is a regular demand for them from Pegu, and various other quarters. The articles which they require in return are cloth of different colours, hatchets, and hanger blades. These last they use in cutting down the nuts. They usually purchase a greater quantity of cloth than is necessary for their own consumption, which they carry to Chowry, a small island to the southward, and exchange it for canoes, which they cannot make for themselves. For this purpose they send a large fleet of boats every year in the month of November, and these they navigate, not by a compass, of which they know nothing, but by the help of the sun and stars. They are very anxious to procure tobacco and arrack; but these, along with knives, handkerchiefs, and other useful articles, they generally expect to receive in presents. Lord Valentia says, that they required money for the provisions which were obtained from them. To the coin of other countries, however, for they have none of their own, they do not attach any value as a circulating medium. They regard it merely as furnishing them with ornaments, which they esteem beautiful; and this is corroborated by what his lordship adds respecting their preference for dollars; strings of which, Mr. Hamilton informs us, are worn by the young women about their necks. They are said to be good judges of silver and gold, which they very readily distinguish from the baser metals that are sometimes, in the course of trade, attempted to be substituted in their place. See Mr. Hamilton's Short Description of Carnicobar, in the Asiatic Researches, vol. ii. p. 337, et seq. Lord Valentia's Voyages and Travels, p. 59, which is accompanied with a view by Mr. Salt of one side of the island of Carnicobar. Mr. Dalrymple, in his Oriental Repertory, vol. i. p. 104, mentions, that, in 1687, Captain Weldon surveyed the Nico
Carniola, a duchy of Germany, in the circle of Austria: bounded towards the north by Carinthia and Styria; on the west by Friuli, the country of Gorz, and the Adriatic Sea; on the south by the same sea, and the part of Istria possessed by the republic of Venice; and on the east by Dalmatia and Croatia. This province is situated in latitude between 44° 48′ and 46° 7′ north, in longitude between 15° 38′ and 16° 40′ east. Its greatest length, from west to east, is about 120 miles. Its greatest breadth is about 100. The face of this country is for the most part mountainous. Some of its mountains are more or less cultivated and inhabited, others are altogether in a desert state; some of them are naked, others clothed with wood. The summits of several of them, especially in Upper Carniola, are continually covered with snow. One of the loftiest mountains in the Austrian dominions occurs in this quarter, namely the Terklou, which rises to the height of 10,194 feet above the level of the sea. This is the principal summit in the southern chain of the Alps, which traverse this duchy in a direction from west to east; and which, to the westward of this central or dividing point, are known by the name of the Carnatic Alps; to the east of it by that of the Julian. Other considerable mountains in these parts are the Caleberg; the Lobel, which separates Carniola from Carinthia, and affords from its summit a very fine prospect; the Rumberg, the Karst, and the Nanas. Among these mountains are interspersed many fruitful valleys and fields, which form an agreeable variety, and are of the greatest consequence to the subsistence and comfort of the inhabitants. The declination of the duchy of Carinthia, as well as generally of the immediately adjoining provinces, is for the most part from west to east. This is evinced by the circumstance, that the rivers in these parts chiefly run in that direction. The same thing is evident from the aspect of the mountains, which obviously decrease in elevation as they are situated more to the eastward. Thus, in the line of the Alps before mentioned, the summits, after the Terklou is passed, decline much in height, and no longer exhibit any thing but the appearance of calcareous rocks, curiously chapped and hollowed out; in some places rising into steep and inaccessible points; in others sinking down into deep caverns, or pierced, in a horizontal direction, into far extending grottos.

The aspect of this country externally, is altogether such as should give reason to expect an abundant supply of valuable mineral substances. Here accordingly are mines of iron, lead, and copper. Quicksilver also and cinnabar are found in great quantity. The most ancient and the most noted of the mines from which the iron is drawn, is situated in the mountain of Eisenberg, or Naseleiro. At Ainem, or Seeleniko, there is also an excellent iron mine, and one at Janerbourg, which is of importance by furnishing materials for the manufacture of steel in this country. There are not in Carniola any mines of gold or silver; but those which it has are perhaps hardly less profitable to it. The quicksilver mines in Iridia are of great celebrity, and equally valuable. They are the richest of this description in Europe, yielding annually to the amount of 12,000 quintals of pure quicksilver, besides about 6000 or 7000 quintals of native cinnabar. The Spaniards have been accustomed to purchase the half of the mercury procured here, at the rate of two piastres per quintal. These mines were accidentally discovered in 1497. They have been hollowed out to the depth of about 900 feet, and the mercury is obtained from the numerous subterranean cavities that have been opened in them in great abundance, being found in stones, in a sort of clay, and sometimes in a disengaged state, issuing from the rocks, and dropping spontaneously on the ground below. There are here various other sorts of mineral produce, some of greater, others of less consideration. The Carniola marble is reckoned beautiful, and it is found in great abundance and variety in different parts of the country. There is found here also alum, nitre, vitriol, bolar earth, and fullers' earth. Rock crystals are frequent, likewise beautiful hyacinths, eagle-stones, and blood-stones.

The vegetable productions of Carniola are of the same kinds that prevail generally in the surrounding district of country. Wheat, barley, rye, various leguminous crops, and others which contribute most directly and essentially to the support of human life, are reared here in considerable quantity and perfection. Millet also is a usual crop, as is buckwheat, especially in the sandy plains. Various and excellent fruits are produced in this country, such as pears, and apples, oranges, citrons, pomegranates, almonds, figs, chestnuts, walnuts, olives, and lemons. Carniola does not yield a great deal of wine; but what it has, both white and red, is of a superior quality. A great deal of cider is prepared in the province; and, with a view to this, much attention is paid to the propagation and the management of the apple trees; indeed, the fruit trees in general are well attended to, and in this department a great number of the inhabitants find employment. Flax is raised here, and a little hemp. The flax is esteemed to be particularly good. Artificial meadows are frequent, from which fodder is procured for the maintenance of domestic animals. The ground in this province that is capable of bearing cultivated crops is generally fertile, and, from the management that is adopted, is often made to yield two harvests in the year; buckwheat being commonly sown after the removal from the fields of the other descriptions of grain, and millet in the places which had been previously occupied with flax or hemp. Truffles, and a variety of medicinal plants, occur in this district; and, in general, many parts of the mountains, by which so much of the whole surface is occupied, present, even in the midst of arid rocks, a brilliant vegetation, which, joined to the imposing aspect of the extended lakes and rapid rivers in the vicinity, forms the most picturesque views, and recalls to the recollection some of the noted scenes of Switzerland.

There is found in Carniola an abundance of good pasturage, by means of which, there are maintained numerous herds of a tolerably good, though not the
largest breed of cattle. The number of horned animals stated to be in the country in the year 1780, was 44,098. The number of horses, at the same period, is estimated at 16,232. A very fine race of horses is not to be expected in mountainous districts like this; yet, on the mountain of Karst, in this duchy, and in the valley of Geil, in Carinthia, more attention, it may be observed, is paid to the horses, than is usually given in other contiguous parts; and the horses of Carniola, though generally only of a middle size, are yet known to be strong, and very sure footed, and consequently well adapted for carrying burdens over those mountainous grounds. Asses and mules, which are in this respect so well calculated to be useful in such districts, and may therefore commonly be expected in them, are here pretty numerous. There are also considerable flocks of sheep, which have been noted for the delicacy and tenderness of their flesh. The rams are without horns; and the fleeces which are borne by the breed of sheep in this duchy, are not inferior in quality to those of Padana. Game and poultry abound here, as also fish. Numerous bees are reared; likewise silk worms; both which classes of industrious insects, from the returns which they have yielded, have been found objects well deserving of the care of those who have directed to them their attention.

The principal rivers of Carniola are the Save, the Laybach, the Gurk, and the Culpa. Of these, the most considerable is the Save, which takes its rise in Upper Carniola, near to the village of Ratchach, and in its course receives the waters of all the other rivers that have been mentioned. This river, though it flows very rapidly, is yet navigable; it discharges itself into the Danube at Belgrade, in Servia. The chief lakes of the duchy are the Feldesser, the Wochein, and the Zirknitz See. Both the rivers and the lakes generally abound with fish.

The duchy of Carniola is subdivided into several inferior districts. These are the Upper, Lower, Middle, and Inner Carnolias, and the Austrian Istria. Certain lines of distinction have been traced, by which it has been considered, that those divisions of this territory might appropriately be marked out, and separated from one another. These distinctions are not, however, in every case very clear, or very significant; and, indeed, any thing of importance relative to this matter might be comprised within very narrow limits. With respect to Upper Carniola, it is observed, that the air of that district is pure and wholesome,—that there is everywhere found in it an abundance of good spring-water,—and that this division of the country raises commonly a sufficient supply of corn for the support of its inhabitants. Vines succeed here, but they are not found in great quantity. The more usually cultivated crops are raised with ease, and yield an early and abundant return. Yet the district is mountainous, and the air on the upper grounds so chill, that the inhabitants are exposed to degrees of cold not inferior to those that are experienced in the higher parts of Scotland. Lower Carniola contains many fruitful valleys and tracts, and yields an excellent wine called Marchein. Middle Carniola is mountainous, and more noted for the number of its villages, which seem to imply an abundant population, than for the production of the crops that might appear necessary for their subsistence. Inner Carniola is also mountainous, and yields little corn. Both of these districts, however, produce considerable quantities of wine; and the latter is noted for its breed of horses, which find a ready market in Austria and Italy. Istria is very fertile in wine, oil, corn, and other articles of subsistence. Indeed, in the southern parts of Carniola in general, the olive, rice, and other productions peculiar to the warm climates, succeed perfectly, and arrive at maturity. But it is a material drawback upon the greater part of this whole province, that water is extremely scarce in it, or of very bad quality.

The capital of Carniola is Laybach. This is a handsome town, containing a great number of elegant structures, and amongst these several public buildings. Some of its churches, especially in the interior, are in a far better taste than is usually found in Germany. The river of the same name runs through the town; but, though navigable, is not turned to any very considerable account. Trieste is more a seat of trade. Indeed, this is what may be called the main rendezvous of the Austrian marine. Here there is a harbour, at once secure and commodious, which is frequented by a great deal of shipping. The number of vessels that depart from, or come into this port annually, is reckoned to be from 5000 to 6000; and the value of the merchandise exported or imported is estimated at from fourteen to fifteen millions of florins. It is chiefly by this port that the trade between the different states of the empire and the Levant, or other maritime parts, is conducted, the necessary communication for that purpose with the interior being maintained, either by the public roads, which are here generally good, or by the navigable rivers. Trieste, as a town, contains a great number of well built houses of stone; the streets are wide, and paved with very large flagstones. The thriving state of the place is evinced by the face of activity which every where appears, and by the rapidly increasing population.

In the duchy of Carniola, in general, the spirit of industry and exertion in the departments of manufactures and commerce is by no means dormant; and if the state of society, or the progress of improvement, seem hardly to be adequate to what might have been expected, from a consideration of the natural riches and advantages which this province enjoys, its situation in these respects is yet far from being wretched or contemptible. One great source of the industry of Carniola is furnished by its mines. There are here several considerable iron manufactories. There is one wire-drawing mill, three forges for steel, and six for nails; in which last there are made annually from 8000 to 10,000 quintals of nails, in value from 150,000 to 200,000 florins. There are in Carniola, besides, two great glass-works; in one of which a sort of Tuscan vessels are made, resembling in their appearance delft or Dutch ware. There is here, also, a manufactury of pipes. Carniola has a woollen manufacture. A great deal of cloth is prepared at Laybach, and woollen hosiery is manufactured in considerable quantity at Wechselburg, at Strachina, and at Newmarktl. A spin
Carniola.

Carniola, a duchy, has likewise been established, a lace manufactory, and a manufacture of linen. The most esteemed linen, procured from this quarter, is made at Bischofshack, in the environs of Laybach, and at Dobronina. There are several bleaching-fields here. The number of looms in the province is estimated at 500; and the value of all the cloth annually made in it has been rated at 600,000 florins.

The exports from this province are chiefly iron, steel, mercury, wines, olive-oil, olives, cheeses, and various other fruits, horses, cattle, linen, woollen stuffs, cheeses, leather, honey, ship-timber, with all sorts of little works in wood, such as boxes, dishes, spoons, &c. One of the most material articles of import is corn, of which the native soil does not in ordinary years raise enough to answer to the consumption of the inhabitants. This province is also without the fossil salt or salt-springs, which, found in other situations, are reckoned among the treasures of Austria. Whatever salt therefore is required, in addition to the quantity of sea-salt manufactured in the province, must be obtained from the sovereign's magazines.

Some idea of the relative importance of this duchy may perhaps be formed, from a consideration of the amount of its contributions at different periods for the support of government. This province, according to Busching, advanced for that purpose in 1770, 2,089,952 florins. In 1780, according to Schlazer, its contribution was 1,650,000 florins. It contributed in 1803, according to the manual of Frankfort, 1,300,000 florins; according to Ockhart, 2,100,000.

That its mines, generally taken, are not of the most considerable order, may reasonably be inferred from the circumstance, that it is not rated as contributing anything to the montanisticum, or the revenue accruing to the emperor from the produce of all the mines. Its wealth in this department has, however, been of not a little importance towards the enlargement of the public revenues. The quicksilver mines of Idria yield annually to the emperor nearly 1,000,000 florins.

Carniola possesses a robust and hearty peasantry. With the common people of this country, it is usual to go barefooted in winter through the snow with open breasts, and to sleep on a hard bench without bed or bolster. The food of this order of people is also very coarse and mean. In winter, when the snow lies deep on the ground, the mountaineers, in the manner of the Laplanders, bind either small baskets, or long thin narrow boards, to their feet, on which, with the help of a stout staff, they descend with great velocity from the mountains. When the snow is frozen, they make use of a sort of skates for the same purpose.

In this duchy there occur numerous natural curiosities. The vast grottos with which Carniola is so much abounds, are such, that nothing similar to them is found in Europe. The principal tract of the grottos is in what is called the Pear-tree Wood, which is one of the most considerable forests in the empire, but marked throughout by a face of the most inhospitable desolation. Some of these grottos, or subterraneous caverns, are said to be upwards of four miles in length. They rise also, in some instances, one tier above another; every several grotto extending in breadth and height from 12, perhaps to 20 feet, and exhibiting in the interior a great variety of stalactites of singular form and appearance. The most noted of these grottos, are the Magdaleno grotto near Adelsberg, that of Lueg, that of St Servio near Trieste, the grotto of Cornale, and those of the lake of Zirknitz. Amongst these, the grotto of Cornale is particularly striking, both in respect of the magnificence and the variety of its stalactites, and the length and massiness of the columns on which the vaulted roof seems to repose. Zirknitz is not more remarkable on account of the grottos in that quarter, than for other natural phenomena of a very singular kind, by which it is distinguished. This place has indeed many attractions. The mountains, the rocks, the woods, the smiling plains, the fertile fields, and the villages scattered here and there, which, in various directions, bound this fine sheet of water, or offer themselves to the eye in striking contrast or connection with it, or with one another, form a scene highly picturesque and agreeable. The prospect is further enriched and animated, by the beautiful and well-cultivated islands which rise from the bosom of the lake, and by the restless activity of several rivulets, which, in different quarters, hasten to convey to it the tribute of their streams. The usual egress of the waters of this lake, is by two openings which nature has formed for them through one of the adjoining rocks.

But besides these two cavities, by means of which the lake is prevented from rising above a certain level, there are several others in the bottom of it, (and this is what has been most noted in these parts,) through the effect of which it every now and then disappears entirely. When this event is about to take place, the waters crowd in succession about the different openings, and in the vicinity of them respectively the bottom is after a time laid bare, till after the lapse of about 25 days no vestige of the lake any longer remains. The period when the water is about to depart is that when fishing is permitted in the lake, and at those seasons accordingly, there is procured an abundant supply of large fishes, chiefly pikes. After the waters are gone, a field is presented, in the channel that they had occupied, very proper for cultivation, which it is immediately begun to labour and sow. An abundant vegetation soon covers the place. Three months afterwards the peasants collect from it crops of hay and millet, and game is pursued in situations where so short a time before there had been no other living creature but fishes. There is no precise time for these departures of the lake. It has been known sometimes to disappear and to return thrice in the course of a year, and some years it has not disappeared at all. Its return, however, uniformly takes place after a space of not more than four months. Then the water is seen for a short time rising with vigour through the different openings, and, within 24 hours, the basin is completely filled as before its de-

* Carniola prepares of sea salt annually, from 30,000 to 40,000 metzen or minots of Vienna. This is a measure of 3.100 cubic inches.
parturc. This singular phenomenon has naturally
ttracted a good deal of attention; and superstition,
as usually happens, has busied itself in converting it
into a source of alarm and terror. It may, however,
without difficulty, be accounted for upon natural
principles. The Carniolan Alps in general, as that
vast chain of mountains is called which traverses this
country from Dalmatia to Carinthia, may in fact be
considered as one great mass of calcareous matter,
which, hollowed into a great number of grottos and
extensive cavities, affords opportunity for the accu-
cumulation in particular places of great quantities of
snow or rain water. With reservoirs of this kind,
there is every probability that the principal cavities
in the bottom of the lake of Zirknitz communicate;
whence it is, that when the water in these recepta-
cles is from any cause considerably lowered, the wa-
ter of this lake falls down to fill up the vacuity; but
when, from other contiguous subterraneous lakes, or
in any way else, more water is brought into them
they are capable of containing, then a quantity of it
is forced up through the cavities mentioned, and thus
the lake of Zirknitz is replaced in its original con-
tin. In connection with these natural curiosities,
there may be noticed here a remarkable work of art.
This is the road known by the name of the pass of
Lobel, by which a communication is formed be-
tween this duchy and that of Carinthia, and which,
in respect of the length that it has been carried over
a very elevated tract of ground, is certainly not equal-
led by any thing to be found in Europe.

Carniola was known so early as the 8th century,
the same name which it still bears. Its more an-
cient name appears to have been Crania. It was at
the period alluded to, that the Christian religion was
introduced into the country. It was endeavoured, in
the 16th century, to communicate to the inhabitants
the benefits of the Reformation. The success, how-
ever, appears not to have been considerable, as even
at present the prevailing system in that quarter is the
Roman Catholic. A few Walachians, or Uskokes,
who have their residence here, are of the Greek
church.

There is a material difference observable between
the different parts of this country, in respect of man-
ers, dress, and language. In Upper and Lower
Carniola long beards are worn. There are two dis-
tinct languages spoken in the country, the Slavon-
ian, to wit, or Wendish, and the German, cor-
responding, it may be observed; to the diversity, in
point of origin, by which this people are distinguish-
ed, of whom the commonalty, it is understood, are
chiefly of Slavonic extraction, the nobility of Ger-
man. The Slaves, or Wends, are said to have taken
possession of this country after the year 548. In the
time of Charlemagne and his posterity, it was go-

ered by the dukes of Friuli, and afterwards by
those of Carinthia. Under Otto II. it became a
distinct margravate. It finally was vested in the House
of Austria; and from a marquisate, which it had
long been, it was, in 1231, raised to the rank of a
duchy. It participated with other provinces in the
effect of the division of the Austrian States, from
1805 to 1496. Otherwise, it has, with little inter-
ruption, ever since its first accession to them, conti-
mued to form a part of the Austrian dominions. To-
wars the maintenance of the military power of that
state, it contributes annually 363,171 florins. The
forces usually quartered in it, are only two regiments
of foot.

The following particulars, relative to this duchy,
are extracted from a statistical account of the Aust-
rian monarchy, published by Messrs Raymond and
Roth, 1809:

The population, in 1783, of the circle of Laybach,
133,239; of Neustadt, 145,479; of Adelsberg,
133,085; and of the whole duchy, 433,000. Num-
ber of marriages, in 1791, including Friuli and Trieste,
5539; of births, 25,723; and of deaths, 17,930.

Dwellings. 1783. 1801.

lics, par M. Malte. Brun; Dictionnaire Universel de
la Geogr. Commercante, par J. Peuchet; and Kutt-
ner's Travels. (K)

CAROLAN, Twalough, a celebrated poet and
musical composer, justly stilled the Irish Handel,
was born in the year 1670, in the village of Nabber,
in the county of Westmeath, on the lands of Carolan's
town, which formerly belonged to his ancestors.
It is greatly to be regretted, that so little is known of
the early part of the life of this eccentric and surpi-
sic genius. His father was only a poor farmer, the
proprietor of a few acres, which yielded him a scanty
subsistence. The cabin in which our bard was born,
is still pointed out to the inquiring traveller. It is
now in a ruinous state, and must soon become a prey
to all-devouring time; yet the spot where it stood
will perhaps be visited at a future day, by the lovers
of national music and song, with as much true de-
vo tion, as the birth-place of Shakespeare, or the cot-
tage of Burns. The small-pox deprived him of his
eye-sight at so early a period, that he retained no re-
collection of colours; yet, from this misfortune, he
felt no uneasiness, and was never heard to complain.
"My eyes," he used to say, "are transplanted to
my ears." It was early discovered, that young Ca-
rolan had a genius for music, and his friends determined to cultivate it by every means in their power. When about ten years of age, a proper person was engaged to instruct him in the practice of the harp; but, though fond of that instrument, he never struck it with a master's hand. It has been justly remarked, that genius and diligence are seldom united; and yet it is to practice alone, that we owe perfection in that art. His harp, however, was rarely unstrung; but, in general, he used it only to assist him in composition; his fingers wandered through the strings in quest of melody, while his mind was only intent on the musical expression of the then vibrating chord. At an early period, our bard became enamoured of a Miss Cruise, of Cruise Town, county of Longford; his harp now, like the lute of Anacreon, would sound only to love. His passion for this lady almost exceeds belief; yet she never gave him her hand, though it cannot be doubted, that he held at one time the first place in her breast. The song which bears her name is his master-piece; it came warm from his heart, while his genius was in full vigour, and inspired by her whom his soul adored. A very extraordinary instance of the effect of Carolan's passion for this lady is related by one of his biographers: He went once on a pilgrimage to St Patrick's Purgatory, a cave in the island of Lough Derg, county of Donegall. On his return to the shore, he met several pilgrims waiting the arrival of the boat that conveyed him. In assisting some of these to get on board, he chanced to take a lady's hand, and instantly exclaimed—"By the head of my gossips, this is the hand of Bridget Cruise!" His sense of feeling had not deceived him; it was the hand of her whom he had once adored. This anecdote is certainly curious, and cannot fail to convey a strong impression of the emotions which he felt, on meeting the object of his early affections. Carolan had been at this time many years married, and was in the middle of his earthly career. Our bard having at length discovered, that it would be impossible for him to gain the consent of Miss Cruise, made application elsewhere; and after a long and tedious courtship, obtained the hand of Mary McGuire, a young lady of good family, in the county of Fermangh; and shortly after fixed his residence on a small farm near Mosshill, in the county of Leitrim. Here he built a neat cottage, where he lived for a while comfortably, and gave every friend that called a kind and hearty welcome. His ardent hospitality, however, soon consumed the produce of his little farm; he ate, drank, and was merry, and imprudently left to-morrow to provide for itself. This mode of life soon occasioned embarrassments in his domestic affairs; but, like too many others on whom nature has bestowed strong powers of mind, he forgot to reflect in due time, that nothing can supply the want of prudence; and that negligence and irregularity long continued, will render even genius itself contemptible. Carolan, finding he could not support his family in this way, resolved to become an itinerant harper and bard, (see Bard,) in which character he continued during the remainder of his life; travelling through the country, mounted on a good horse, attended by a domestic on another, who carried his harp. Where-
at this time his principal place of residence.

There, whilst under this severe regimen, he wandered about the streets; his usual gaity forsook him; no saliies of his once lively imagination broke out; every moment was laden with care, and marked with a dejection of spirits bordering on the deepest melancholy; his favourite harp lay in an obscure corner of his habitation, neglected and unstrung. In this deplorable situation, passing a whisky shop one day in town, after having abstained six weeks from tasting spirits, he was tempted to step in, undetermined whether to yield to the temptation, or adhere to his late resolutions. "Well, my dear friend," said he to the young man who stood behind the counter, "you see I am a man of constancy; for these six long weeks I have refrained from whisky—was ever there so great an instance of self-denial? But a thought strikes me—you will surely not deny me the favour I am about to solicit. Bring me a measure of my favourite liquor, that I may just smell it, and I assure you I will not put it within my lips." The young man complied with his request, and no sooner did the fumes ascend into his brain, than every latent spark within him was rekindled, his countenance glowed with unusual brightness, and he poured forth the effusions of a heart newly animated, in wild but poetic expressions over the bowl to which he owed his inspiration. At length, to the great peril of his health, and contrary to the advice of all his friends, he once more drank the prohibited beverage, renewing the draught until his spirits had fully resumed their former tone. He then immediately set about composing the much admired and far famed song, which goes by the name of "Carolan's Receipt for drinking Whisky." He commenced the words, and began to modulate the air that evening in Boyle; and, before ten o'clock the next morning, he sang and played this noble offspring of his imagination in Mr Stafford's parlour at Elphin. In justice, however, to Carolan, it must be remarked, that notwithstanding his fondness for spirituous liquors, he very seldom carried his drinking the length of intoxication; but he imagined that whisky assisted him in his musical composition, and therefore never composed without a bottle of it beside him. To deny Carolan his favourite beverage, was a certain method of robbing his satire. Being one time in the house of an old lady, who was remarkably parsimonious in this way, he chanced to hear the butler, whose name was O'Neill, open the cellar door, and laying aside his harp, followed him into the cellar, requesting a cup of beer; the butler, in rather an insulting tone, ordered him out, declaring he would give him nothing without orders.

Carolan indignantly exclaimed,

"What a pity Hell's gates were not kept by O'Neill, So surly a dog would let nobody in!"

The fame of Carolan, as a musician, having reached the ears of an eminent Italian music-master in Dublin, he determined to put his abilities to a severe trial, the result of which convinced him how well-founded had been whatever was said in his favour. The method he made use of was this: he selected an excellent piece of music in the Italian style; but here and there either altered or mutilated it in such a way, that none but a real judge could detect the alterations. Carolan bestowed the deepest attention on the performer, while he was playing it, not knowing it was intended as a trial of his skill, and that the critical moment was at hand, which was to determine his reputation, as a musician, for ever. He declared it to be an excellent piece of music, but to the astonishment of all present, he said, very humorously, in his own language, "La se air chois air bacaha, that is literally, "Here and there it limps and stumbles." He was then requested to rectify the errors, which he accordingly did; and in this state, the piece was sent from Connaught to Dublin. The Italian no sooner saw it than he pronounced Carolan to be a true musical genius.

In 1733, Carolan experienced a severe domestic affliction in the death of his wife, which had a visible effect on his constitution. His spirits greatly forsook him, and the only piece of composition that he attempted from that to his death, was a monody on her death, known by the name of "Mary McGuire." Carolan, while on a visit at Mrs M'Dermott's of Alderford, in the county of Roscommon, was taken suddenly ill, and died there in the month of March 1738, in the 68th year of his age; and was interred in the parish church of Kilronan, in the diocese of Ardagh. But no memorial exists of the spot in which his remains were laid. He had seven children by his wife, six daughters, and one son, who studied music, and went to London, where he taught the Irish harp. Before his departure, he published, in 1747, a collection of his father's music; but omitted, through mercenary motives, some of the very best of his pieces. It was republished in Dublin, by John Lee, in 1780.

Carolan, as a musician, stands in the very first class, and has added considerably to the ancient stock of Irish music, for which his country has been, from the earliest times, so celebrated. Many of his pieces, it is to be feared, are now lost; but we hope, that most of them may yet be recovered, through the indefatigable exertions of the ingenious Mr Bunting of Belfast. See his General collection of the Ancient Music of Ireland; and the Belfast Monthly Magazine, No. 12, vol. iii. (g)

CAROLINA, North, one of the United States of America, is bounded on the north by Virginia, on the east by the Atlantic Ocean, on the south by South Carolina and Georgia, and on the west by the state of Tennessee. According to its charter limits, however, it extends much farther on the west, including the state of Tennessee, as far as the river Mississippi. By the treaty of 1763, Great Britain gave up her claim to all territory westward of the Mississippi; and the courts of France and Spain, at the same time, granted her the free navigation of that river. At the termination of the American war, Great Britain transferred her interest in that river to the United States. But since Spain, forgetting the treaty of 1763, now claims the exclusive right of navigating the Mississippi, North Carolina resumes her claim to the lands beyond it, included within the limits of her original charter. By that charter, it extended 756 miles in length, and 110 in breadth.
CAROLINA.

North Carolina.

between 34° and 36° of north latitude, and 76° and 92° of west longitude. As these boundaries, however, are disputed by the Spaniards and Carolinians, it is safer to adhere, in a geographical description, to the limits which are generally recognised. Exclusive of the state of Tennessee, North Carolina is situated between 35° 30' and 38° 30' north latitude, and between 76° 8' and 83° 8' west longitude, being about 450 miles in length, and 180 in its greatest breadth, and containing about 34,000 square miles. Its districts, eight in number, are classed in three divisions: The eastern districts, Edenton, Newbern, and Wilmington; the middle districts, Fayette, Hillsborough, and Halifax; and the western districts, Morgan and Salisbury. The eastern districts stretch along the sea coast, from the Virginian line to South Carolina; the other five include the whole state west of the maritime districts, and the greater part of them extend across the state, from north to south. These districts are subdivided into fifty-eight counties, in the following order: In Edenton are the counties of Chowan, Churrituck, Cambden, Pasquotank, Perquimans, Gates, Hertford, Bertie, and Tyrrell; in Wilmington are the counties of New Hanover, Brunswick, Onslow, Duplin, Bladen; in Newbern, the counties of Craven, Beaufort, Carteret, Pitt, Hyde, Jones, Wayne, Glasgow, Lenoir, Johnston; in Halifax, the counties of Northampton, Halifax, Martin, Edgecomb, Warren, Franklin, Nash; in Fayette, the counties of Moore, Cumberland, Sampson, Richmond, Robeson, and Anson; in Hillsborough, the counties of Granville, Pearson, Caswell, Orange, Wake, Chatham, and Randolph; in Morgan, the counties of Burke, Wilkes, Rutherford, Lincoln, and Buncomb; in Salisbury are the counties of Rockingham, Guilford, Montgomery, Stokes, Surry, Iredell, Rowan, Cabarras, and Mecklenburg.

General aspect.

The general aspect of North Carolina is by no means interesting. In its whole width, for about sixty miles from the sea, it is a dead level, varied only by occasional openings in the immense forest with which it is covered. After traversing this tedious plain, we are at length relieved by the appearance of hills and mountains; from the summits of which we behold a beautiful country, stretching west far beyond the range of vision, watered by the broad stream of the Tennesee, and adorned with forests of lofty trees. The general aspect of this state, which, in all its features, resembles that of South Carolina, will be found more minutely described under that article.

In the level part of North Carolina, the soil is but indifferent. On the banks of some of the rivers, however, and particularly of the Roanoke, it is remarkably fertile. Even in the other parts of this champaign country, glades of rich swamp, and ridges of oak-land, of a black and fruitful soil, form an exception to its general sterility. The whole of this level tract abounds with marine productions, which are found by digging a few feet below the surface. The sea coast, the sounds, inlets, and lower parts of the rivers, have invariably a soft muddy bottom. That part of the state which lies west of the mountains, extending in length about 500 miles, and up-wards of 100 in breadth, is, with a few partial exceptions, remarkably fertile, and abounds with oak trees of various kinds, walnut, elm, linn, and cherry trees; the last of which grows here to such a size, that many of them are three feet in diameter. In the hilly country, the soil and productions are nearly the same as in the northern states. Wheat, rye, barley, oats, and flax, are the crops most generally cultivated, and seem to suit the nature of the soil. Throughout the whole of North Carolina, Indian corn and pulse of all kinds are reared with success. Here is a species of pulse, pretty common in this country, called ground peas, which run on the surface of the ground. To bring them to perfection, they are covered with a light mould, and the pods grow under ground. They may be eaten either raw or roasted, and in taste resemble a hazel-nut. Cotton is planted in considerable quantities, though the culture of this plant might still be greatly increased. As the stalk is killed by the frost, it is necessary to plant it yearly.

The indigenous productions of this country are not unworthy the attention of the botanist and natural historian. Of the plains in the low country, the large natural growth is almost universally pitch-pine, a tall and beautiful tree, which grows here to a size far superior to the pitch-pine of the northern states. This valuable tree affords pitch, tar, turpentine, and various kinds of lumber, which, together, constitute at least one-half of the exports of North Carolina. It is of two kinds, the common, and the long-leaved. The latter differs from other pines, not in the shape, but in the length of its leaves, which are nearly half a yard long, and hang in large clusters. This country produces white and red oak of the finest quality, and its swamps abound with cypress and bay trees. Oak, walnut, and pine, are the most common species of timber in the back country. In the moist gravelly soil, there grows a kind of stunted oak, called by the inhabitants black jack, which seldom exceeds eight or nine inches in diameter. The trees in the low country, near the sea-coast, are loaded with quantities of a long spongy moss, which, by absorbing the noxious vapour exhaled from stagnated waters, is supposed to contribute much to the healthiness of the climate. The hypothesis is supported by experience; for it is generally observed that the country, after being cleared, is less healthful than before. The misletoe frequently engraves itself upon the trees in the back country. Plums, grapes, strawberries, and blackberries, grow spontaneously in this happy soil. Besides being covered with herbage of various kinds, and with a species of wild-grass, it abounds with medicinal plants and roots; the most valuable of which are the ginseng, Virginia snake-root, Seneca snake-root, an herb of eminent quality resembling ipeccocanha, and lion's heart, a sovereign remedy for the bite of a serpent. In many places there is found a sensitive briar, which, on the slightest touch of a leaf, turns, and clings close to its stalk, and in about two minutes after, perfectly recovers its former situation. The stalk of this plant dies in winter, but its root survives, and shoots forth a new stalk in spring. To this list of indigenous plants and herbs, we may add the Mucipula veneris.
The rich bottoms are overgrown with canes, the leaves of which continue green all winter, and afford excellent pasture for cattle.

Of all the United States, North Carolina seems to be farthest removed from that perfection of culture, which is necessary to give it the full advantage of the natural richness of its soil, and the value of its productions. One great cause of its backwardness is the want of inland navigation and of proper harbours. The first impediment arises in so much from the smallness or shallowness of the rivers, as from the bars of hard sand which block up their mouths.

The Chowan river, formed by the confluence of three streams which rise in Virginia, is three miles wide where it falls into Albemarle Sound, but narrows very rapidly in its ascent. The Roanoke, though a river of great length, is so extremely rapid, and so full of water-falls, that it can be navigated only by row-boats, nor by these more than sixty or seventy miles from its discharge into Albemarle Sound. The Pamlico, or Tar river, flowing into Pamlico Sound, is navigable for vessels drawing nine feet of water, as far as the town of Washington, about forty miles from the coast; and for scows or flatboats, to the town of Tarborough, fifty miles farther up. The Neuse river, falling likewise into Pamlico Sound, is navigable for ships of considerable burden, about twelve miles above the town of Newbern, for scows fifty miles, and for boats two hundred miles. Besides these, there are many smaller rivers, all of which are navigable so long as they continue broad enough for a vessel to turn. The Tennessee, too, rolls part of its majestic stream through this state, and receives in its course several tributary waters. In bursting through the Cumberland or Laurel Mountains, it occasions a remarkable whirlpool. From an expanse of half a mile, it is here confined to the width of about 100 yards. Just as it enters the mountain, a large rock, projecting obliquely from the northern shore, renders the channel of the river still narrower, and causes a sudden bend. The water, thrown with great force against the southern shore, rebounds around the point of the rock, and produces the whirlpool, which is about eighty yards in circumference. In less than a mile below this whirl, the river expands into its usual breadth, and continues to flow in placid beauty, till it mingles with the Ohio. These rivers, if accessible to ships of any magnitude, would greatly facilitate the internal commerce of North Carolina; but they are unfortunately rendered almost useless in that respect by the sand bars at their entrance.

Nor is this inconvenience compensated by any fine harbours, spacious bays, or bold inroads of the ocean into the country. It has, indeed, some extensive sounds, such as Pamlico, Albemarle, and Core sounds; but these may be regarded as mere lakes, for the inlets by which they are connected with the ocean are so small, as to be navigable only to boats or small vessels, and admit so little of the tide, that the rivers which flow into the sounds receive not, even at their mouths, the slightest taste of brine. This state cannot boast of one good harbour throughout the whole extent of its coast. It is said that there was formerly an excellent haven in Cape Lookout, which, since the year 1777, has been completely filled up with sand. The best of the harbours now to be met with in North Carolina, is Wilmington, which admits vessels of 300 tons burden; but the entrance to it is rendered extremely dangerous and difficult, by a large shoal, to which mariners have given the name of Cape Fear. The northeastern branch of the river Fear is navigable as far as Fayetteville, one hundred miles beyond Wilmington, for vessels of eighteen or twenty tons burden. This is the greatest river navigation in the state, and serves greatly to enliven the trade of Wilmington.

A considerable traffic is carried on between this port and the Antilles; and European goods are conveyed thither from Charleston, Baltimore, and Norfolk. The exports of Wilmington amounted, in 1791, to $258,792 dollars; in 1792, to 262,498 dollars; in 1795, to 171,669 dollars; in 1794, to 153,167 dollars; and in 1795, to 254,151 dollars.

Next to Wilmington, the most considerable ports are Newbern and Edenton. Newbern is seated on the river Neuse, at its confluence with the Trent, about one hundred miles from the sea, from which the whole coast of North Carolina is separated by long and small inlets from Cape Lookout to the borders of Virginia. The exports of Newbern amounted, in 1791, to 105,685 dollars; in 1792, to 101,367 dollars; in 1795, to 60,695 dollars; in 1794, to 69,617 dollars; and in 1795, to 73,659 dollars.

Edenton is situated on the river Roanoke, near the point of Albemarle Sound, about 150 miles from the inlet which takes its name from the Roanoke. Ships of 150 tons burden can sail a few miles above Edenton. Its exports amounted, in 1791, to 92,800 dollars; in 1792, to 87,203 dollars; in 1793, to 59,576 dollars; in 1794, to 50,648 dollars; and in 1795, to 77,907 dollars.

From the books of the custom-house, it appears, Commerce, that in 1791, the total amount of the exports from North Carolina was 524,548 dollars; in 1792, 227,699 dollars; in 1793, 365,414 dollars; in 1794, 321,587 dollars; and in 1795, 492,161 dollars. Of the produce of the back country, a great proportion is conveyed to South Carolina and Virginia: the southern interior counties send their produce to Charleston, and the northern to Petersburg in Virginia. The exports from the latter parts of the state are tar, pitch, turpentine, rosin, Indian corn, boards, scantling, staves, shingles, furs, tobacco, pork, lard, hogs-wax, myrtle-wax, with a few other articles. The commerce of North Carolina is chiefly with the West Indies and the northern states. From the former, it receives rum, sugar, and coffee; from the latter, flour, cheese, cider, apples, potatoes, ironware, cabinet articles, hats, teas, and dry goods of all kinds imported from Great Britain, France, and Holland.

Like all the southern states of United America, Climate, North Carolina has a considerable diversity of climate, diseases, occasioned by the physical peculiarieties of its different parts. In the level part of the country, intermittent fevers are frequent during summer and autumn; which, though seldom immediately dangerous to those whose constitutions are not injured by intermence, yet, if neglected at first, invariably bring on other disorders, which destroy the vigour both of mind and body, and generally terminate in death.
During these sickly seasons, the countenances of the inhabitants have a pale yellowish hue, occasioned by the prevalence of bilious affections. Yet more, fall victims during winter, to pleurisy and peripneumonies, than to the fevers occasioned by the heats of summer. Physicians allege, that these fatal diseases, which are generally brought on by intermixture, and an imprudent exposure to the weather, might in general be escaped by sobriety and caution. The use of flannel next to the skin, they recommend as an excellent preventative of the diseases incident to this climate and season. In the western hilly parts of the state, the air is as pure and salubrious as in any part of America, and the inhabitants in general live to a great age. The heat of the summer’s day is succeeded in the evening by a grateful and refreshing coolness; autumn is temperate and serene; and in some years the winters are so mild, that autumn may be said to continue till spring. Wheat harvest commences in the beginning of June, and that of Indian corn early in September.

When the conduct of the British government had roused the Americans to an assertion of their independence, a constitution was framed for each individual state, by its representatives assembled in congress. The constitution of North Carolina, ratified in December 1776, vests all legislative authority in two distinct branches, both dependent on the people, viz. a Senate, and House of Commons. Each county in the state is represented in the Senate by one member, chosen annually by ballot; and in the House of Commons by two members, elected in the same manner. The towns of Edenton, Newbern, Wilmington, Salisbury, Hillsborough, and Halifax, have each, likewise, the privilege of having one representative in the House of Commons. The Senate and House of Commons, assembled for the purpose of legislation, are styled the General Assembly. No person can be elected a senator who has not resided at least one year immediately before the time of election in the county which he has to represent, or who does not possess there 300 acres of land in fee; and those who vote for his election must be freemen, not below twenty-one years of age, who have resided in the state one year previous to the day of election, and have possessed a freehold of fifty acres of land, for at least the last six months of that time. The candidate for a seat in the House of Commons must have resided one year previously to the election in the county which he is to represent, and must have possessed for at least six months, and continue to possess, not less than 100 acres of land in fee, or for the term of his life; his election is decided by a majority of the freemen in the county, not under twenty-one years of age, who have resided in the state a year before the time of election, and have contributed their portion of public taxes. These two houses, when convened, choose each its own speaker, and decide on the qualifications and elections of their respective members. At their first meeting, after each annual election, they jointly choose by ballot a governor for one year, who is not eligible to that office oftener than thrice in six successive years. The governor must possess a freehold of more than £1000, and must have resided in the state at least five years. At the same time, and in the same manner, they elect a council of state, consisting of seven persons, to assist the governor in discharging the duties of his office. They appoint one or more treasurers for the state; a state secretary, who continues in office for three years; judges of the supreme courts of law and equity, judges of admiralty, and an attorney-general, who are commissioned by the governor, and hold their offices during good behaviour. Intended laws must be proposed in the form of bills, which must be read three times in each house, and signed by the speakers, before they can be enacted.

Judges of the supreme court, members of council, judges of admiralty, treasurers, secretaries, attorney-generals for the state, clerks of record, clergymen, receivers of public money whose accounts are unsettled, military officers in actual service, and persons who deny the being of God, the truth of the Protestant religion, and the divine origin of the Old and New Testament, cannot hold a seat either in the senate or House of Commons. No business can proceed in either house, unless a majority of its members be present.

We are not able to state precisely what the public expenditure of this state may be at present. A few years ago, it fluctuated from about 38,000, to 45,000 dollars. The public debt, which was chiefly contracted during the revolutionary war, consists in bills of credit to the amount of £150,000, which are either in the treasury, or in circulation. By the determination of the commissioners, the debt, which the Union owes to this state, amounts to 500,882 dollars, or £200,752 sterling. The money necessary for the exigencies of the state is raised by the following taxes: 1. Eight-pence for every hundred acres of land, whatever its situation or quality may be. 2. Two shillings for every hundred pounds of taxable property, in town lots. 3. Two shillings for every inhabitant, whether white or black, Freeman or slave, from 12 to 15 years of age. 4. Ten shillings for every stallion. 5. Forty shillings for the licence to keep a tavern, or for selling spirituous liquors. 6. For every sentence for debts, from eight to twenty shillings, according to the different counties by which it is pronounced. The justices of the peace are in virtue of their office, collectors of the taxes: they receive six per cent, on the amount of the taxes which they collect, and sixpence for every mile which they travel on that errand. In 1798, the taxes amounted to £18,447, 4s. sterling, or 99,200 dollars, in the following proportions: The taxes on town lots, to 2500 dollars; on lands, to £5886, 10s. sterling; the poll-tax, 25,400 dollars; the taxes on law suits, billiards, and horses, 2500 dollars; making in all 46,118 dollars, or £18,447, 4s. sterling. Deducting from this sum the expenses of collecting the taxes, and the loss arising from defaults, there remains a net surplus of £15,681 sterling, or 99,200 dollars.

In North Carolina, as in all the other states of the Religion, Union, the establishment of any religious sect or denomination, in preference to others, is expressly prohibited by the constitution. The western parts of the state, which have been settled within the last 50 years, are chiefly inhabited by Presbyterians from Pennsylvania, the descendants of people from the north of Ireland. The Moravians form a very numerous sect, and have many flourishing settlements in the state, particularly in Surry county, between the rivers Dan and Yadkin. The Quakers have a
settled in New Garden, in the county of Guilford, and several congregations in Perquimans and Pasquotank. The Methodists and Baptists are numerous, and are daily making converts. In the districts of Wilmington, Newbern, Edenton, and Halifax, the inhabitants, amounting to about three fifths of the population of the state, profess themselves of the Episcopal persuasion. At present, however, they have no house for public worship, nor is there much external appearance of religion among them in general.

The character of the North Carolinians is neither respectable nor engaging. Indifference and indifference are their prevailing dispositions—dispositions which display themselves not only in the slovenly and inactive manner in which they conduct their secular business, but in their general neglect of religion. The Sabbath is disregarded, or is distinguished only by the convivial mirth of the white inhabitants, or the noisy diversions of the negroes. The women, though remarkably affectionate, mingle but little in society; nor are they treated with that respect and attention which is universally paid to their sex in more civilized countries. The men, of course, want that polish and refinement of manners which the society of the fairer part of our species, and an anxiety to win their regard, alone can impart. Living on their plantations, at a considerable distance from each other, and in a state of seclusion from the world, they delight to meet together in convivial parties, and enjoy the visit of a stranger with a relish which displays itself in the most unbounded hospitality. But even in their hospitality there is a coarseness which can only be redeemed by the benevolence which it indicates; and their conviviality almost invariably degenerates into gross intemperance. Drinking, gambling, and every species of dissipation engross the time and the attention which should be employed in the culture of their plantations, or the improvement of their minds. To the amusements of cock-fighting and horse-racing they are as passionately addicted as our keenest British sportsmen; and enjoy the spectacle of a boxing-match, in a style of perfection of which our most knowing ones have scarce an idea. When two Carolinian pupillists have exhausted their strength in fair bruising, they have at length recourse to going on, which is thus performed. Each of the combatants endeavours to twist his fore-fingers in the ear-locks of his antagonist. When these are fast clenched, the thumbs are extended each way to the nose, and the eyes gently turned out of their sockets. The victor, for his expertise, receives shouts of applause; while his eyeless antagonist is laughed at for his misfortune. We regret, for the honour of humanity, to state, that this shocking entertainment is not confined to North Carolina, but is sometimes enjoyed by the lower classes in its sister province and in Georgia.

From this short sketch of the manners of the North Carolinians, it will easily be perceived that the education of their youth is an object of little attention. There is not, in the whole state, a single college or university; a defect which is the less excusable, as it is expressly enjoined in the original constitution, that "there shall be one or more seminaries of learning maintained at the public expense."

Academies or schools, however, have been established at Newbern, Salisbury, and Hillsborough. The academy at Salisbury had, in 1786, about fifty scholars, under the tuition of a clergyman. The number of students in Hillsborough may be from 60 to 80; what number there may be in Newbern we have not been able to ascertain.

The increase of population in North Carolina has been amazingly rapid. In the year 1710, it contained no more than 1200 males; and in 1810, it contained 565,516 inhabitants, and is, in regard to population, the fourth state in the union. To this rapid increase of numbers, successive emigrations from Pennsylvania, Virginia, and other states, have greatly contributed. Now, however, the increase arises more from its own stock than from emigration; for, though colonists do arrive from these quarters as formerly, many settlers, on the other hand, emigrate again to Georgia, South Carolina, Kentucky, and Tennessee.

The towns in this state are few, and of little importance. Newbern, Edenton, Wilmington, Halifax, Hillsborough, and Fayetteville, are the most considerable, and have each, in its turn, been regarded as the capital. Since 1788, the seat of government has been fixed at Raleigh. (μ)

CAROLINA, SOUTH, one of the United States of America, is bounded on the north and north-east by North Carolina, on the south and south-west by Georgia, and on the east by the Atlantic ocean; extending from the 33° to the 35° of north latitude, and from the 78° to the 81° of west longitude from London. Its limits may be more minutely traced as follows. Its northern frontier is determined by a line commencing at a cedar stake, marked with nine notches, on the shore of the Atlantic ocean, near the mouth of Little River. It then pursues, by many traverses, a course W. N. W. till it reaches the fork of Catawba river; and next runs due west to a point of intersection in the Appalachian or Alleghany mountains. It thence takes a southerly direction, till it meets the Chatuga, the most northern branch of the Tuguloo river, and then proceeds along the Tuguloo to its confluence with the Keowee. From this point it stretches along the Savannah, till that river flows, by its most northern mouth, into the Atlantic ocean. It then runs north-east along the Atlantic, including the islands which stud its shore, till it intersects the northern boundary, near the entrance of Little River. These boundaries include an area, somewhat triangular, of about 2180 square miles.

South Carolina is divided by nature into two parts, which, from their physical situation, have been called the Upper and Lower Carolina. Towards the coast, the country is a level plain, extending more than one hundred miles westward from the ocean. Here the eye finds no relief from the dull uniformity of boundless forests, swamps, and level fields. This fatiguing plain is succeeded by a curious range of little sand-hills, exactly resembling the waves of an agitated sea. This singular country occupies an extent of about sixty miles. It is extremely barren,—enlivened here and there by spots of verdure, or by some struggling pines; and its few inhabitants earn a scanty subsistence by the cultivation of corn and sweet potatoes. After passing these sand-hills, we come next to a remarkable tract of ground, which, on its
approach from the sea, is lofty and bold, but on the
north-west is level from its summit. This tract, called
ed the Ridge, is a fine belt of land, extending from
the Savannah to Broad River; fertile, well cultiva-
ted, and watered by some considerable streams. The
country beyond this ridge resembles, in its scenery,
the most interesting of the northern states. The tra-
veler is perpetually gratified by the pleasant alternation
of hill and dale; the lively verdure of the hills
is contrasted with the deeper tints of extensive forests
which decorate their sides; and in the valleys, broad
rivers roll their shining streams through the varied
beauties of luxuriant and highly cultivated fields.
From these delightful regions, the ground still con-
tinues to ascend; every hill we pass yields in height
to its successor;

"Hills peep o'er hills, and Alps on Alps arise;"

until, after many a toilsome step, we reach at length
the western terminating point of the state.

As the coast of South Carolina forms the base of
the triangle which his boundaries describe, only its
apex, containing four of the 25 districts into which the
state is divided, can properly be called moun-
tainous. The districts of which this apex consists,
are Pendleton, Greenville, Spartanburg, and York.
Here seven or eight mountains run in regular direc-
tion, the most distinguished of which is Table
Mountain, in the district of Pendleton. This stupendous
mountain, towering to the height of 3000 feet from
its base, and 4000 above the level of the sea, presents
on one side an abrupt precipice of solid rock, nearly
perpendicular; at the bottom of which is a dismal
valley, apparently sunk as much below the level of
the surrounding country, as the mountain rises above
it. The precipice, viewed from the valley, appears
like an immense wall stretching up to heaven; and
the awe which it inspires is considerably increased by
the quantities of bones which lie whitening at its
base; the remains of various animals which had incau-
tiously approached too near its edge. The summit
of this mountain is frequently enveloped in clouds. In
winter, prodigious masses of snow tumble from its
sides, the sound of which is heard at the distance of
seven miles. Its forests produce excellent mast. They
are frequented by wild pigeons in such flocks as
sometimes to break the limbs of the trees on which
they alight. The upper regions are the resort of
deer and of bears. Olenopy Mountain, in the vicinity
of the Table Mountain, is remarkable for a cata-
ract, the descent of which is from 600 to 700 feet.
Oconee mountain, near the head-waters of the rivers
Savannah and Tugaloo, is five or six hundred yards
above the adjacent country. Between this and Table
Mountain the country is generally wild, but the val-
leys are highly cultivated, and so fertile as to produce,"
in many instances, 100 bushels an acre. On a stream
which flows among these mountains, there are several
fine waterfalls. From one of them in particular,
which is about 130 feet high, the water dashes with
such violence, as to occasion a current of air which
keeps the leaves in perpetual agitation, and to scat-
ter a spray, like rain, to a considerable distance
around. The other considerable mountains of South
Carolina are Paris's mountain, in Greenville district,
from which issues a spring impregnated with iron and
sulphur, said to be efficacious in curing ring-worms,
and other diseases of the skin; the Glassy and
Hogback mountains, situated near the boundary line
of Greenville and Spartanburg, from which issue the
streams which form the sources of the Tyger and
Pacolet rivers; and King's mountain, in York dis-
trict, on which has been discovered the real limestone
rock. These mountains afford a profusion of rich
grass, and are clothed to their summits with lofty
forests. Copious streams of the finest water pour
from their sides; and the intermediate valleys, though
small, are amazingly fertile. The boundless view of
the upland country, becoming more level as it ap-
proaches the sea, is finely contrasted with the wild
irregularities of those immense heights which diver-
sify the western extremity of Carolina.

Though but a small part of this country is occu-
pied with mountains, every part of it is intersected by
rivers. Towards the sea it is watered by the Waccam-
waw, Pedee, Black River, Santee, Wando, Cooper,
Ashley, Stono, Edisto, Asheppoo, Combahee, Coo-
saw, Broad and Savannah rivers. Most of these ri-
vers have a margin of swamp, extending from half a
mile to three miles. All of them run in a southe-
astern direction from their heads to the sea. Broad
river, Coosaw, Port Royal, and other short rivers,
are properly arms of the sea, deep, and of easy navi-
gation. Broad and Port Royal rivers can accommo-
date a large navy with convenience and safety. Wando
river, which flows into the Cooper about three
miles above Charleston, is navigable for about twen-
ty miles. Cooper river may be navigated for about
fifty miles by schooners and sloops; and its eastern
branch is navigable for a considerable way to vessels
of a similar description. Where it empties itself into
Charleston harbour, it is about one thousand four-
hundred yards broad. The harbour is formed by
the junction of the Cooper with the Ashley river,
which, rising in the Cypress, and other contiguous
swamps, expands opposite Charleston to a width of
two thousand one hundred yards. To vessels of con-
siderable burthen it is navigable for only a few miles,
but admits of sloops and schooners for many miles
higher. The Savannah river is bold and deep. Boats
of seventy tons burthen can advance on this river
from the sea to Augusta, in the upper district of
Georgia. Here the falls of the river commence, be-
yond which the navigation continues for boats of 30
tons to Vienna, sixty miles higher. The Santee is
navigable from the sea to the fork of the Congaree
and Wateree rivers; thence up the Wateree to Cam-
den on one side, and up the Congaree to Granby
on the other, for boats of seventy tons. At these places
the falls and rapids commence; the upper branches
of the rivers are dispersed extensively over the coun-
try. Though sometimes obstructed by rocks, their
current is in general deep and gentle. In full rivers,
light boats, containing several hogsheads of tobacco,
have been floated down their streams with safety.
The Pedee river, stretching from the sea towards the
mountains, through the northern part of the state, is
navigable to vessels of seventy tons as far as Green-
ville to Chatham. There the navigation is obstruc-
ted by rocks and shallows, though, in full rivers, boats
of light burden descend with the stream from North
Carolina. The Stono, Asheppoo, Combahee, Edisto,
and Black rivers, though much inferior to those
which we have mentioned, are all navigable for some
miles, and greatly facilitate the internal communication of different parts of the country. The large rivers spread themselves, by innumerable tributary streams, throughout the upper country. Some of their branches are even wider than the rivers themselves. Kewee, though two hundred yards wide for several miles above its confluence with the Tuguloo, is the narrowest of these two streams, whose united waters take the name of Savannah river.

In most of the upper districts, but especially in those at a moderate distance from the mountains, interesting facilities are afforded for mills, and other machinery. The springs which issue from the sides of the mountains, after running sixty or seventy miles, become streams from 100 to 200 yards in breadth. These, as they spread wide, have many shoals, and are so shallow as to be generally fordable. At many of those shoals the falls are sufficient, with the aid of a small dam, to impel the most weighty machinery. At some of them the falls are so great and so abrupt, as to admit twenty feet wheels upon the overshot construction, without any races, or, at most, with very short races; and, at others, the ledges of rocks form a natural dam, quite sufficient for obstructing as much water as is necessary to drive any kind of mill. Besides these rivers, smaller streams called creeks spring from the foot of the hills; and with the advantage of their falls, are sufficiently powerful to impel machinery of any magnitude. The inhabitants are now beginning to avail themselves of these natural advantages. Many valuable machines have been erected for improving and facilitating labour, particularly saw-mills and corn-mills; though it must be owned, that their improvement in manufactures have by no means kept pace with their progress in wealth, and are far from being adequate to their opportunities.

The mineral productions of this country have not yet, perhaps, been sufficiently explored; but those which are known are of considerable importance. Asbestos is found near the sources of Lynche's creek. Soap-stones, slate-tites, rock-crystal, white flint, fuller's earth, clays of different kinds and of beautiful colours, pottery's clay, isinglass, ochres, chalks, and marls, have been found in different parts of the state. At Beaver's creek, there is a quarry of grey stone resembling freestone, which works well, and splits easily. Rocks suitable for millstones are common in the upper country; good slate has been found in some places; and some fine clay was brought to Charleston, about the year 1769, from the Cherokee country, which, being sent to England by Dr. Garden, was manufactured into a tea equipage, equal to the finest imported from China. The upper country, particularly the mountainous districts, abound with iron ore of so good a quality, as to yield a fourth of its weight in excellent iron. The Cherokee mountains furnish great abundance of lead ore, so rich as to produce two-thirds of its crude weight in pure lead. Specimens of copper and of several other metals have likewise been found, and mines of these metals might perhaps be wrought with advantage. There are many valuable medicinal springs within this state, some of which are rising into fame; but their component parts and real virtues have not hitherto been ascertained with satisfactory precision.

Many circumstances concur to render it probable, or rather certain, that all the low country of Carolina has once been under the dominion of the ocean. In the deepest descent into the ground, neither stones nor rocks are ever discovered. The strata generally consist of rocks or beds of shells, with which petrified fish are sometimes found intermixed at a considerable depth from the surface. Extensive beds of oyster shells have been discovered at a great distance from the present limits of the sea shore. The most remarkable of these extends from Nelson's ferry on the Santee river, sixty miles from the ocean in a south-west direction, passing through the intermediate country, till it crosses the Savannah river in Burke county, and continuing on to the Oconee river in Georgia. These shells are uncommonly large, and quite different in kind from the oysters now found on the shore of Carolina. They lie about seven feet below the surface: the incumbent stratum consists of common earth: below the oysters, the soil, for the next four feet, is a whitish coloured mass, intermixed with shells; a blue hard substance resembling stone succeeds for the next three or four feet; and under this is sand, the depth of which is unknown.

Almost the only lake of which South Carolina can boast, is a sheet of water in Barnwell district, nearly a mile in circumference. In several places, the large rivers have broken through peninsulas formed by their streams, and work a channel as wide and deep as the circuitous channels in which they formerly flowed. When the mouths of these channels are partly choked up, and the streams in them become slow, they are denominated lakes. Such is Lounder's lake on Pedee river, over which the surrounding lands project elevations of near one hundred feet.

Along the coasts of South Carolina, neap tides rise, in common weather, from six to eight feet; and spring tides from eight to ten. They are much influenced, however, by the wind; for, with a south-easterly wind, neap tides rise higher than spring tides when it blows from the northwest. The depth of water for some miles from the shore, is from two to five fathoms. In rivers, whose streams are not impetuous, the tides ascend from thirty to thirty-five miles in a direct line from the sea. In the Santee and Savannah, the influence of the tide is not perceptible for more than fifteen miles; and the powerful column of water which they pour down, makes them retain their freshness till within two miles of their disemboguement.

The mineral productions of this country may be conjectured from the size of its ribs, one of which, when dug up, was nearly six feet long, and from one of its jaw teeth, which was 3½ inches long, 3½ inches wide, and its root 1½ inches long. The depth of the tooth, from its sur-
The coast of Carolina is intersected by inlets, cracks, and marshes, from the meanderings and junctions of which many islands are formed. Of those islands some are increased on their western extremities by accretions, and diminished on their eastern border by the dashing of the ocean. On those which are contiguous to the main, monuments of Indian antiquity are occasionally discovered. There are other islands entirely of marine origin, which appear to be accumulations of increments thrown up by the action of the Atlantic waves. The mainland, contiguous to these islands, has a surface of light black earth upon a stratum of sand. For 80 or 100 miles it is quite free of stones; and has a gradual ascent, which, at least for a considerable distance from Charleston, has been ascertained, with mathematical precision, to be three feet in a mile.

The soil of South Carolina is naturally, as well as politically, divided into six classes: 1. Tide swamp. 2. Inland swamp. 3. High river swamp, or low grounds, distinguished by the name of second low grounds. 4. Salt marsh. 5. Oak and hickory high land. 6. Pine barren. The two first classes are peculiarly adapted to the culture of rice and hemp; the third is most favourable to the growth of hemp, corn, and indigo. The salt marsh has hitherto been much neglected, though there is every reason to believe that it would amply repay the trouble of cultivation. The oak and hickory land is remarkably fertile, and is well adapted to the culture of corn, as well as of indigo and cotton. The pine barren, though the least productive, is so much more salubrious than the other soils, that a proportion of pine barren is an appendage indispensably necessary to every swamp plantation. It is remarkable, that this species of soil, though comparatively barren, bears pine trees of the largest growth, which maintain their verdure through winter, and, as Dr Ramsay justly observes, administer more to the necessities and comforts of mankind, than any other species of tree whatever. The cause of this seems to be, that the pine land is only superficially sandy; for, on digging into it a few feet, the soil is found to change, in many places at least, from sand to clay. The tide swamps are so level, that a few inches of water can frequently cover them sufficiently for agricultural purposes. In the legal valuation of the land for taxation, these lands hold the first rank. As the swamps above the influence of the tide are subject to river floods, which the Americans call freshets, they are somewhat precarious, but on other respects are of immense value. The sand hills in the middle country are so extremely barren, as to produce scarcely a pile of grass. On the low grounds between them, however; a rich mould is frequently deposited; and the margin of the rivers which flow among them are always abundantly fertile. The hills of Santee, situated likewise in the middle country, are elevated two hundred feet above the adjacent lands. Their soil, which is a mixture of sand, clay, and gravel, is admirably adapted to the culture of highland grain and cotton; and affords to the inhabitants the pleasures of health, and the various comforts of life in a greater combination than is common in the southern states.

Agriculture, though the grand business of Carolina, is far from having reached the perfection of which it is susceptible. The art of managing land is little understood, and even less practised. Most of the planters, relying on the fertility of the soil, of which they have generally extent enough to enable them to change what begins to fail for that which is fresh, seldom give themselves much trouble to keep their fields in heart. So little was the value of manure understood only twenty years ago, that it had no fixed price in Charleston, but was given to the first who chose to carry it out. To their cattle, hogs, and sheep, they pay little attention. Allowed to roam at large in the woods, where they find abundance of excellent food and shelter, they depend but little on the care of their owners, and can hardly be regarded as domesticated animals. Hence, it often happens, that a planter, who possesses twenty or thirty milch cows, derives less advantage from them, than cottagers derive in other countries from two or three, which they tend with proper care. Much valuable high land remains yet unbroken. Extensive marshes, which might easily be converted into productive rice swamps, are left in a state of nature. Indeed, it is only a small proportion of the ground lying on the margins of rivers and of swamps, that has yet been brought under proper cultivation. Immense forests of pine land, which have hitherto produced little else than lumber, might, with the help of manure, be made to produce abundance of kitchen vegetables, with good crops of corn, potatoes, and turnips; and, instead of remaining unproductive deserts, might be improved to the support of a numerous and healthful peasantry. Rice, which is the most nutritious and useful aliment made use of by man, is the grand staple in the agriculture of Carolina. It was introduced into that country about the year 1693, by Landgrave Thomas Smith, who, having procured a bag of rice from the cook of a vessel from Madeira, that anchored near Sullivan's island, sowed it in a spot of moist low ground at the bottom of his garden. It grew luxuriantly. The crop was distributed among his planting friends; and in a few years rice became the chief support of the colony. The variation in the amount of the crops of this valuable aliment forms an important document in the history of South Carolina; for it has been materially affected, not only by the introduction of other staples, but by the political changes of the country. When it was first introduced, the number of negroes in the province was small, the government was unsettled, and the kind of soil and mode of culture most favourable to its growth were unknown. For twenty years after its introduction, its exportation was rendered so hazardous by the ravages of pirates on the coast, that it was not cultivated to any great extent. In the year 1724, about six years after the suppression of the Buccaneers, 18,000 barrels of rice were exported; and each succeeding year brought an additional quantity to market. The quantity exported in 1740 was 91,110 barrels; in 1754 it amounted to 104,682 barrels. Hitherto rice had been the chief article of export from Carolina; but soon after the middle of the 18th century, much of the attention of the planters

† Similar bones have been found in various parts of America; as Kentucky, the banks of the Ohio and Missourie, and the north-western territory.
Indigo.

Next to rice, the most important article of agricultural produce in South Carolina, for a long time at least, was indigo, which was first introduced about the year 1742. The cultivation of this plant went on with such spirit and success, that, in the year 1747, a considerable quantity of it was sent to England; and, in the following year, a bounty was obtained from parliament of sixpence per pound on indigo, raised in the British American plantations, and imported directly into Britain from the place of its growth. Thus encouraged, the planters of Carolina proceeded in the cultivation of indigo with such spirit and success, that the export of this article amounted, in 1734, to 216,992 lbs.; and before the revolution, it had risen to 1,107,660 lbs. Though neglected during the war, the cultivation of it was eagerly resumed after the restoration of peace; and it continued for some years to form a valuable export, till its price was greatly lowered, by large importations of the same commodity from the East Indies into England. The attention of the planters was, towards the close of the 18th century, directed to cotton; and as the same soil was adapted to the cultivation of both it and indigo, the latter was in a great measure neglected for the new staple.

Cotton.

Though the climate of Carolina was known to be similar to that of the East Indies, where cotton had grown abundantly for many centuries; though Dr Hewat, in his valuable history of South Carolina, had declared, so early as 1719, that the climate and soil of the province were favourable to the culture of cotton; and though the first provincial congress, held in January 1775, had recommended to the inhabitants the raising of that useful plant; yet a very trifling quantity only was raised for domestic manufactures, previous to the year 1795. In that year, however, cotton was exported to the amount of L. 1,109,653. Since that time the quantity of cotton raised has been annually increasing; and, in the first year of the present century, eight millions of pounds of it were exported from South Carolina. Two kinds of cotton are raised in South Carolina. On the level lands of the low country, the kind chiefly cultivated is the black seed, or long staple cotton, which is admirably adapted to the finest manufactures. The wool is easily separated from the seed by roller-gins, which do not injure the staple. In the middle and upper country, the cotton universally cultivated is the green seed kind, which, is less silky, and adheres so tenaciously to the seed, that it cannot be separated without the action of a saw-gin. This cuts the cotton exceedingly; but, as this kind is unfit for the finer fabrics, the cutting is scarcely consi-

dered injurious. Though the wool of the green seed cotton be cheaper than the other, it grows likewise more luxuriantly. An acre, which will produce 150 lbs. of black seed cotton, will generally yield 200 lbs. of the green seed kind.

These staple articles have so engrossed the attention of the planters, that the culture of wheat, barley, oats, and other crops, equally useful but less profitable, has been almost wholly neglected. So little wheat is raised throughout the state, that considerable quantities of it are annually imported. Barley has occasionally been cultivated with such success on the low grounds that seventy bushels have been procured from an acre; and as it ripens there early in May, another crop might easily be raised on the same ground in the course of the year. Notwithstanding these advantages, however, the culture of this grain has not been pursued with any degree of spirit. Hops are annually raised in small quantities, and the cultivation of them might easily be carried so far as to answer any probable demand. As mulberry trees grow in Carolina spontaneously, and native silk-worms, producing well-formed cocoons, are often found in its woods, there can be no doubt that the country is naturally adapted to the raising of silk. For a considerable time the culture of silk was carried on by the Swiss colonists near Purysburgh, and occasionally by private persons as late as the year 1787. At present it is successfully continued at New Bourdeaux in Abbeville; but the conviction that greater profits may be obtained more easily by other means, has prevented the culture of this commodity from being carried to any great extent.

The soil is well adapted to the cultivation of the soil, vine and olive trees; for the woods abound with native grapes, from which, as well as from the fruit of imported vines, wine has been occasionally made; and from the olive trees which have been naturalised in Carolina, olives are prepared and preserved equal to any that can be imported. The culture of these excellent fruits, however, has been almost entirely neglected, in the general eagerness of the planters to have extensive crops of the more profitable articles, rice and cotton. Hemp and flax have been raised in considerable quantities, and in the year 1784 were noted as articles of export, though only to the trifling amount of three tons of the former, and 171 casks of the latter. Tobacco, which is an indigenous plant of America, thrives remarkably well in Carolina. The exportation of it amounted in 1799, to 9046 hogsheads, and it might be raised to any extent; but the superior value of cotton has left the culture of tobacco comparatively neglected. The soil both of the swamps, when completely drained, and of the highlands, is admirably adapted to the growth of maize or Indian corn. But the culture of that grain, which is considered as a more nutritious aliment for labouring people than even rice, has given place to that of cotton, and it is even imported in great quantities on the sea-coast for domestic use.

Such are the articles of agricultural produce in Carolina, with the relative importance assigned to them by the planters. The genial soil of that country is equal to almost any production, and with proper culture might be made to yield at least ten times its present-value. A society was incorporated in 1785, for the purpose of promoting the improvement of agricul-
The period of vegetation in Carolina comprehends, in favourable years, from seven to eight months, commencing in January and February, and terminating in October or November. The frosts which generally prevail in the months of November, December, January, and February, are so severe for the delicate productions of more southern latitudes. Carolina cannot be reckoned a remarkably good fruit country, yet there is scarcely a month of the vegetating season which does not furnish some species of fruit. Blackberries, strawberries, raspberries, and apricots, are ripe in April and May; plums, blackberries, early pears, apples, peaches, figs, and nectarines follow; water melons and musk melons continue from June to October; pomegranates, late peaches, pears, apples, grapes, and winter plums, come in towards the termination of the hot weather; haws, sloes, and fox grapes, in October; chinquapins, chesnuts, and persimmons, still later. Gooseberries, currants, and cherries, have never grown to any purpose in the low country. Wild cherries are common in the woods, but in gardens, cherry trees, though they grow well, have never good crops of fruit. Figs, apricots, nectarines, apples, pears, peaches, olives, pomegranates, almonds, and the pecans or illinois nut, though exotics, have been naturalized to good purpose in Carolina, and endure all the varieties of season; orange trees can stand the frosts of ordinary winters, but in very severe seasons their stems are occasionally destroyed.

No species of fruit thrives so well in this country as pears, pomegranates, and water melons; the latter, in particular, grow to an enormous size, and are superior perhaps to any in the world. The forests of South Carolina abound with many valuable species of timber; and its fields yield a profusion of plants, whose curious structure, singular beauty, or medicinal virtues, render them alike interesting to the botanist and physician. Of these Dr Ramsay has given an extensive list, which we regret that our limits will not allow us to transcribe.

Of the aboriginal animals of South Carolina, several species have disappeared. Of those which remain, the most remarkable are the bear, panther, wild cat, wolf, beaver, grey fox, red deer, otter, wild rat, black squirrel, grey squirrel, flying squirrel, ground squirrel, polecat, mink, opossum, racoon, lizard, alligator, scorpion, toad. The following animals have been imported and domesticated; the cow, horse, ass, hog, sheep, dog, and cat.

Of the immense variety of birds with which South Carolina abounds, the most remarkable are, the bald eagle, fishing hawk, pigeon hawk, grey hawk, swallow-tailed hawk, night hawk, turkey buzzard, carion crow, large owl, screech owl, Carolina cuckoo, porroquet, blue jay, purple jackdaw, red-winged starling, or blackbird, rice bird, large white bellied woodpecker, gold winged wood pecker, red bellied wood pecker, hairy wood pecker, yellow bellied wood pecker, small spotted wood pecker, nut-hatch, great and small sanguillah, wild pigeon, turtle dove, ground dove, May bird, robin, thrush, Carolina bull-finch, large swamp sparrow, little gnatcatcher, snow bird, mocking bird, blue grosbeck, purple finch, painted finch or nonpareil, blue linnet, chatterer, blue bird, crested fly-catcher, black cap fly-catcher, swamp red bird, highland red bird, summer red bird, crested titmouse, yellow titmouse, pine creeper, yellow throated creeper, humming bird, king fisher, chattering plover or kill deer, whistling plover, hooping crane, blue heron, little white heron, crested bittern, cormorant, white curlew, brown curlew, oyster catcher, Canada goose, small white brant goose, great grey brant goose, duck and mallard, canvas-back duck, (found in Carolina every spring,) gannet, large black duck, ball neck duck, round crested duck, summer duck, little brown duck, blue winged teal, white-faced teal, black cormorant, flamingo, water pelican, wild turkey, peasant or mountain partridge, small partridge or quail, wren, swallow, martin, whip poor will or goat-sucker, snipe, wood-cock, marsh hen, Indian pullet.

Many species of serpents, some of them of the most dangerous kind, are natives of South Carolina. Among these are, the rattlesnake, water rattle-snaile, small rattle-snake, water vipher, copper belly snake, bluish green snake, hog nose snake, wampumi snake, horn snake, thunder snake, black snake, little brown head snake, ribbon snake, chain snake, moggason water snake, coach whip snake, corn snake, green snake, glass snake, bull snake.

The rivers and coasts of Carolina teem with many varieties of fish, some of them of the most delicate kinds. In the fresh water are found, sturgeon, pikes, trout, broom, roach, or silver fish, perch, sucking fish or carp, herring, cat-fish, garfish, rock fish, eel, and of shell fish, the soft shelled turtle, terribine, and cray fish. In the sea which washes the coasts, are shark, porpus, drum, bass, sailor's choice, shad, sheephead, crocus, whiting, porgy, black fish, soles, angelfish, mullet, herring, skipjack, yellow tail, alewife. The shell fish found in the salt water, are some kinds of large and small sea turtle, oysters, crabs, shrimps, clams, and muscles.

There is a frequent multiplication of fish in particular circumstances, which forms a remarkable peculiarity in the natural history of South Carolina. In every plantation, great care is taken in making drains to preserve water for overflowing the rice fields in summer. Soon after these ponds are made, they swarm with various species of fish. Various theories have been devised, to explain in what manner they breed, and whence they come. Some suppose, that their spawn is exhaled from the large lakes of fresh water on the continent, and being borne along in thunder clouds, falls with the drops of rain into these reservoirs of water. Others are of opinion, that the spawn has remained mingled every where with the sand, since these maritime parts of the continent were relinquished by the sea. While others imagine,
that young fish are brought by water fowls from one pond to another, by which means the new made pools receive a plentiful supply. Of these theories, we are inclined to give the preference to the third; for we do not believe, that the specific levity of spawn is such as to admit of its being raised in vapour in the clouds, nor can we easily bring ourselves to think that it could remain for ages in the sand, without being destroyed by putrefaction. None of these theories, indeed, appears to us at all satisfactory; but as the fact is notorious all over the country, its solution is worthy of the attention of naturalists.

By the degree and duration of its summer heat, South Carolina is allied to countries within the torrid zone; with those within the temperate latitudes, it is still more intimately connected by its winter's cold, and its general variability. In tropical countries, the extremes of heat and cold are not removed from each other farther than by sixteen degrees of Fahrenheit's thermometer, so that there is but little distinction in point of temperature between their winter and summer. In South Carolina, there has sometimes been a difference of 85 degrees between the temperatures of different days in the same year, and the temperature has even varied 46 degrees in the course of one day. From 1791 to 1808, the difference between the coolest and warmest summers ranged from 88° to 93°, and the difference between the mildest and coldest winters, on a few particular days, from 50° to 17°. In Charleston and the low country, the degree of heat is considerably more moderate than in the interior parts of the state. At Columbia, in the summer of 1808, the mercury in the thermometer frequently rose to 96°, 97°, and sometimes to 98°, while at Charleston it did not exceed 91°. The number of extreme warm days in Charleston is seldom above thirty in a year, and three of such days scarcely follow one another in succession. On an average, there are about thirty sultry nights in the low country in the course of the year, when the heat and closeness of the air is such, as to prevent the enjoyment of sound sleep; but this severe heat is in general soon followed by cooling showers. Of piercing cold days, there are in general a greater proportion in winter, than there is in summer of those which are exceedingly hot; but of these, as of the severely warm days, more than three seldom come together. Within the last fifty years, the transitions from cold to heat have occasionally been so great and rapid, that the thermometer has been observed to fall more than fifty degrees in less than fifteen hours. The hottest day in the year is sometimes as early as June, sometimes as late as September, but most frequently in July or August. A stranger going to Carolina, should study to arrive there either in November or December; he should be particularly cautious not to make his first appearance there in summer, or in the first months of autumn. September, when the heat begins to abate, is more sickly than the preceding months, and the heat becomes then more oppressive. Perspiration is diminished and frequently interrupted, and the system, relaxed and debilitated by the relentless fervency of July and August, feels more sensibly and frequently an overpowering lassitude. The coolness of the evenings, and the heavy dews that then fall, multiply the chances of getting cold, so that it is upon the whole the most unpleasant, as well as the most dangerous, month in the year.

The low country is seldom covered with snow; but the mountains near the western boundary of the state are often mantled in that wintry robe. Frost sometimes binds up the earth, but seldom penetrates deeper than two inches, or lasts above three or four days. These transient frosts are succeeded by weather so mild, as to render fires unnecessary in the middle of the day. Such sudden and frequent changes affect the feelings and health of the inhabitants much more than equal or greater degrees of cold can do in countries where the climate is more steady, and the transitions more gradual. In February the weather is particularly variable. When a clear warm day has called forth vegetation, and inspired the hopes of an early spring, a north-west wind suddenly arises, accompanied with frost, and blasts the pleasing expectations. In this month rains are frequent. The planting season begins in March and April, and continues till June. In July and August, when the heat is most severe, heavy rains set in, accompanied frequently with violent storms of thunder and lightning. These thunder storms are said to be much less frequent and injurious now than they were about half a century ago. Yet during the summer, there are few nights in which lightning is not visible in some part of the horizon. The fury of the storm is generally spent on the lofty trees with which the country is covered; but the lightning sometimes does considerable damage to ships in the harbours, and is not unfrequently attended with showers of hail, so large as to break down the crops in the fields, and to shiver windows of glass. In September, which is the principal harvest month, storms of rain are frequent, and are sometimes accompanied by hurricanes, which prove extremely destructive.

The hygrometer in Charlestown shews an almost constant humidity in the air. For seven years previous to 1809, it had not marked more than 24 dry days in any one year; and the average of the whole seven years was less than 16 dry days for each. The variation of the barometer is inconsiderable. It generally stands between 29 1/2 and 31°, but has been as low as 29° 7', and as high as 31° 8'. The medium temperature of well water in Charlestown is 65°, twelve degrees above that of well water in Philadelphia. By the observations of the medical society in Charlestown for ten years, (from 1797 to 1807,) the average quantity of rain in a year was found to be 49.3 inches. The greatest quantity in any one of these years was 83.4 inches, and the smallest quantity was 38.6. The greatest quantity in any one month of these ten years was 12.9 inches.

The climate of South Carolina is generally regarded as unwholesome, an opinion which is neither strictly true, nor entirely false. A great proportion of the state, particularly of the low country, is for the most part inundated; and from its sluggish rivers, stagnant swamps, ponds, and marshes, which are perpetually generating putrefaction, the seeds of feverish diseases are widely and profusely disseminated, particularly between the months of June and November. The sea shore and islands, and the ridges of land between the rivers, extending from 10 to 40, sometimes 50 miles, are for the most part salubrious. Beyond the swamps, which terminate about 120 miles from the ocean, the blessings of health are generally enjoyed, except on the margins of the rivers, and in the vicinity of ponds and mill dams. The districts of
the upper country enjoy as salubrious a climate as any part of the United States.

The lower country of South Carolina is infested with all the diseases which spring from a warm, moist, and unelastic atmosphere. Of these, the most frequent are fevers, from which the inhabitants of Carolina suffer more than from any, or perhaps than from all other diseases together. In their mildest aspect they appear as intermitents; in their next degree they are bilious remittents; and, in their highest degree, and under particular circumstances, they are converted into yellow fever. That dreadful distemper has made frequent ravages in Charleston. From the year 1700 to 1748, it raged at five different periods in that town, and numbers perished by its attacks. For 44 years after that period, there was no epidemic visitation of it, though it appeared in different summers in a few sporadic cases. A new era of this fever commenced in the year 1792. It raged in Charleston in that year, and in 1794, 1795, 1796, 1797, 1799, 1800, 1801, 1802, 1804, and 1807. The number of its victims in its worst years, were, in 1799, 259; in 1800, 184; in 1802, 56; in 1804, 148; in 1807, 162; in the year 1793, 98. In 1806 it is not mentioned at all. In 1803 and 1805 it appeared slightly; in both years its victims did not exceed 69. In 1806, it is mentioned as having occurred in a very few cases under particular circumstances. In its visitations it extended from July to November, but was most ripe in August and September. With a very few exceptions, chiefly children, it fell exclusively on strangers. Unseasoned negroes were not safe from its attacks, but they escaped oftener than other strangers. When attacked, they had the disease in a slighter degree, and, with proper treatment, were more generally cured. The variable weather of Carolina often produces inflammatory affections of the throat. A disease of that organ, accompanied with the scarlet fever, frequently recurs, but is seldom fatal. Measles, influenza, hooping cough, and small-pox, are the other epidemic diseases of South Carolina. The practice of vaccination was introduced into Charleston by Dr. Ramsay in 1802; and we are happy to have his authority for stating, that, among many thousands who have been inoculated, no instance has yet occurred of a clearly marked small-pox following a clearly marked case of vaccination.

The colony which sailed from England, under the auspices of the proprietors in 1669, and which was continually increased by new acceptions of adventurers from the same country, was the stock from which the present population of South Carolina has sprung. On this stem, however, several foreign branches have been at various times engrafted. France, Switzerland, Holland, and Germany, have each contributed largely to the population of this country, which was long regarded as the best asylum for the oppressed and unfortunate. Of these foreign emigrants by far the largest proportion were French Protestants and German Palatines. Ireland supplied an immense number of adventurers; Scotland no inconsiderable share; and many likewise emigrated from the more northern states of America. In the course of 141 years, the population of South Carolina has increased from a handful of adventurers to 414,935 inhabitants, its population in 1810. Now, however, the new states, and territories to the southward and westward, draw to them so many of the inhabitants of South Carolina, that any casual accessions to its population are more than counterbalanced by its emigrations; so that its future population must depend chiefly on the natural increase of its own inhabitants.

A population derived from so many various sources, cannot yet be expected to present such an uniformity of manners as is necessary to establish a national character. The various groups of emigrants, particularly from foreign countries, having settled in so many separate colonies, still retain many of those peculiarities, in manner and habits, which characterized the nations to which they originally belonged. As the connection between the different parts of the state is becoming daily more intimate, these peculiarities are gradually disappearing. The native languages and dialects of the different colonies are beginning to give place to the English, and there is even now such a similarity among the present inhabitants of Carolina, that a stranger would find it difficult to ascertain, from the language or manners of any portion of them, from what country their ancestors had emigrated. People living under the influence of the same climate, and the same government, must necessarily, indeed, acquire a strong resemblance in many of their physical and moral qualities. While there prevails among the Carolinians a diversity of character, which marks them out as the descendants of different races, there are at the same time a few general properties which they all possess, and which may therefore be regarded as the endemic qualities of the nation. Of these qualities the most pernicious are indulgence, intemperance, and a propensity to contract debts; all of which have been induced either by the influence of climate, or by some peculiar circumstances in their condition.

These faults, however, are more than redeemed by several valuable qualities, though some even of these are apt to be carried to an excess that becomes culpable. A jealous regard to individual and public liberty, the surest bulwark of their civil rights and privileges, is the leading feature in the character of the Carolinians. It is only to be regretted, that the love of liberty is carried, particularly by the young Carolinians, to an excess, which seems rather to threaten the subversion of public order, than to promise security to the invaluable rights which their ancestors have purchased by their blood. So jealous are these republican sparks of what they conceive to be the national privileges of men, that they spurn the restraints even of parental authority; and are so impatient of subordination, that many people of business choose to import from Europe clerks trained to obedience, rather than to be taxed by the refractory insolence of the saucy youths of Carolina.

With this love of liberty is connected a nice sense of honour, which, though favourable in general to politeness and propriety of behaviour, is indulged to such an extreme sensibility, that the slightest breach of respect, however unintended, must be atoned for, either by a submissive apology, or by a meeting in the field. So fiery, indeed, are the Carolinians, and so jealous of their honour, that more duels are fought in Carolina, than in all the nine states north of Maryland. In Carolina, as in our own country, the duelist who kills his antagonist, may be prosecuted for
Virtues of a less stern complexion, and amiable even in their excess, form the more engaging features in the character of the Carolinians. Their hospitality to strangers, and charity to the indigent and distressed, are scarcely limited, even by their pecuniary circumstances. The doors of every Carolinian are opened, not without reluctance merely, but even with eagerness, to decent travellers; and the whole state may be traversed at very little expense, by a person who, with or without letters of introduction, chooses to call at the houses of private gentlemen on his way. Among this generous people, the voice of misery is never raised in vain. Whatever can relieve the wants of poverty, or heal the pangs of distress, is administered with an unspiring bounty and affectionate sympathy, which would cover more numerous and more enormous sins than any which can be fairly laid to the charge of the Carolinians.

The prevalence of these amiable qualities may perhaps be ascribed, in no inconsiderable degree, to the influence of the ladies, whose character shines forth in Carolina with peculiar lustre. Generally well educated, their information, without fostering their vanity, enables them to maintain, with dignity and spirit, a refined and rational conversation. The politeness and elegance of their manners, imparts to all they say and do a charm, which is the more irresistible, as it seems to proceed less from art and culture, than from the native goodness of their hearts. With the vivacity and love of pleasure natural to their sex, they unite a sweetness of disposition, and a discretion, which, while they delight and animate every social circle, save the hearts of their friends from all feelings of anxiety with regard to the propriety of their behaviour. It is in the bosom of their own families, however, that their amiable qualities are most endearingly displayed. To soothe the cares and increase the comforts of a father, to administer with affectionate attention to the happiness and respectability of a brother, are the favourite occupations, from which no allurements of pleasure can withdraw a young lady of Carolina. In the discharge of their duties as wives and mothers, they are particularly assiduous and faithful; and their prudent management and kind attention, render home a most pleasing refuge from the bustle of business, and the jarring contentions in which the rougher sex are too frequently engaged.

In Carolina, the subordinations of rank which prevail in other countries, are almost unknown. Among the white people, the relation of master and servant is scarcely to be found; and the relation of master and tenant is, in the country at least, equally rare. The most obvious subdivision of its inhabitants is into planters, farmers, cottagers, and squatters. Each of these classes has a peculiar character.

The planters, who have in general large incomes, live in a luxurious and splendid style, devoting much of their time to the pursuit of pleasure, engaging in no employments which require great or continued exertions of mind or body, and possessing much of that pride and dignity of spirit, which characterises an independent country gentleman.

The virtues of the farmers are less brilliant, but more substantial, and their vices fewer than those of the planter. More dependent on their own exertions, they are consequently more active; their desires, like their incomes, are more limited; in the reverses of fortune, they exhibit greater fortitude, and have ampler internal resources to meet extraordinary emergencies.

The cottagers long continued in a state of depression. Cottagers. Unwilling to mingle in the labours of the field with the slaves of other people, and unable to procure the situation of overseers, many of them were compelled to engage in some trivial business, which afforded them only desultory employment. Without the incitements of regular gain to stimulate their exertions, the sole end of their labours was to earn a supply of the plainest necessaries of life, which, in a country like Carolina, was so easily obtained, that much of their time remained unemployed, and all the vices which result from idleness of course disgraced their character. Of late, however, both their condition and their character have been considerably improved. The culture of cotton holds out to this class of the community strong inducements to personal industry. It enables them to work their own lands, to procure a large share of the comforts of life, and daily to acquire consequence in society.

'Squatters.' The squatters have been at all times, and still continue, great nuisances to the public. Settling on any man’s land, paying no rent, cultivating no ground, they lived by their guns ostensibly in hunting, but often in shooting down the domestic animals of their industrious neighbours. In the vast tracts of poor and unoccupied land with which Carolina abounds, these people found it easy to make temporary settlements. From these, as centres, they made their excursions, returning to them regularly with their bounty and their game. In several places, the Methodists have had such influence on many of this class, as to induce them to engage in regular industry. The number of squatters has thus been considerably diminished, and of industrious cottagers or farmers increased.

Since the establishment of the federal constitution of the United States, the government of South Carolina has become somewhat complex. Acknowledging a federal legislative, executive, and judicial authority, and ceding to the union every power that is necessary to a common national government, it restricts these powers to objects of a general nature, and reserves for its own local jurisdiction the management of every thing that is purely domestic in its operation and consequences. By a convention of the people, held in 1790, the constitution of South Carolina was new modelled, so as to harmonise with the general constitution of the United States. The legislature, as in the other states, is composed of a senate of 45 members, and a house of representatives of 124 members, elected by the inhabitants of the districts which they represent. The governor is elected for the term of two years; and, after an interval of four years from the expiration of his authority, may be elected again. The governor and lieutenant-governor are nominated by the legislative body, and both at the
same time. The same body nominates the judges, commissioners of the revenue, the secretary of state, the commander in chief, and the sheriffs, all of whom, except the judges, hold their offices for the term of four years. Bills cannot be passed into laws till they have been read three times on three different days in each house, and have been agreed to by both, deliberating apart. To expound these laws, and apply them to particular cases, is the duty of the judges, who, though commissioned by the legislature during good behaviour, are, immediately after their appointment, rendered independent, both of the legislature and the people. The law of England is adopted, with a few variations, as the common law of South Carolina.

For ninety-nine years after the colonization of South Carolina, no courts were held beyond the limits of Charleston, and no officer but the provost-marshal could serve a process in any part of the province. For two-thirds of that time the courts of common pleas, and of king's bench, were held by the same judge, from whose decision there lay no appeal, but to himself on a new trial.

There are now twenty-five districts, in each of which there is a circuit court, invested with complete powers, both of original and final jurisdiction. These districts are, 1. Abbeville. 2. Edgefield. 3. Newbury. 4. Laurens. 5. Pendleton. 6. Greenville. 7. Spartanburg. 8. Union. 9. York. 10. Chester. 11. Lancaster. 12. Fairfield. 13. Kershaw. 14. Chesterfield. 15. Marlborough. 16. Darlington. 17. Sumter. 18. Marion. 19. Horry. 20. Georgetown. 21. Charleston. 22. Colleton. 23. Beaufort. 24. Barnwell. 25. Orangeburg. For these twenty-five districts, six judges are appointed, to each of whom is granted an annual salary of L.600 sterling, to enable them to devote themselves to the duties of their office. In addition to the courts of common pleas and of sessions, South Carolina has always had its courts of ordinary, of admiralty, and of chancery. The two first of these courts have been held by governors or judges appointed by the proprietors, the sovereign, or the state; but since the establishment of the national government in 1789, causes in the court of admiralty, and the appointment of judges for that court, have been transferred to the United States, as pertaining to the general government. The court of chancery was likewise held by the council of the proprietors, the king, and the state, in succession, till the year 1784, when it was new-modelled, and three judges were appointed to preside over it. Since the year 1791, when it received some new modifications for the more speedy advancement of justice, it has been called the court of equity. Before the revolution, there was but one ordinary for the whole state; but since the peace of 1783, an ordinary has been appointed to each of the districts.

Under all the governments to which South Carolina has been successively subject, it was a received principle, that every subject or citizen should also be a soldier. Till lately, however, their military regulations were extremely incomplete. By some new arrangements which took place in the year 1794, the whole state is now divided into two parts, one of which comprehends five brigades, and the other four. Each brigade is divided by the commanding officer into as many regiments as the population will admit. The two majors-general who command the two divisions, the nine brigadiers under whom are placed the different brigades, and the adjutant-general, are all appointed by the legislature. The other officers are nominated by the regiments, battalions, and companies, to which they belong; but they are promoted in the order of their service.

Since the termination of the revolutionary war, annual taxes have been imposed on the inhabitants to defray the current expenses of the state. Till the year 1790, the state had the income of the impost duty, and from that fund paid its civil list; but the general government of the United States has now the command of that fruitful source of revenue. The state now depends for the support of its government, on taxes imposed on lands, negroes, money at interest, stock in trade, factorage, employments, faculties, and professions; and a few incidental sources of revenue, such as duties upon sales at public auction, on licenses granted to hawkers, pedlars, and theatrical performers, the interest of the paper medium loan, the interest and instalments of the debt due to the state from the United States, the dividends from its shares in the state bank, fines, forfeitures, &c. The average amount of taxes annually collected, is about 135,000 dollars; and the state receives from other sources about 175,000 dollars. The appropriations of revenue are, first, for paying the expenses of the civil list, and other incidental expenses of government, both of which amount, in common, to a sum between 70,000 and 80,000 dollars; and, secondly, for pay extraordinary, expenses, and contingent accounts. These are so variable, that they cannot be stated with precision; on an average, they amount to about 145,000 dollars per annum. From the last report of Mr Hamilton, the comptroller of revenue, made in 1804, it appeared, that there is a balance due to the state of 754,755 dollars.

The internal resources of South Carolina are so commerce, great, and its population is so rapidly increasing, that it ranks among the first commercial states in America. Of the amount of its exports for the first fifty years after its settlement, nothing is known with certainty. There is reason to believe, that it began to export rice about the beginning of the 18th century; for Anderson states, that between the years 1720 and 1729, 264,488 barrels were exported to England, and that 495,525 barrels were exported in the course of the ten following years. About the year 1740, the trade of the province began to be considerable. It then contained about 4000 negroes; for whom, and for all other articles of importation, payments must have been in rice, naval stores, lumber, peltry, and furs. To these articles of export was added, indigo from 1747, tobacco from 1752, and cotton from 1792. The minor articles of export are, Indian cori, coco-pesce, beef, pork, leather, shingles, staves, rosin, turpentine, &c. The aggregate value of exports was in a course of such rapid increase, that in the last year of the 18th century, it amounted to 10,554,842 dollars, and in the first year of the 19th century, to 14,504,045 dollars. Previous to the revolution, all the trade of South Carolina centered in Great Britain and her dependencies; with the exception of as much rice as, under a special act of parliament, was exported to the southward of Cape Finisterre. During that period...
the trade of Carolina was daily increasing in prosperity; and notwithstanding the many circumstances of exasperation which necessarily occurred in a country which was long the scene of civil contention, peace was no sooner restored than the commercial intercourse with Great Britain was renewed, and carried to a greater extent than it had ever reached at any former period. We cannot ascribe this to any friendly disposition on the part of Carolina, for no state of the union was more inveterate or more determined in its enmity to the country by which it had been long and peculiarly cherished. Interest is the only tie which now connects this state with Great Britain. The ingenuity of our manufacturers, the long credit which our merchants can afford to give, and the facility of making remittances to this country as the purchaser of a great portion of the native commodities of Carolina, have secured to us all the advantages which we could have derived from that state, had she continued in her former relation of provincial dependence. She has of late, indeed, been more profitable to us than she would ever have been, perhaps, in that relation; for while we are freed from the responsibility of governing, and the expense of protecting and fostering her, her exports to Great Britain far surpass their former amount, and her own politicians acknowledge, that the trade between the two countries for a single year of general peace, would now be of greater value to England than all she derived from Carolina for the first half of her colonial existence.

Few colonies have ever been established under circumstances more favourable to their literary improvement than those enjoyed by the first settlers in South Carolina. The country from which they emigrated was then in the full meridian of literary splendour; and the facilities for the diffusion of knowledge were greater than they had ever been at any previous period in the history of the world. Though in the first years of their settlement their attention must have been chiefly occupied in preparing the soil for cultivation, and providing the necessities of life, this was no sooner accomplished than they began to adopt measures for their own literary improvement, and for bequeathing to their posterity the inestimable blessings of knowledge. So early as the year 1700, we find a law enacted, “for securing the provincial library in Charleston.” Libraries were soon after formed in the different parishes, though chiefly for the use of the rectors and ministers. A free school was erected in Charlestown about the year 1712; another was established at Childsbury, in St John’s parish, in 1723; and a third, at Dorchester, in 1733. Besides these, several other seminaries were instituted and supported by general contribution, or by the donations and legacies of public spirited individuals. The corporations of these schools were cherished by government. They were favoured in taking up lands, which have ever since been increasing in value. They were enriched by the gifts and bequests of the charitable, and from the triple source of tuition money, public money, and private liberality, a fund was created which diffused the means of education far beyond what could have been effected by uncombined and desultory exertions.

In 1795 the citizens of Beaufort obtained a charter for the establishment of a college in their vicinity, with the privilege of such funds as they could collect from the sale of escheated and confiscated property in the district, and of vacant lots in the town of Beaufort. These funds turned out extremely valuable, and there is every reason to expect that the seminary will in time realize the warmest hopes of its founders. By far the most important literary institution in South Carolina is the state college established at Columbia, the seat of government, by an act of assembly in 1801. This college, though yet in its infancy, possesses a select and extensive library, and a philosophical apparatus, not inferior to any on the American continent. Persons of any country or of any religious denomination, if qualified by their literary or scientific attainments, are eligible to the office of professors in this seminary. The number of students at this college in 1809 was eighty-seven; and two classes had at that time graduated to the number of about forty. Students at Columbia, if not wanting to themselves, may be amply instructed in every language, art, and science, necessary to prepare them for the service of their country. Though such exertions have been made for the advancement of learning, its progress in South Carolina has not hitherto been great. In genius its natives are far from being deficient; their apprehension is quick, their imaginations lively, their enthusiasm ardent. But they are too apt to shrink from that steady persevering exertion, by which alone the candidates for literary fame can overcome the difficulties which they meet with in their progress, and securing the ground over which they have already passed, prepare themselves for farther advances and acquisitions.

For almost all our information relating to South Carolina, we are indebted to a valuable history of that state published by Dr David Ramsay of Charlestown, so late as the year 1809. Of that history, yet unknown in Europe, we procured a copy directly from Charlestown through the kindness of Mr Robert Henry of Charlestown, now studying at the university of Edinburgh, who, uniting genius with invincible industry, promises one day to be an ornament to his native land. See also Chalmers’ Political Annals of the United Colonies; Hewet’s History of South Carolina and Georgia; Drayton’s View of South Carolina; Travels in North America by Liancourt, Duke de la Rochefoucault; Morse’s American Geography; Morse’s American Gazetteer; Ogilby’s Geographical Account of America; and Campbell’s History of America.

CARPATHIAN MOUNTAINS, or KRAPACE MOUNTAINS, is the name of an extensive and interesting chain of mountains, which bounds Hungary, on the north and east. A very full and recent account of this range will be found in our article on HUNGARY. In the mean time, the reader may consult Townson’s Travels in Hungary; Demian’s Tableau Geographique et Politique des Royaumes de Hongrie, D’Eslovion, de Croatie, &c. Paris, 1809. (This work is translated from the German.) Esmark, Journal des Mines, No. 47. p. 819; Lefebre, Id. No. 12, p. 39; Schedius, Journal de Hongrie, No. III. Art. 6; Stutz, Description des Mines de Nagyag, Vienne, 1803, in German; Hassel Tab. Statist., and Liechtenler Tab. Statistique.
Carpentry. Carpentry is the art of fashioning and framing timber for the purposes of architecture, machinery, and the like. It is distinguished from Joinery, which considers only the fashioning and adaptation of the smaller and more curious works in wood, where the chief requisites are convenience, neatness, or elegance of form; whereas carpentry is applied to the fitting together of the greater masses, so as to combine with magnitude, strength, durability, and economy.

It is evident, therefore, that the intelligent carpenter would require an intimate acquaintance with the strength of the materials he employs; the cohesion and corpuscular force of their particles; the principles of statics and mechanics, to enable him to discover what may be the stress acting upon his work; and the mode in which strains are propagated through the different parts of his framing, that he may be thereby enabled effectually to resist them.

Carpentry, therefore, is an important department of physics. It constitutes one of the most beautiful and useful applications of the liberal sciences to the arts of life, and is a necessary part of the learning of the engineer.

The performances of the ancients in this art have none of them reached our times. But the works of modern carpenters are such as leave us little room for regret. They might many of them challenge comparison with anything that has ever appeared in the world.

Amidst modern nations, the value of the art is universally acknowledged. But perhaps there was never a nation upon earth to which the science of carpentry was of such immense consequence as our own. Thousands of our ships, those noble specimens of art, traverse the ocean. We have risen at home to a pitch of wealth and prosperity unequalled in the history of the world. We have attained it, by the extent of our commerce, the superiority of our manufactures, and the improvement of our agriculture.

And this chiefly by the wonderful multiplication of machinery, and its application to almost every description of labour. Our many great works of public utility, or private magnificence, have rendered our country the seat and theatre of art. Add to all this, that our declared enemy, by endeavouring as far as in his power to prevent our usual supplies of timber, has threatened to cut off the very sources of our prosperity. In such a nation, where the physical sciences have been successfully and diligently cultivated, which possesses many men of sufficient genius and ability ardently desirous to promote the prosperity of their country, it were natural to think that this important science (for it well deserves the name) would have received the greatest attention, would have been prosecuted to the utmost limits of investigation, and would long ago have been arranged into a body of doctrine, founded on the extensive experience of our great masters, and illuminated by the powerful torch of mathematical and physical learning.

And strange to tell, we may search through the compass of English literature, and scarcely find a single work which professes to treat of the science of carpentry.

The books which are usually in the hands of the workman are totally destitute of any thing like principle, and content themselves with showing the method of forming the draft which is to guide the saw or the chisel. Neither the Royal Society of London, or any other of our learned societies, has ever published a single paper for the instruction of the public in these matters. Indeed, almost, the only information our language can produce, is the result of the labours of a single individual, detailed in a work like our own.

A work of much merit, which appeared from the pen of a member of our national school for engineers, contains, on this subject, little more than we find delivered two centuries ago by the learned Galileo.

To look for any thing of the same nature in the flimsy productions of our itinerant lecturers, and popular books of philosophy, were to seek for knowledge and learning among the school-books of children.

And in the present article, we pretend not to give a complete treatise on the science of carpentry. Such an undertaking would far exceed the limits of a work like ours. But we can give a compendium of the most useful information respecting the strength of timber, and endeavour to elucidate the mode of action in some of the more simple cases, that we may from thence draw some practical maxims of construction, which may be of use to the inquisitive but inexperienced carpenter. It is matter of regret, that almost the whole of our knowledge of this useful science is due to the labours of several learned foreigners, to whose works alone we must have recourse for any thing like profound investigation. But these are, in a great measure, locked up from the access of our national artists, and they have been left by intuitive feeling, as it were, to elicit those principles, and establish those maxims, which might have been expected from the speculations of their learned countrymen. Their success has shown us, that the efforts of genius rise superior to the defects of education. Although we are very far from wishing to decry the well-earned fame of the great masters of our day, yet it is not to be doubted, that even their own confidence in their undertakings would be greater, and their success more certain, were their experience digested and regulated by scientific principles.

We should wish to call the attention of some of our learned countrymen, who have leisure and opportunity, to the prosecution of these investigations. There is a wide field for research, and their labours...
Carpentry cannot fail of being well received in this age of improvement. It is hard that the nation, which boasts of Newton and Wren as the very founders, so to speak, of the modern mechanics, should neglect the path which originally led it to distinction among the scientific people of Europe. Our workmen are acknowledged to be the ablest, the most scientific, and intelligent in the world. They well deserve to have their labours assisted, and their desire for information gratified, by the researches of speculative men. Let the latter enter the workshop, the building yard, or the manufactory, they will find themselves in the midst of an assembly of men of science, where, ere they can pretend to communicate instruction, they will perceive that they themselves have a great deal to learn.

It is to be hoped, that the late national establishment for the education of master shipwrights, will go a great way towards extending our knowledge of the science of carpentry. We were glad to see, that a superior degree of information is expected in the candidates for admission, than in those of our national establishment for engineers. This is as it should be. The nation may then expect those only to be admitted, who evince at least some ability for the office, and some aptitude for instruction; and who will acquire under its care that superior knowledge which may qualify them for directing the labours of artists, confessedly the first in the world, instead of issuing from the seminary with no more learning or experience than what might have been equally well obtained at any country school.

We propose to divide the present article into two Parts; the first containing the Theory of Carpentry, and the second Constructive Carpentry.

PART I. THEORY

OF CARPENTRY.

The science of carpentry depends on two principles: The strength of the timber employed, and the strains to which it is exposed.

The strains to which timber is exposed are various. They are simple, when the energy of the straining force acts directly in overcoming the cohesion of the particles; or they are compound, when it acts by the intervention of a lever, or other mechanical power.

The simple strains are,

1. The piece may be pulled or drawn in length, as in the case of a king-post, the upright rod of a pump, or the like; it is then usually named a tie.

2. It may be compressed in length, as a post or strut.

3. It may be strained laterally or crosswise, as when a tenon breaks off, or a rafter fails at the wall.

The piece of timber is also exposed to similar strains, acting on the softer connecting matter, instead of the woody fibre. It may be split or torn asunder; it may be compressed or squeezed as a wedge or tree-nail; or it may be pushed out in the direction of the fibre, as sometimes happens in the heel of a mortice.

The compound strains of most importance are,

4. The piece may be strained directly across, as a joist or lintel; or obliquely, like a rafter.

5. It may be twisted, as in the axles of mills, ship-rudders, and screws.

6. It may be bended or crooked; and then subjected to any of these strains, or to several of them together.

I. Of the Resistance to Distension in Length.

The resistance to distension, or, as it is termed, the tenacity, of substances, is one of the most essential qualities in the strength of a building. A timber must be able to sustain the continuous tension put upon it to prevent it from shrinking too much; for if every particle of the wood were to contract equally, the wood would not only lose its natural beauty in being shrunken, but it would also lose the power of holding the cohesion together, the cohesion of the wood consisting in the mutual attraction of the molecules of which it is composed.

Substances, of which the texture is uniform, such as metal, glass, stone, or the like, resist a strain which tends to pull them directly asunder, by the simple force of cohesion among their particles; and supposing the force of every particle to be the same, the total amount will be as the number of particles, that is, as the area of the section. But should the body be of a fibrous texture, as timber or cordage, the disruption may take place, not only by the snapping of each individual fibre, but also by their separation, owing to one parcel being torn from among the others with which it is joined. The resistance to the fracture in that case will be produced by the friction of one fibre against another, increased in the case of ropes by twisting, and in the case of timber by the softer connecting matter intermingled with the ligneous fibres.

Should we suppose, with Galileo, that the fibres give way all at the same instant, then it is perfectly evident, that the direct or absolute force must be proportional to the area of the section. But it is doubtful how far we can depend upon that principle, even in this simple case; for it was long ago observed by Leibnitz, Mariotte, &c. that there was no matter how hard soever, were it glass itself, but would undergo some extension before absolute rupture. There is little doubt, but this property may have some effect, even in the case of simple distension. It certainly produces important modifications in every other case. The fibres, in extending, may compress each other, at least, unless they are perfectly parallel and longitudinal—a rare, and indeed only a theoretical case; while, even there, each fibre, by the diminution of diameter, gets loose, and is deprived of the benefit of lateral friction; so that, by snapping at their weakest parts and tearing out, they may afford us a surface of fracture, having any given ratio to the transverse section. But at present, perhaps, it will be more useful to the practical carpenter, to defer our inquiries into this department of our subject; we shall find another opportunity of resuming them. This is a subject on which theory can afford us little real information; the absolute strength must be left for the object of actual and judicious experiment.

The inquiries which have been instituted for the discovery of the strength of timber by means of experiment, are by no means so numerous as could be wished; neither have they always been conducted with due attention to those numerous precautions, and exact historical description, which are absolutely necessary to render them useful. Hence, there are in almost all of them great and anomalous differences. Many experiments have, indeed, been made on the transverse strength; perhaps the most magnificent.
Theory of Carpentry.

are those of Buffon, recorded in the Ann. Paris Acad. 1744 and 1742. Duhamel has given a great many in his Traité sur la Conservation de Bois; but they have omitted that primary and most essential object of their inquiry, the direct and absolute strength of the timber employed, by which it resists extension and compression. Experiments made on the transverse strength are so much modified by the different degrees with which timber resists those strains, that little satisfactory reasoning can be founded on them, however numerous they may be, or however carefully performed and faithfully described.

Muschinenbroek is almost the only author who has enabled us to judge of the accuracy of his experiments; he details those on the ash and the walnut, stating the weights requisite to tear asunder slips taken from the four sides of the tree, and on each side in a regular progression from the centre to the circumference; and he says all the others were made with equal care. We cannot, therefore, see any reason for distrusting the results. Yet they are considerably higher than most other writers have given. The probability is, that they were made in such small specimens, that any want of soundness, which would of course be easily detected, induced him to reject the example, although absolutely requisite to give a fair average. Perhaps, too, he gives us the utmost load which may be borne—rather that which will break the bar in a few seconds. This is much more than can be safely trusted to the beam.

In the English language, we have hardly any thing to guide us. The Royal Society appear at an early period, to have paid some attention to the subject; but they have recorded nothing. Emerson gives a list said to be derived from experiment; but we are not even told, whether it refers to the transverse or the longitudinal strength of the material. To these we shall add some related by the late Dr. Anderson of Glasgow, a man fond of experiments, and probably faithful in relating them.

According to Emerson, a cylindric rod of good clean fir, an inch in circumference, drawn in length, bears 400 lbs. and a spear of fir, two inches diameter, bears 7 tons, but no more; a rod of good iron, one inch in circumference, bears nearly 3 tons weight, and a hempen rope of one inch in circumference carries 100 lbs.

He also gives the following rule: Square the diameter expressed in inches, and multiply for

<table>

| The result gives the load in cwts., which may be safely trusted.

It is to be observed, that all these results are derived by proportion from the strength of very small specimens; and this may account for such great anomalies. It is highly probable, that the cohesion of timber, especially that of which the fibres are much intertwined, such as as oak, increases in the thicker pieces in a ratio which is greater than that of the area of the section. Such fibrous bodies, by being drawn in length, are strongly compressed together, and those weaker fibres are more firmly retained, which, by breaking at their finest part, might otherwise tear out. This is indeed always the way in which such bodies fail, viz. by the fibres sliding out from among each other, and not by an absolute snap. In this respect, therefore, timber may be compared to cordage; and there we have several examples of the truth of this principle.

Duhamel mentions, that a 6 thread rope bore 631 lbs., but that thicker cords bore more in proportion. We have arranged the results below.

11. Of the Resistance to Compression in Length.

Timber, when so placed, that the strain tends to compress the piece length-wise, is perhaps in the most favourable position for taking advantage of its strength. We can be absolutely certain, that the whole of the fibres are called into action, and we may, by forming the joint exactly at right angles to the strain, be ensured of the uniform action of each. When drawn in length, on the other hand, it frequently happens, that bolts, mortices, or joggles, are the only way in which we have a hold of the beam; and, that so far from having the strength of the whole transverse section to depend on, we have only the lateral cohesion and friction of those fibres, which form the heel of the mortice, or shoulder of the joggle. While, therefore, long heels and joggles, deep scarfing, or stout bolts and straps, are the chief objects to be attended to in the one case, the same difficulties do not occur in the other, and we have not the same chance of failure from defective workmanship. We have, therefore, much hesitation in admitting the maxim of an author, to whom this department of engineering is greatly indebted, that "ties are in general better than struts." It is true indeed as he says, that a small iron rod will support a load as a tie, which could not resist a moment were it compressed by a similar strain. But this does not arise from the mere circumstance of its acting as a tie; for the strength of cohesion must be pretty much the same either way, it is only from the chance of bending, and becoming thereby subjected to powerful cross strains, where the small diameter of the iron rod enables the distant strain to act by the energy of a powerful lever. When bending is altogether prevented, as in the case of an iron truss inclined between the two halves of a girder, we know that the resistance to compression may be safely relied on. And, when with the same area of section, the power of leverage is diminished, as by shortening the length of the strut, or by increasing its diameter, as by deep flanging, or forming the rod into a hollow tube, we know the resistance to compression is at least as powerful as in any form of a tie.

In investigating, therefore, the resistance to compression, and especially in endeavouring to obviate those unavoidable weaknesses which this position involves, we must attend carefully to the mode in which the strain is propagated through the parts of the beam. We would recommend to the inquisitive reader, to study what we have said in the "Article Boscovich's Theory, on the mutual action of points of matter": he will find it greatly facilitate his acquiring correct notions of this subject. We shall hereafter have occasion to refer more particularly to that article; but, in the mean time, we would wish to give the intelligent practitioner some simple ideas of this matter, which may possibly tend to assist and direct his practice.

It is to be regretted, that the experiments on the strength of timber against compression, are still fewer than those which refer to the first mentioned strain, although they are certainly of equal importance.

When we press a rod of soft clay or wax endwise, it bulges out in the middle; a beam of wood cripples, swells out in the middle, the fibres lose their cohesion, rents appear, and it speedily yields to the strain.

Take a bundle of small rods, or even rushes, set them on end loosely and compress them, they will separate from each other in the middle, bulge out, and speedily give way; bind them firmly at two or three places, their strength is greatly increased; wrap them up entirely from end to end, they are stronger still: the resistance, therefore, to compression, depends intimately on the lateral adhesion. Separate the whole into several smaller parcels, of which, while some are firmly wrapped up, let others be held more loosely; place the loose parcels on one side, and repeat the compression, the looser part will yield, the others following will be bent, and may snap with a much smaller force than they would have resisted alone, because the bending enables the strain to act with the energy of a powerful lever. The exterior fibre, which is most bent and strained, gives way first, the strength of the others can be acted on.

It is evident that the fibres, which are twisted, must resist compression much less than those which are straight. And accordingly, if the experiments of Muschenbroek are to be relied on, oak will hang more than twice as much as fir, yet the latter will support nearly three times as much as the former.

The resistance to compression, therefore, depends greatly on the power by which bending is prevented, either in the individual fibre, or in the entire piece. Now suppose that a bar of an inch square can support a given quantity M as a ton, then it is evident, that before we produce the same strain in the fibres of a bar of two inches, we must at least lay on four tons N. But, in truth, we may lay on a great deal more; for, supposing this smaller beam has been bent a little, until the fibres on the weaker side were just as much compressed, and those on the stronger just as much dilated, as could be done with safety, then we may say, that there is some intermediate place, which, having neither suffered dilatation nor compression, may be considered as the fulcrum or centre of conversion about which this motion has taken place. Let this be the point A, or a, it is evident, that the distance of the exterior, or any other resisting fibre from the centre A, will be to the distance of every similar fibre from a, as the diameter BC to b c. The fibres of the large bar, therefore, in so far as bending is concerned, are not in the same situation with those of the smaller, and before they arrive at it, the weight N must be farther increased in the ratio of the diameters of the bars; that is, N must be to M in the ratio of the cubes of BC and b c. Indeed there is reason to believe, from the experiments of Muschenbroek, and the investigations of Euler, that the resistance to compression increases in a still higher degree than this, perhaps in the ratio of the fourth powers of the diameters, at least for those of which the fibres are ridged, as fir, oak, c. and which were found by Muschenbroek far better adapted to this purpose than the oak, and others of which the fibres are twisted.
Carpentry.

The relative strengths are by him for a bar 4 feet long, 7/8 inch square.

which are very different from the order in which these woods resist being drawn in length.

Oak has borne a pressure of 4000 lbs. per square inch. Six of the pieces of oak in Girard's experiments, broke with 2910 lbs. pressure per square inch; but 15 others bore much more. A great deal depends on the length and uniform soundness of the pieces.

Perronet gives the following proportions from experiment:

His experiments were made on short specimens.

Mushenbrook says, the relative strength of pieces of wood against compression, is as the cube of their diameter directly and inversely as the square of the length. This is after some investigations of Euler. They are founded upon principles that are somewhat dubious. He merely assumes a certain value for what he calls the rigour of the beam or post, without much inquiry as to the way in which that rigour is effected.

The resistance increases much faster than the area of the section; and in so far as the failure arises from bending, this observation becomes of the utmost importance. We can frequently confine the bending to one direction only, in which, by placing the greater dimension, we will vastly strengthen the post without increasing the scantling. This principle has been forced upon the attention of the carpenter in the case of cross-strains; and joists and rafters have gradually become thinner and deeper. But we doubt whether the majority of carpenters have even thought whether a square upright, in a partition of 6 inches, or one of 4 inches by 9, is the best. Yet the latter will be trussed sidewise in the building, and its resistance to bending in the direction of its breadth, is at least three times as great as the other.

We shall have occasion to resume this subject. Our investigations respecting it can be pursued with much more facility, when we comprehend the principles of the transverse strength of timber.

Experiments on this kind of strain should be multiplied. It is that against which we must guard in the most difficult and delicate cases which come under the consideration of the engineer. But such experiments must be entrusted to men of science; for we see that the modifications arising from bending, &c. are so great, that a set of them made in the form most likely to be adopted, would be so completely anomalous, as to afford no rule of practice whatever. We must attend particularly to the manner in which the fracture is produced; we must endeavour to discover the means of opposing it. Thus we know, that friable matter, as stone, cracks obliquely under pressure, and the pieces slide along the surface of fracture; that fibrous matter, as wood, splits longitudinally, and bulges out. Now, both of these may be prevented by hooping, and that even loosely. On the other hand, should the interior fibres of the timber yield, by penetrating through the softer parts, we may condense the whole, by driving the hoops tight along a very gentle taper. By this means again, we diminish the diameter of the strained part, and, consequently, expose it more to the risk of bending. This last may be obviated by thin flanges, cross bridles, and trusses. An increase of the diameter acts both as a hoop against bulging out, and as a truss against bending.

If, by these several or by similar precautions, we can reduce the strain to an absolute crush, there is no question but we shall have resistances vastly greater than what have been usually experienced, and to which, in truth, it is difficult to perceive any limit. The science of carpentry consists, indeed, entirely in the reduction of all strains to this one; and after all we do not yet know in what situation this resistance acts most favourably. There is a most extensive field here for research, but all that can be done by an individual is to regard, that while so little progress has been made in forwarding this inquiry, the necessary experiments are beyond the means of a private person. We shall at present, therefore, take it for granted, that the resistance to compression among the particles, is much the same as that against distension. It is highly probable, that this is the case just at the beginning of the strain. And although this principle, when applied to practice, becomes liable to great modifications—for the strength increases rapidly with an increased diameter, while it diminishes greatly by increasing the length—yet we shall perceive the reason of these modifications much more distinctly, as we proceed in our investigations respecting other strains.

III. Of the Lateral Resistance.

The piece may be crushed across, as when a pin or a tenon fails, or a joist gives way at the wall, where we have the strength of one section to overcome; or when a piece is torn out crosswise by a square edged tool; in which case we have the united strength of the two sections. Some experiments were made by the late Dr Robison, with a view to determine the resistance to this strain.

Two iron bars were disposed horizontally, at an inch distance; a third hung perpendicularly between them, being supported by a pin made of the substance to be examined. This pin was made of a prismatic form, so as to fit exactly in the holes in the three bars, which were made very exact, and of the same size and shape. A scale was suspended at the lower end of the perpendicular bar, and loaded till it tore out that part of the pin which filled the middle hole. This weight was evidently the measure of the lateral cohesion of two sections. The side bars were made to grasp the middle bar pretty strongly between them, that there might be no distance interposed between the opposite pressures. This would have combined the energy of a lever with the purely transverse pressure. For the same reason, it was necessary that
Carpentry.

The internal parts of the holes should be no smaller than the edges. Great irregularities occurred in the first experiments from this cause, because the pins were somewhat tighter within the mortise than at the edges, but when this was corrected, they were extremely regular. He employed three sets of holes, viz., a circle, a square, (which was occasionally made a rectangle whose length was twice its breadth,) and an equilateral triangle. In all these experiments, the strength appeared exactly proportional to the area of the section, and quite independent of its figure or position; but it was considerably more than twice the force to tear out this middle piece, than to tear the pin asunder by a direct pull. A piece of fine freestone required 205 pounds to pull it directly asunder, and 575 to break it in this way. The difference was very constant in any one substance, but varied from 4 to 5 in different kinds of matter, being smallest in bodies of a fibrous texture. But indeed he could not make the trial on any bodies of considerable cohesion, because they required such forces as his apparatus could not support. Chalk, clay baked in the sun, baked sugar, brick, and free-stone, were the strongest that he could examine.

We conceive that a good reason may be given why the resistance to the strain should be greater than the direct cohesion. The exterior line of particles is supported by those behind. Before any remarkable shift in the place of the exterior line takes place, the cohesion of the whole section may be called into action. This will certainly be the case with the granular and less compressible kinds of matter. But this is not all. The lateral motion of the first particle will, to a certain degree, be communicated to that adjoining and within it; this will, in its turn, exert a similar resistance, and communicate the force still farther. The pressure, therefore, is not confined to the area of section, but is propagated into the body of the beam; it not only forces each particle to slide along its neighbour, squeezing and crushing those which are in the neighbourhood of the section of fracture, but likewise tearing them away from those on the side opposite to the pressure. Fibrous matter, such as timber, must especially act in this way. We cannot expect the fibres to snap and fly at once, unless where the motion is exceedingly rapid, as in the penetration of cannon-shot. The fibre will yield gradually, and bend. The bending will be propagated into the beam, to a distance which we cannot well tell, but which seems proportional to the tenacity of the fibre. At length, it will yield much in the same way as it does to a direct pull; which accounts for the smaller excess of strength found in fibrous bodies.

This case is, therefore, by no means so simple as may appear. Although there be reason to believe that the strength is proportional to the surface of the section, we should think it advisable that the bearing surface should be as wide and flat as possible, for all matter is compressible, and wood, especially, is most so across the fibre. Should the part, therefore, which first receives the strain be narrow or thin, it is possible that the front fibres may be crippled or give way ere those intended to support them can well be brought into action. This principle should always be kept in view in the formation of tenons and mortices, or joints of a similar kind, and appears well known to the intelligent carpenter. The same thing is frequently aimed at, by making the tenon long, and giving it a deep hold in the mortice. Such a practice gives no additional strength whatever; it is even injurious. For if the tenon bear upon the interior part of the mortice instead of the outer edge, the strain comes to act upon it with the energy of a lever, and may thus be increased in any degree. The bearing side of the tenon being no longer than sufficient to give a firm hold, the end may be bevelled above, till flush with the upper side of the beam. We may trust to every square inch of the section of such a tenon the weight stated under the first head; for though experiments shew it to bear more, it is as well that this excess of strength should not be depended on.

What we have now stated may throw some light upon the resistance which a wedge or tree nail affords to compression. It is obvious that this must chiefly depend on the structure of the timber; and we have hardly any experiments worthy of memory upon the subject.

Respecting the resistance to splitting, and that which hinders a piece of straight-grained timber from sliding out in the direction of the fibre, we are equally at a loss for information. The strength is, without doubt, proportional to the surface of fracture, but we cannot state its amount. Straight fibred timber is very weak in this way, and the reason is obvious; it is the cohesion of the soft connecting matter, and not of the woody fibre, that we have to resist the strain.

Emerson has said, that tough wood, such as elm or ash, across the grain, is from seven to eight, or even ten times weaker than when strained in the direction of the fibre. These woods may be supposed, therefore, to resist a force tending to split them, or to tear out the heel of a mortice, with about 700 lbs. on the square inch of the surface of fracture. But he says, that the wood of straight fibre which easily splits, such as fir, is 16, 18, or 20 times weaker than in the length of the fibres. Their resistance will, in that case, be from 250 to 300 lbs. per square inch of section.

We have now considered those strains in which the cohesion of the timber is directly opposed to the strains. We have sound reason to regret, that the paucity of the experiments hitherto made on the direct cohesion, has prevented us from giving such satisfactory information respecting the corresponding strength as might be wished. We regret this the more, as it is to some one of these simple kinds that the carpenter should endeavour to reduce every other: he is then sure of benefiting by the whole cohesive strength of his materials. In the others, or compound strains, he has not the same advantage.

Of the Compound Strains.

The variety of compound strains is inexhaustible; compound we can only be expected here to treat of the simplest strains and most important.
IV. Of the Resistance to Cross Strains.

The usual form of this strain is when the points of bearing are at some distance from each other, and the load is somewhere applied between them. This case has attracted the attention of many writers, and has been made the subject of numerous experiments. The benefit derived from these experiments, however, has not been so great as might have been expected; and we are yet very far from being able, with precision, to determine the strength of timber against a cross strain.

The first who attempted to give any theory for the transverse strength of timber was the celebrated Galileo. He supposes the prismatic body, ABCD, is fixed at one end into a wall, from which it projects horizontally, and is acted on by the weight W, hanging from the farther end. Let the body be supposed to break across in any line EF. In the instant of fracture, the surface EF is supposed to exert everywhere an equal cohesion. As the section across is therefore, everywhere the same, it is evident that the energy of the weight W will increase with the length of the lever CE, and of course the greatest strain will be at the wall, and in the line DA. The action at the point C tends to make the body ABCD turn round the point D as round a centre; and therefore the parts at AH must separate from each other in the horizontal direction. If we suppose all the particles in the section AD to be exerting an equal force, and that the resistance takes place at once, then the total force may be supposed accumulated in the centre of magnitude G; and the energy of the weight W, at the instant of fracture, will be to the absolute strength of the beam in resisting a direct pull, as the distance of the centre G from D, to the length DC.

Now if the beam be rectangular, the centre of magnitude G will be in the middle of its height or depth AD; wherefore we should have for the strength of the beam as the length of the bearer to half its depth, so the absolute cohesion in length to the transverse strength.

It will be improper for us to pursue this view of the subject any farther. It has led to very erroneous conclusions: and, from being all that is to be found in our common treatises, has become, in them, the foundation of very false maxims of practice.

Succeeding writers, such as Mariotte, Leibnitz, &c, have perceived that this supposition of equal cohesion, exerted by all the particles in the instant of fracture, was not conformable to the proceeding of nature. We know that there is no body, however hard, but is somewhat extended before breaking. When a force is applied across the beam at C, the beam is bent downwards, becoming convex on the upper side. That side is therefore on the stretch, and the particles at AH being farther removed from each other, are exerting greater cohesive forces. We know that these greater forces are, while the body is not crippled, proportional to the extensions. Suppose, then, the beam to be so much bent, that the particles at AH are just giving way; it is plain that a total fracture must immediately ensue, for the force which exceeds the whole cohesion of the particle at A, and a certain portion of the cohesion of the rest, will still more exceed the cohesion of the particle next within A, and a smaller portion of the cohesion of the rest. Now, since the force of any fibre is as its distance from the fulcrum D, in order to find the amount of the whole, take DM = x, DA = a, and the greatest force of the exterior fibre AH = \( f \), then the force of any fibre MN, being \( (DA : DM : : a : x : : \frac{f}{a}) \), and from the usual fluxionary notation, the force of a fibre \( x \) will be \( \frac{f}{a} \), this resists the strain by the leverage \( MD = x \). Its energy therefore is \( \frac{x^3}{a} \), and that of the whole section, or \( \int \frac{x^3}{a} \) is \( \frac{x^3}{a} \times \frac{a}{x} \), which when \( x = a \) is \( \frac{a}{a} \). Now \( f \) is the force of absolute cohesion, and therefore the force resisting the transverse strain is the same as if the whole absolute cohesion were accumulated in a point G at one-third of AD from D.

This hypothesis assigns a smaller relative strength to the beam than the hypothesis of Galileo. In that, the section is supposed to have an energy equal to half the absolute strength of the rectangular beam. In this it is found to be only one-third.

But ere we proceed to draw any conclusions from what we have now stated, it will be proper to observe, that even this supposition does not fully explain the mechanism of the transverse strain. The force bending the body ABCD, not only stretches the fibres on the convex side of the beam, but compresses the lower or concave side. There must be some material support as a fulcrum for the lever when it stretches the fibres or tears them asunder, and this can be found in no other way than from those particles which are thus compressed. Let CDG be considered as a bent lever, having the fulcrum DC, by means of which the weight W, and cohesion of the surface AD, are in eqilibrio. We know that the pressure on D will be the same as if the other pressures were both applied to that point, each in its proper direction. The pressure at C is to that at D, as DC to DG. Completing, therefore, the parallelogram GC, and drawing the diagonal KD, it will express the direction and magnitude of the equivalent pressure on the fulcrum D. This pressure is opposed, by the resistance to compression of the particles towards D, which may be expressed by DC; and, again, by the cohesion of the particles in the line of section DA, which of course is expressed by DG. The particle D is not only pushed backward, but drawn downward. This last observation is easily verified. Take a stick of soft wax and bend it gently, the lower or concave side will be observed to swell out, and the convex side to get flat before it cracks and gives way. Take a parcel of the leaves of this book, and holding them firmly together at two parts of the edge so as to give them adhesion, attend to the effects of bending them, the leaves in the hollow side will bulge out and separate, those on the opposite side become flat and clap closely together. Attend now to the cracks and fissures, that is,
The openings which are to be seen among the leaves, they afford much room for observation, and will be found to give good notions of the effect of the transverse strain; the parcel may be bent so much, that every leaf will separate to the very last, which therefore is the only one that resists the folding by its cohesion. The open part of the rest shows us the form of the splinter IRS, Fig. 3, which would fly off, were not the matter so coherent. It is somewhat triangular, and the direction of its sides appears to be much the same with KD, and its correspondent on the opposite side. Slacken the parcel on one side, and pinching again, observe the slide which has taken place among the leaves. Thus the cohesion of the ligneous beds has an important effect in the transverse strength of beams. And, of balks cut out of the same tree in different ways, that in which the layers are placed on edge, will always bear much more than that in which they lie on their sides. This cohesion is not only useful in preventing slipping, but also in preventing the fibres on the concave side from parting too easily from the rest. This consideration is of importance, especially in the building up of girders, and the formation of masts. It shows that we must not be too hasty in saying, that fir should always be chosen for the sides made hollow by the strain, in preference to oak, merely because it is stronger as a pillar, though oak be tougher as a tie. There are other circumstances to be thought of.

The fibres of fir have little lateral cohesion; and unless we can secure them, and contrive to bring them all into action, we may be led into serious mistakes. But let us now examine the mathematical consequences which this last supposition involves. Let ARSB, Fig. 4., be the vertical section of a beam so constituted, that when the beam is loaded at one end with the weight W, the fibres in CR are in a state of compression; while those in CA are in a state of extension, that in the instant of fracture any particle in CA, as E, adheres by the force Ee, and one in CR, as F, resists or repels with the force Ff. The force of each particle being expressed in this way, some line a D r, limits the whole of these ordinates, and the area a D A, expresses the total force of adhesion, while DR r expresses the force of repulsion. Should the force of each particle be proportional to the extension or compression, which is highly probable, at least for the safer strains, then a D and D r will be straight lines; and if the resistance to compression be exactly equal to the resistance to a similar extension, a D r will be one straight line. But this is not to be expected; for in most bodies which are tolerably firm, the resistance to compression is likely to be the most considerable; and therefore the ordinates Ee are likely to be smaller than Ff. But since the weight W is understood to act perpendicularly to the length of the beam, the adhesion and repulsion in the section of fracture must be equal, and therefore the area of AD a equal to the area DR r. Now we have said, that in firm bodies, for the most part, the ordinates Ee are smaller than Ff, the perpendicular AD must therefore be longer than DR, and the neutral point D nearer the lower side of the beam.

In soft and compressible bodies, RD may equal or even exceed AD. The experiments of Duhamel show this to be remarkably the case in willow, and even in pine. He took 24 pieces of young willow, nearly of the same size, and formed them into bars of 3 feet long, 14 inch square, taking care to have the heart of the tree in the centre; supporting these by props 1/4 of an inch each end, he broke them by weights hung on at the middle.

The mean weight borne by six entire bars was 524.5 lbs.

He next cut two of the bars one-third through with the saw, and filled up the draft with a wedge of dry oak. The mean of these was 551 lbs.

He cut two others one half through, and wedged up the cut as before; and although one of them broke short on account of a concealed knot on the lower side, yet the mean of weight borne by these was 542 lbs.

He cut another set of six bars, three quarters through in the same way, and the mean weight borne was 530.5 lbs.

It is worthy of remark, that one of these last, when loaded with 435 lbs. was unloaded, and a thicker wedge put in place of the first slip of oak, it then broke only with 576 lbs. Had it been successively supplied with thicker wedges, it might possibly have carried a great deal more.

From these experiments, it is evident that more than two-thirds of the thickness, or perhaps three-fourths of it, does not contribute by its tension to the strength of the original bar. The compressibility of this kind of timber, appears much greater than its dilatability, and some other experiments of Duhamel seem to confirm this.

He has also given us some experiments on Baltic fir. The battens he employed were three feet long, fifteen lines thick, and seven broad.

Two such bars, when entire, bore 144 lbs. 9 oz. at a medium; three bars sawn one-third through in four places, and the cuts fitted with slips of hard wood, bore 132 lbs. 2 oz.

Two others, cut half way through in four places, bore 146 lbs. 7 oz.

Two others, cut two-thirds through in four places, bore 136 lbs. 15 oz.

One bar had a cut made on one side of a foot long, and half an inch deep, the space filled with a piece of oak, it bore 509 lbs.

Another, when the cut was only one-fourth of an inch deep, bore 554 lbs.

An entire bar, of equal dimensions, bore 576 lbs. nearly.

Observe that the oak is more compressible than the fir.

The point D being the centre of fracture, the centre of effort of the attractive forces will be found as in the last hypothesis. Let this be E, if the beam AS be a rectangular prism, the distance DE is one-third of DA. In like manner, the centre of the repulsive forces F will be similarly situated with respect to the line AR. The distance between these two points will be the shorter arm of the lever, by the energy of which, the force of attraction resists the effort of the weight W, while the centre of repulsions serves as the fulcrum; or if we choose to con-
Carpentry.

The point D, therefore, becomes the virtual fulcrum of the lever, by which the forces of attraction and repulsion in the section AR resist fracture; the action of the part above D is precisely the same as in the last hypothesis; and in a rectangular beam, upon the supposition of the force increasing as the extension, the centre of effort E will be at one-third the distance DA from D. But in addition to this, the resistance to compression in the part DR acts precisely in the same way, and its effect may be supposed condensed in the centre F at one-third of DR from D: the whole resisting energy will therefore be the absolute cohesion of DA drawn into one-third DA, and added to the force of repulsion in DR drawn into one-third DR. If we suppose the forces of adhesion and repulsion to be equal, DR and DA will be equal, and taking, as before, a the whole depth, \( f \) the force of a fibre, whether against compression or dilatation, the energy of the section will be \( \frac{2}{3} a \times \frac{4}{3} f + \frac{2}{3} a \times \frac{2}{3} f = \frac{8}{9} a f \); that is, the whole absolute strength may be conceived to act at the distance of one sixth of the depth of the beam from the fulcrum; or the absolute strength is to the resistance to cross strain as the length of the beam to one sixth of its depth.

We have found, then, that the principle of compression makes an important change in our views of the strength of timber. It shows the transverse strength to be only one half of what the supposition of Mariotte, and only one third of what the hypothesis of Galileo had made it. The difference might be still greater, were the body much more contractible than expansible. For in that case, the quantity of fibres in a state of expansion being smaller, would not only have less force in themselves, but would act with a shorter arm of the lever. Thus, in the same figure as before, suppose DA = \( \frac{2}{3} \) AR, and we have DE = \( \frac{1}{3} \) AR, the resistance of the upper or dilated part would be \( \frac{1}{3} a \times \frac{2}{3} x \), and the resistance of the lower part being the same, the whole is \( \frac{2}{3} a \times \frac{1}{3} x \) or nearly \( \frac{1}{3} \) of the strength which Mariotte’s supposition would give.

Observe, that although a body may, by the facility of extension, be readily bent or broken, though not very compressible, yet in this respect the other two theories would not be found so very erroneous, as it is the resistance to extension alone which they have considered.

It would be of vast service in calculating the strength of timber, if we could distinguish, even with tolerable correctness, the amount of the fibres under compression from those which were in a state of dilatation; or, what would be much the same, could we learn what proportion there is between the compressibility and extensibility of the timber. But this is matter of fact, and not to be looked for as the result of any theory. The strain now under consider-
Let ABC be the cross section of fracture of the triangular bar; MN the neutral line, or separation between the parts compressed and those dilated; oprq an indefinitely thin slip of the fibers. The length of the slip op will be proportional to its distance from the angle; the stretch or compression which it undergoes, will be proportional to its distance from the neutral line; and upon the supposition formerly made, of the resisting force being proportional to the tension, being the law of elastic bodies, the resistance it makes will also be proportional to that distance. Lastly, the lever by which it acts in resisting a bend or fracture, is the same distance, and therefore its energy is as the square of its distance from MN. Take this distance DE=x, and making DC=a, MN=b, we have for the length of the slip,\( \text{op} \),\( \text{CD} : \text{MN} = CE : op \), or \( a : b : b = x : a \); and making, as before, \( f \) the force of each fiber exerted at the greatest distance \( a \), the strength of this will be \( \frac{bf x^2}{a^2} \); at the distance \( x \); its energy therefore by means of the lever \( b \), \( \frac{bf x^2}{a^2} \), The fluent of which, or total energy, is \( \frac{bf x^2}{3a} - \frac{bf x^2}{a} \); which, when \( x \) is \( a \), becomes \( \frac{bf x^2}{3a} - \frac{bf x^2}{a} = \frac{1}{3} bfxa = \frac{1}{a} bfx^2a \). That is, as \( \frac{1}{3} a b f \) represents the absolute cohesion of the triangle CMN; the actual force is as if the absolute cohesion of MNC acted at the distance of \( \frac{1}{3} \) of its perpendicular from the neutral line MN, which is the solution usually given for the transverse strength of the triangle.

Before proceeding farther we may observe, that this shows us the ratio of the strength of a square, or rhomboidal joint, lying on edge, compared with the same joint lying on one side. Upon the supposition of the equality of compression and dilatation, the triangle below will just exert the same strength as the one above, and the whole will be as if twice the absolute cohesion of the half beam, that is, as if the absolute cohesion of the whole beam were exerted at the distance of one sixth of the half diameter from the centre. In the other case it will be as if the absolute cohesion were exerted at the distance of one third of the side from the centre, and therefore it is stronger in the proportion of 166 to 118. But it must be observed, that the supposition of equal compression and dilatation is the most unfavourable for the diagonal position, the strength of the broadest part of the beam being lost by being in the neutral line.

Let us next inquire into the action of the broader part of the triangles, viz. MABN. Here, as before, the length of the slip \( x, y, z \) increases with the distance from \( C \), and calling \( DF = x \), we find,

\[
a : a + x : b : bx = b + \frac{bx}{a};
\]

and, by reasoning as before, the energy of the whole MABN will be \( \frac{bf x^2}{3a} + \frac{bf x^2}{4a^2} \).

It is evident that we cannot, in this case, take \( x = a \) upon the supposition of equality of compression and dilatation. Let us, therefore, assume the whole energy of the side AN, to be equal to that of the side MCN, then making \( \frac{bf x^2}{3a} + \frac{bf x^2}{4a^2} = \frac{1}{3} a^3 bfx \), we find

\[
x^3 + \frac{x^4}{3a} = \frac{a^3}{12},
\]

and taking the root of this equation, we get \( x = 1.785 \), or nearly \( \frac{a}{6} \), in which case it must be observed that the fibers of the broad side are strained little more than one half of those at the opposite edge. It is perhaps possible, therefore, that a triangular bar may fail at the edge, and yet not be broken by the strain, it would be very desirable that experiments were made on this point.

Upon the principle of equality of compression and dilatation, which is certainly the most probable at the beginning of the bending, it does not appear how the superabundant strength of the broad side of the beam can be brought into action; its superiority, therefore, in one position over another, is a mere deception of hypothesis. But if we suppose the compressibility and dilatibility different, which without doubt is ultimately the case in most bodies, (thus oak carries

less than far as a pillar, but more as a tie, then we may suppose the greater breadth of the side of the bar to become useful in resisting a strain; but this is a question of fact and not of theory, and, according to circumstances, the bar may be best situated either way. In the mean time, it is a question of high importance to the engineer; for until it be ascertained, it is evident that the form of flanges, scantlings of trusses, &c. must be left entirely to chance, and in making them he may, instead of strengthening his work, be only adding a cumbersome load.

We may collect from the above enquiry that our triangular section will begin to give way at the point, when the distance of the neutral line from the base is \( \frac{1}{3} \) of its distance from the vertex, and therefore \( \frac{2}{3} \) of the altitude of the triangle. At that time the vertical part being on full stretch, we have its energy acting at \( \frac{1}{3} \) of \( \frac{2}{3} \) of the altitude of the triangle from the neutral line MN, and the part CMN will be to the whole bar as the squares of the altitudes CD and CR, viz. 9 : 14\(^2\) = 81 : 196, that is, the energy of the vertical part of the triangle is \( \frac{1}{16} \) of the absolute cohesion, acting at the distance of \( \frac{1}{3} \) of \( \frac{2}{3} \) of the depth or altitude; the other, or trapezoidal part, must of course be exerting the same energy, so that in triangular bars we may suppose the absolute cohesion acting at the distance of 0.88, or about \( \frac{2}{3} \) of the depth of the triangular bar from the neutral line: or the absolute strength is to the resistance to cross strain, as the length of this beam to about \( \frac{2}{3} \) of its depth, so that it is little more than half the strength of a rectangle of equal depth, and the same contents.

We may learn from this case of how much importance it is that the compression should be attended to. By neglecting to do so, some writers of reputation have fallen into serious mistakes. There is another case, similar to this, given by Emerson and others: it is said that a hollow tube becomes stronger by bringing the interior opening nearer to the side, which becomes concave by the strain; but like the above, this depends entirely on the relation between the compressibility and dilatibility of the materials of the tube. In like manner we reject the propositions said to point out the strongest position of a beam having a trapezoidal section, and others of the same kind usually given by authors; they are merely deceptions of hypotheses. The truth is, that in most kinds of timber the position of the beam is just the reverse of that usually recommended. In most of them we shall find the compressibility to be much greater than the dilatation. The greater dimension must, therefore, be thrown to that side which is likely to be compressed, and a beam broader on one side than the other will be strongest with the broad side uppermost, when it is supported at the two ends.

In stone, however, the reverse is most likely to be the case; but is needless now to go farther, the reader must perceive that the whole is matter of experiment.

We may see the propriety of several maxims, which have been long familiar to the experienced workman. If a mortice is to be cut out of a beam, the worst place is to take it out of that side which becomes convex by the strain, as (Fig. 7. No. 1.) The concave side (as No. 2.) will be much better, since its place will be, in a great measure, supplied by the tenon, but towards the middle (No. 3.) will be the best of all, since the parts near the neutral line are suffering little or no strain, and even there it should be placed towards the concave side rather than the convex.

When a fish, or strap, is to be applied to a piece of timber, it must be applied to the convex side, as Nos. 4 and 5.

Though we have supposed, hitherto, that the beam is fixed in a wall, and strained by a load at the outer end, it is not difficult to extend the results we have got to the more usual case of a beam supported at both ends, and loaded in the middle.

Let AB, Fig. 8, be such a beam, resting on the props E, F, and bearing the weight W on its middle C. It is clear that the props E, F, between them, bear the whole weight of W; and that the resistance of E, F, produces a strain exactly the same as if two weights \( e, f \), together equal to W, were hung at the ends of the beam a, b, balanced at the prop c; only the forces will have the opposite direction. In this case, we know, that the weights \( e \) and \( f \) will be to each other inversely, as their distances from the prop c. That is, \( e : f = b d : a d \); the ends a and b tend to descend, and the beam to part in the section DC.

The situation of each half is therefore the same as if the other were built into a wall as far as the part CD; thence we conclude that a beam, which is supported at both ends, and loaded in the middle, will carry twice as much as a beam which projects half its length from a wall, and loaded at the extremity.

It is evident that the cross strain produced in CD is the greatest; and that it diminishes as we pass towards the end of the beam. For the same force \( f \) acts in \( g h \) by a shorter lever \( b g \). If we suppose the weight W shifted off to G, then the pressure on A is as GB, and the lever by which it acts at GH is AG; the effort is therefore as AG \( \times GB \), or as the product of the two segments of the beam.

Again, the strain at CD will be as GB \( \times AD \), which will also be the strain at GH, when the same weight is applied at CD. We are now therefore sufficiently informed as to the strains produced on one part of the timber, by loads laid on at any other part.

Suppose, next, the ends of the beam prolonged beyond the props to the points M and N, and to be there firmly held down, the beam will be able to bear twice the load W that it carried before. For suppose the part CD to be sawn through, the weight W is just sufficient to break it at A and B; and another weight of equal magnitude would have been required to overcome the cohesion at CD, independent of the exterior support.

It may appear from this, that the joists of floors would be stronger by being built firmly into the walls. But the hold that is thus obtained is much too short to be of great service; and besides, it acts as a powerful lever, in tending to shatter the wall. But when joists can be carried across partitions, purlins extended to three or more truss frames, or rafters extended over the purlins, &c. it is of great importance to make them in one piece, as they are then of double the strength.

3
Let us now proceed to the strain which arises from a load distributed uniformly over the beam; of which kind the weight of the beam itself is one of the most important.

We must suppose the whole of the load thus diffused, to be united in its centre of gravity, which, in the case of uniform distribution, will be the middle of the piece.

Thus, to find the strain at GH arising from the weight of the beam AB, we may suppose the weight of the beam accumulated in the point D, and the strain, which the weight of a part AD produces at GH, will be as the weight $AD \times DA \times GB$.

Therefore the strain on the middle of a beam uniformly loaded, is half the weight of the load acting by the lever $DB$; and the strain at $G$ is half the load acting by the lever $GB$, and is therefore greatest of all at the point $D$, or in the middle of the beam.

Since the strain in the various sections of the beam also varies considerably, it becomes of importance to determine the various proportions of the beam, so that it may be equally strong in every part. The strength must be everywhere proportioned to the strain; should it be anywhere greater, this additional power will be useless, for it cannot be brought into action.

Suppose the beam fixed in the wall, and strained by a load at the extremity.

If the upper and lower sides are parallel, i.e., if the depth be given, the horizontal section must be a triangle; or the two sides are vertical planes, meeting in an edge at the extremity. For the strength, as we have shown above, is as the breadth, multiplied into the square of the depth, and divided by the length. That the strength may be everywhere the same, the breadth must therefore be proportional to the length, for the depth is given. See Fig. 9, where $BC = CE$.

Fig. 9.

If the breadth be given, we must have the length proportional to the square of the depth, which is done by making the depths the ordinates of a common semiparabola, (Fig. 10,) where $BC = CD^3$.

If the beam be pyramidal or conical, having its base in the upright wall, i.e., if its vertical sections be similar figures, as circles, squares, &c.; then since $d' = d^3$, we must form the diameter or side so as to have its cube proportional to the length, or so as to be the ordinate of the cubic parabola, (Fig. 11,) $BC = CD^3$.

The same forms are proper for the arms of a lever, observing that the greater of the three pressures is to be applied at the junction of the bases, or thickest places.

It is worthy of remark, that although the different forms of Figs. 9, 10, 11, are all equally strong, they are not, however, equally stiff; Fig. 9, having the upright end, will bend least on the whole; Fig. 10, will bend most, a property which may have its use in forming springs, &c.

It is not necessary, theoretically speaking, that the upper or under side of Fig. 10 should be straight. The proper depth being preserved, we may place the beam either way, divide the curvature between the upper and lower sides, or give the beam any proposed camber. In straight-fibred timber, however, we will naturally put the straight face to that side which is stretched by the strain; as well to prevent their parts from tearing, as to procure greater stiffness. The same remarks may be applied to the other figures. They will occur to the intelligent engineer. It is evident that the same remarks and construction will apply to a joint which is loaded at a particular point, and supported at both ends. It is in the same state as the lever above-mentioned.

When the weight to be supported is uniformly distributed over the beam, the forms are considerably different from these.

The strain on any section arises from the weight distributed over the part beyond it. This weight, being distributed uniformly, will be as the length beyond the section, and it may be supposed accumulated in the centre of gravity, which will be in the middle of that length; so that it acts with a leverage also proportional to the length; and the strain produced is therefore proportional to the square of the length. Now the strength of the section is as the breadth multiplied into the square of the depth.

If the breadth, therefore, be given, that is, if the beam must have upright parallel sides, we must make the square of the depth proportional to the square of the length beyond the section, that is, the breadth as the length; and the beam becomes a triangular prism, as Fig. 9, only having the extreme edge at $B$ placed not vertically, but horizontally.

If the depth be given, or if the upper and under sides be parallel planes, then the breadth must be formed proportional to the square of the length beyond the section; and the beam becomes the same as Fig. 10. only placed on the flat side, or the horizontal section is formed by arches of the common parabola.

If the beam must be of a conical or pyramidal shape, or rather if the vertical sections must be everywhere similar figures, then the cube of the diameter must be as the square of the distance from the end, and the sides of the beam are arches of the semicubical parabola.

It is evident that the same observations as formerly made respecting camber may be again repeated here.

It will not now be difficult to apply these deductions to the form of a joist uniformly loaded through its whole length.

We have already shown that the strain on any point $C$, Fig. 8, from a load laid on another point $G$, is proportional to the rectangle $GB \times AC$, being the distances of the points $G$ and $C$ from the ends next each. The strains, therefore, which are produced at two points on the same side, will be to each other as their distances from the end; and the strain under the load is as the rectangle of the segments on each side, and is therefore greatest in the middle.

For the strain produced at any point $G$ by a load uniformly distributed, we may suppose the load on the part $GB$ accumulated in its centre of gravity, which will therefore be distant $\frac{1}{2}GB$ from $B$; its effort at $G$ will be proportional to $GB \times GA$; and the load in the part $AG$ will, for the same reason, produce a strain as $\frac{1}{2}GA \times GB$; the sum of these will therefore be likewise proportional to the rectangle of the segments $AG$ and $GB$; and we have the same proportion of strain for the load uniformly distributed over the part beyond the section.
distributed, as for a load laid on directly at the point
G, therefore, to make a joint equally strong in all
its parts against a load laid on at any point taken at
random, or against a load uniformly distributed over
it, we must have the square of the strength at each point proportion-
al to the rectangle under the two segments of the beam.

If therefore the breadth be given, the square of
the depth must be everywhere proportional to the
rectangle of the segments, that is, the depths must be
the ordinates of an ellipse.

If the depth be given, the breadth must be as
\( AG \times GB \).

If the beam be pyramidal, or have its cross sec-
tions everywhere similar, the cube of the diameter
must be as the rectangle of the segments \( AG \times GB \).

The joist which is loaded at some particular point
will be of equal strength throughout, when the
strength of each transverse section between the load
and either end is as the distance from that end. It is
needless here to repeat the forms, being merely ex-
tensions of the Figures 9, 10, 11, to the opposite side,
at the point of support, which here becomes the
point loaded.

The strain upon a beam may be merely that aris-
ing from its own weight. The determination of the
proper form for such a case is not quite so simple as
the others, for the very form which is sought must be
known ere we can discover the weight to be resi-
sed.

To consider this subject in a familiar way, it is
evident that the increase of breadth merely gives no
additional strength, since the load to be resisted in-
creases along with it. The increase of length dimin-
ishes the strength, first, by increasing the load; se-
condly, by increasing also the leverage with which it
acts.

The increase of the depth, though it brings a pro-
portionally greater load, yet, since the strength also
increases as the square of the depth, the resistance
to fracture increases with the depth; and we may on
the whole infer, that the power of a beam to carry its
own weight, is directly as its depth, and inversely as the
square of the length. We must therefore make these
two dimensions proportional; that is, the depth CD,
Fig. 10, the breadth being given, must be propor-
tional to the square of the distance BC, or the side
BDF must be the curve of a common parabola.

The reader acquainted with the art of analysis may
wish to see this problem resolved in another way.
Let the distance \( BC=x \), and \( CD=y \), CD \( de \) an in-
definite small increment of the magnitude, it is equal
to \( y \). Its momentum round the fulcrum B is \( xy \).
Suppose now that \( y \) is as \( m \), or as some power of \( x \),
then the contents, or weight of BCD is \( \frac{x^{m+1}}{m+1} \); also
\( xy = x^{m+1} \), of which the fluent or whole momen-
tum is \( \frac{x^{m+1}}{m+2} \). The distance of the centre of gravity
of BCD from the point B, will be found by dividing
this by the weight, viz. \( \frac{x^{m+1}}{m+1} \), the result is
\( \frac{x^{m+1}}{m+2} \), and the distance of the same point from c is
\( \frac{x}{m+2} \). Multiply this by the weight, or \( \frac{x^{m+1}}{m+1} \), and
we have the strain, or \( CD = \frac{x^{m+1}}{(m+1)(m+2)} \). This
strain must be as the square of the depth, the breadth
being given, or as \( y^2 \), or as \( x^{m} \), therefore \( m^2+2=2m \),
and \( m=2 \), or the depth is as the square of the distance
from the extremity, as before.

It is evident, that a projecting beam becomes less
able to bear its weight as its length is increased. An
enlargement of the depth gives us strength only pro-
portioned to that enlargement, while a proportional
enlargement of the length gives a strain which is as
the square. By enlarging any structure, therefore,
we weaken it. By diminishing it proportionally, we
strengthen it. This increase of relative strength al-
lows a reduction of weight and stuff, by which means
we have a diminution of expense, and an increase of
mobility. Hence, a structure may appear very strong
in the model, which will not hang together in the
great; and there seems to be a limit set by nature to
the increase of structures composed of given mate-
rials. The cohesion of the tree is greater than that
of the shrub, which again is greater than that of the
herb. The sapling gets firmer as it increases to the
oak, which, were it to grow 50 times bigger than it
is, could not stand, though, with the lightness of fr
it should have the toughness of iron. Were a man
two times as long as he is, he would break his bones by
falling along.

We have hitherto considered the strain as acting Obliquely
perpendicularly to the beam; This is the simplest
case, and one of most frequent occurrence; but it
often happens that the load acts obliquely to the
beam. The slanting rafter, for example, is obliquely
strained by the weight of the roof, since gravity
acts in vertical lines.

It is not difficult to compute the effect of this modi-
fication, as far as to find the equivalent perpendi-
cular pressure. Let the load \( W \), Fig. 2, act in
the line CX, and be represented by it.

Then, according to the usual theory of the reduc-
tion of pressures, its effect will be equivalent to two
others, viz. CT directly across the beam, and CV
in the direction of the beam; CX is to CT as ra-
dius to the cosine of TC, wherefore the cross strain
is diminished in the ratio of the cosine of the angle
of obliquity from the perpendicular. This is all that
is usually given by authors on this modification of
strains; and they thence infer, that an oblique beam
OP will bear as great a load (Fig. 1.) as the hori-
zontal beam MN, of which the vertical section is the
same.

But this is a very imperfect view of the subject.
We might as well infer, that a beam perfectly up-
right need have no thickness, which would be ab-
surd. There is one part of the strain kept out of
view. The beam is loaded lengthwise, by being
pressed or drawn longitudinally by the force CV.
We must provide for this force in addition to the strength required against the cross strain. And, independent of the strength which this load requires, the resistance to the cross strain itself is greatly modified by it. The quantity of the beam in Fig 4, which is under compression, will be increased; when XCV is an acute angle, the neutral point D will therefore be nearer the upper side, and the quantity of fibres under dilatation will be diminished. The reverse will be the case when the oblique force acts in any direction beyond the perpendicular CW, so that VCX becomes an obtuse angle. The dilated part will then increase, and the part under compression will diminish. We know too little of the corpucular forces, to say exactly what may be the effect of this; but it is clear, that it may tend materially to weaken the beam. The compression or extension may be so very great, that a very small cross strain may suffice to complete the rupture; yet this is a case which is sometimes unavoidable. The most enormous strains to which framings of carpentry are subjected are of this kind; and the skill of the engineer is particularly shown in reducing every load to a direct pressure or pull in the length of the beam, and to avoid every thing which may tend in the smallest degree to disturb this arrangement. By the setting and sagging of the work, pieces come often to exert very various and yet very considerable strains, which were originally supposed and intended to be inactive.

When the oblique load upon a beam is such, that it increases with the increase of length, as the roof over a rafter or the like, we have another reason for giving the beam a greater scantling. If MN and OP, Fig. 1, be loaded equally per foot in length, OP carries more in the ratio of PD to DN. To be equally strained, therefore, DP must be made broader, or placed nearer its neighbours, in the ratio of DP to DN; or its depth increased, in the ratio of the square root of DN to the square root of DP. In the case of a rafter, it is to be observed, that the weight increases as we pass downwards; and hence they must be thickened below. In a kingpost, on the other hand, the weight of the post itself is a load which increases towards the top; and we place the thick part of that post (as it is improperly called) to the upper end.

We may now return again to the case of a beam compressed lengthwise, which is liable to be so much modified by the resistance to bending. It is needless to inquire how a pressure acting on a straight beam or post in the direction of its length can bend it. It is evident, that the case arises from the unequal compressibility of the sides. One side of the beam must be supposed to act as a fulcrum, to enable the incumbent weight to compress the other side. But this state of the case soon ceases. As the compression goes on, the fulcrum or centre of support shifts gradually towards the concave side; and when the post is so far bent, that the line of direction of the load passes without it, the concave parts must be in a state of compression, and if the post supports the load, the convex parts must be in a state of extension. This situation of things bears an intimate resemblance to the action of a cross strain on one end of a beam, of which the other end is built into a wall; we may say, it is exactly the same with the condition of such a beam, when pulled in the same direction as that in which the load acts.

Let ACB, in Fig. 2, represent the position of the neutral fibre; then drawing the perpendicular DC, we may say, that the strain on the section $ef$ is the same as if the weight $A$ were applied at the end $D$ of the lever $DC$, of which $e$ is the fulcrum, and balanced by the resistance to compression in the part $Cf$, and to dilatation in the part $Ce$; or as these two resistances must be equal, we may conceive it balanced by twice the resistance to dilatation in the part $Ce$, in addition to its own weight.

If therefore we knew exactly where the neutral point $C$ was situated, we would thereby be enabled at once to determine the strain on a post or strut, which was bent to a given degree. But, unfortunately, theory seems here to fail us. The proportion between the extension and compression produced by equal forces can only be learned by experiment.

We may, however, draw some useful general inferences.

I. It is evident, that the greatest strain will be at the place where the post is most bent from the straight line. For the arm of the lever $DC$ will then be the greatest, and it is not likely that the arm $Ce$ will be any where less.

II. The strain appears to be nearly proportional to the distance of the section from the line $AB$. But we cannot say so with certainty, as there may possibly be the same change in the arm beyond the neutral line, as in the part $CD$, by a shift in the virtual fulcrum. Euler, therefore, the only author of reputation who has treated of this subject, and after him Emerson upon Euler’s principles, have fallen into considerable errors, when they say the strain is proportional to the ordinate $CD$, or rather $fD$, as they have it. In the first and second hypotheses above mentioned for the cross strain, this would be indeed true; but we have already shown the falsity of these hypotheses, and the necessity of attending to the compression. If that be necessary in treating of the strain directly across, it is still more indispensable here, where the very essence of the strain consists in its compressing the timber.

In the great and most dangerous loads, as the trussed centres for heavy vaultings, or the like, the compressed part occupies the greater part of the section, which, by removing the neutral point very near to the convex side, not only increases the strain, by extending the arm $DC$, but diminishes the power of resistance, by leaving fewer fibres for distension; and these few acting by a shorter arm of the lever than before. Upon this principle, we may again account for the facility with which a very tridling cross strain is enabled to break a beam which is under very great compression.

III. At the point $B$, where the crooked beam is intersected by the line of direction of the load, there is, properly speaking, no cross strain; it does not follow, however, that there is no strain at all, as Euler has hastily supposed. The truth is, the strain is of the simple lateral kind, and the upper part $AB$ tends to part from the lower, by sliding along the section
CARPENTRY.

Theory of Carpentry.

The strain is the simple load $A$, laid on at the point $O$, and the strength resisting it is as the depth or area of the section $OP$, as mentioned in the section on lateral resistance.

Practical estimator.

We have already proceeded to compare the theoretical investigation just given with the results of experiment; but, as we have already stated, there are few of that kind recorded, which can be turned to any good purpose. The compressibility and dilatibility of the timber has been seldom thought of, at least so far as to subject it to experiment. We can therefore infer little from the numerous experiments on the transverse strength. The various series of experiments by Beidaon, Duhamel, Buffon, &c. seem in general to confirm the truth of the strength being in proportion to the breadth and square of the depth, directly and inversely as the length. Those, indeed, of Buffon, by far the most valuable that are on record, and which, by being made on large scantlings, were free from the irregularities unavoidable in small specimens, would show that the strength diminishes in a ratio greater than the inverse proportion of the length; and reasons might perhaps be given why it should be so. But we have already occupied too much time on this subject; and perhaps it will be better to give the practical carpenter a simple arithmetical rule derived from these experiments, the result of which very nearly coincides with them, for finding the weight which will break a bar of any scantling.

Divide the number 651 by the length in feet, subtract 10 from the quotient, multiply the remainder by the breadth into the square of the depth, both expressed in inches. The result is the greatest load in pounds. This rule applies only to scantlings of oak.

Example. Required the weight necessary to break an oak beam of 8 inches square, and 18 feet long, between the supports.

\[ 651 \times 18 = 26.16 \text{ and } 26.16 \times 8 \times 8 \times 8 = 13384. \]

The experiments of Buffon gives 13200.

Ex. 2. Required the weight for a ½ inch bar of 7 feet long.

\[ 7 \times 651 \times 93 = 8.5 \times 64 = 5312. \]

Buffon’s experiment gives 5312.

Observe, that this weight is that which will break the beam in a few minutes. One half of this load may be safely laid on the beam, but will give it a set which it does not recover. One third may be laid on it for any length of time without injury.

It is to be regretted, that we have no series of experiments on the other kinds of timber. Fir is said by Buffon to be $\frac{3}{4}$ of the strength of oak; Emerson makes it $\frac{4}{5}$. Parent $\frac{5}{4}$. We shall adopt the proportion $\frac{3}{4}$ as a sort of mean.

Required the load which will break a beam of fir of 14 feet long and 3 inches broad, by 5 deep.

\[ \frac{36.5 \times 5 \times 5 \times 3 = 2737.5}{2} \text{ weight to break an oak beam.} \]

\[ \frac{3}{5} \text{ of this, or } 1825 \text{ lbs. to break the fir beam.} \]

Required the load which may be borne by the same beam with safety at 4 feet from one end.

\[ 4 \times 10 : 7 : 7 : 40 : 49 : 1825 : 2235 \text{ lbs. will break the beam there. One third of this, or } 745 \text{ lbs. may be borne with safety.} \]

According to Emerson’s experiments, a rod of good oak, one inch square and one yard long, supported at both ends, will bear in the middle a load of 330 lbs. avoiding 9; but this only for a short time, and it breaks with more. The rule above mentioned would only give 207 lbs.; and, as Emerson says, that $\frac{3}{4}$ or $\frac{7}{8}$ of this load only may be depended on, we think, on the whole, the rule above given from Buffon may be safely trusted to in practice. Emerson also states the relative strength of other timbers as follows:

V. Of the Resistance to Twisting.

This is the strain that is of most importance in Twisting, the axles of mills or other machinery, in screws of all kinds, and in the rudders of ships; it frequently also occurs in masts. If we suppose the twist to be confined to one plane of section, passing directly across the axle, as to the joints between the two parts of a flute, we must suppose the resistance to arise from the force of cohesion in the particles, and to have some relation to their number. It is clear that the particles on the outside of the axle will be more strained than those nearer the centre. As heretofore, we may suppose them exerting proportionately greater forces. The section will give way when the exterior particles begin to give way; for a particle nearer the centre, though strained to the same degree, acts by a shorter leverage. When the section begins to give way, therefore, we may suppose each particle to be exerting a force proportional to the distance from the centre. The number of particles in any ring or circle, is as the distance of that circle from the centre. Wherefore the effect of each ring will be as the square of its radius. But the number of rings is also as the radius of the axle. Wherefore we find a very simple rule for the strength of axles, viz. It is proportional to the cube of the diameter.

We may draw several useful conclusions from this principle, even before we endeavour to determine the amount of the resistance to twisting, by drawing it from the direct cohesion.

It is plain that the interior parts of the axle are not so useful as the under the outside, inference. Suppose we bore out the heart of the axle as far as half the diameter, the strength of the remainder will be as the difference of the cubes of 1 and 2, that is, it will be $\frac{7}{8}$ of the entire piece, but the stuff is diminished one fourth. A saving is therefore practica-
The whole cohesion of the exterior circle of particles being supposed exerted, the force of any interior circle will be less than that in the proportion of the squares of their diameters or radii. The effect of the whole, therefore, will just be 4/3 of the lateral cohesion of the section, or one third the force required to cut the piece across, by means of a square edged tool. The force required for this, as we have already mentioned, appears from experiment to be considerably greater than that which would pull the parts of the beam directly asunder.

To determine the effect of this, in resisting an external force which tends to break the axle, let \( f \) represent the lateral cohesion of any particle, \( r \) the radius of the arch, \( x \) the distance of any circle from the centre; then \( x \) is the flexionary increment of the radius, or breadth of an indefinitely small concentric ring, we have the force of any particle as its extension, or as the distance \( x \) from the centre. That is,

\[
r : x : f x^2 : r,
\]

taking \( \pi \) as the number 3.1416; we have the cohesion of a ring \( = \frac{\pi f x^2}{r} \); its energy is found, by multiplying this by the length of lever or distance \( x \), and is therefore \( = \frac{\pi f x^3}{r} \); the fluent of this is \( \frac{3}{2} \frac{\pi f x^4}{r} \), which, when \( x = r \), gives for the whole energy of the axle \( \frac{1}{2} \pi fr^3 \). Now \( \pi r^3 \) is the area, and \( \pi fr^4 \) is the lateral cohesion of the section; wherefore the energy will be found by supposing the whole lateral cohesion exerted at \( \frac{1}{3} \) of the radius from the centre.

Example. Required the weight which would wrench off an axle of fir 1 foot in diameter, acting on it by a lever or wheel at the distance of 3 feet from the centre.

Take the absolute cohesion of fir 8000lbs. per square inch.

\[
8000 \times 144 \times 7854 = 904781,
\]

the cohesion of the section;

36 ins. \( : 1 \frac{1}{2} \) : 904781 : 37700 lbs. weight required.

Though the length of the axle has not been alluded to in these deductions, it is probable that a considerable degree of importance should be attached to it. In fibrous matter such as timber, the fibres will be twisted up like a skain, and made to close upon each other. The diameter of the axle will be somewhat diminished, and with that the energy of each fibre. The twisting produces also a species of cross strain upon them, while they are violently drawn in length; so that on the whole, the length of the axle seems to have somewhat of the action of a lever in facilitating the disruption. It is not easy to subject this to calculation; but it is obvious that the result for a simple twist will be thereby considerably reduced.

The various forms into which timber may be bent are innumerable, and to discuss completely the strains to which even the most simple and common may be subjected, would be occupation for volumes; nevertheless we cannot entirely omit them. We have already, in examining the effects of bending, when treating of cross strains, stated some of the most important conclusions. We shall now, therefore, be very brief.

Let ACB, Fig. 2, be the piece of crooked timber, loaded at A to the utmost. Join AB and the perpendicular \( C D \). Let ACB represent the neutral fibre. It is evident that the first change likely to take place, is the slipping of the fibres on each other; for as the beam bends under the load, the concave parts will be somewhat protruded beyond the convex: the parts \( A \) and \( B \) are stretched. And we might consider the whole as a framing, in which \( AOB \), \( f \) are struts, and \( A \) and \( B \) are ties. But this would necessarily lead us to anticipate other matter; we shall therefore consider the weight \( A \) as applied to the virtual lever \( DC \), of which the fulcrum will be \( C \). The weight of \( A \) applied to \( D \) will be balanced by the resistance to extension in \( eC \), an equal resistance to compression in \( Cf \), added to the weight of \( A \), also compressing \( fC \); since the force in \( fC \) will be equal to the sum of the other two in the opposite direction.

Now the weight of \( A \) is constant. The extension in \( eC \), and equal compression in \( Cf \), will therefore increase with, and be proportional to, the distance \( CD \). Its amount would be known as aforesaid, did we know the position of the neutral line. The part \( C \) has a tendency to fly out from \( AB \), which is resisted by the extension \( AD \); so this tendency of \( C \) to fly out is measured by the cosine \( DC \), which shows also the strength of the bridle that should prevent it. Hence we may observe, that cross bridles made to preserve straight posts from yielding, may be vastly smaller than those fir beams which have already taken a set, or were originally crooked.

If the piece ACB were under distension, the reasoning and magnitude of the parts would be the same, the mode of action of the concave and convex sides only changing. And in like manner, by attending to the virtual leverage, it will not be difficult to form a conception of the mode of action in every oblique strain. When the beam ACB is distended, the parts \( C \) and \( f \) will tend to part from each other, and hooping the beam there may have a good effect. The same thing is likely to occur in various other instances.

When the piece is exposed to a cross strain, acting in \( CD \), and the ends \( A \) and \( B \) have abutment, each part is undergoing a longitudinal strain, the amount of which, in proportion to the force applied, is greater as \( AD \) to \( DC \) nearly, and may readily be discovered by the resolution of forces. When the parts \( A \) and \( B \) have no abutment, then the parts \( BY \) must resist by being extended, and the case returns to one in which the parts \( AB \) are distended. It is evident that the power of the cross strain will be greater the nearer ACB is to the straight line. In such a case
again, hooping the part of must be useful; and the carpenter of the bridge of Schaffhausen has very properly introduced it. And upon similar principles, we should doubt the propriety of such erections as the Coalbrookdale bridge and others, where several parallel and curved bars are exposed to strains of this kind, without proper pains being taken to secure the connection between them.

Of Joints.

Having now considered in general the various kinds of strains which occur in the works of the carpenter, and having endeavoured, as far as was in our power, to show how the strength of the timber is made to resist them, and how this resistance can be brought under calculation, we proceed to examine upon similar principles, the modes of connection by which these strains are propagated through the different parts of a framing. Upon this part of our subject we shall be the more brief, as it is handled in more detail in the practical part of this article, by a gentleman of well known ability. Another opportunity will occur for treating of the more complicated framings, as trusses, roofs, centres, bridges, ship frames, &c. where we can consider this subject upon principles that are common both to carpentry and iron work. In the latter we can form frames composed of one single piece, and we can, in like manner, accommodate the thickness and breadth of the parts, or their length to the strength we require, or the uses they are applied to, without any weaker connecting parts. But in the former, we must accommodate our framings to the size of our materials; and when these are too small, we must endeavour to join or piece them, till the requisite magnitude or strength be attained. The best method of constructing these joinings, is one of the most delicate parts of the art of carpentry.

The different forms are very numerous. Each of them has its advantages in particular cases. The leading principle with the carpenter and joiner should be, to make every joint, even those intended only to please the eye, as strong as the case will admit. He will attend to the changes that may take place in his work, by swelling, or shrinking; for as this is a force altogether insuperable, unless the change in the whole assemblage be made to act in the same direction, he cannot prevent the smaller parts from crushing or tearing away.

When the thickness or depth of a beam is to be increased, other pieces are applied over or under it. If the strength of the beam is to be combined with pliability, these pieces are not fixed to the beam, but bend and yield gradually like the plates of a coachspring, Fig. 3. Where the assemblage is intended to act like an entire log, the parts must be attached together. Iron or wooden bolts may be driven through them, or they may be dovetailed within, by letting pieces of tough wood into the solid on each side of the joint, Fig. 4, 5. The pieces may be fitted into the face of the joint like tenons, or driven across it like keys or wedges. They may be also attached by coaking, or tabling, Fig. 6, 7, &c. which is uniting two or more pieces together in the middle by small tabular parts formed from the solid of one, and sunk into corresponding cavities in the other; the butts or ends of these prevent the pieces drawing asunder lengthwise.

When the butting surfaces brought into action are equal, dowelling (Fig. 5.) is certainly preferable to coaking or tabling, for this obvious reason, that the depths of the two beams are preserved entire; and we know that the thicker beam will be stronger, in proportion to the greater distance of the compressed or dilated fibres from the neutral line. Observe, however, that the beam is not stronger in proportion to the square of this greater depth, for the quantity of fibres left entire is supposed, in both cases, to be the same. If the fibres which are cut across be contained within that part of the beam that is compressed, and if close work be made, the assemblage will, indeed, be nearly as powerful as a solid beam of equal depth, which is a still stronger reason for preferring the method of dowelling; nevertheless, perhaps, because it appears less ingenuous, many carpenters appear to prefer the other.

The intention of both these methods of joining, is to prevent the two pieces from slipping on each other. Where there is no great risk of that, the indented need not be very deep; at all events, when the butting surfaces are so great as to be able, without crippling, to shove off the coak along the plane, there can be nothing gained by making them deeper. When the one piece is laid into the other, we have an increase of hold and consequent strength, by deepening the indenting so far; but we have also a diminution of strength by lessening the scantling of the beam. There is therefore a maximum here, or certain depth, to which we should cut, so as to make the strongest compound beam of two given balks.

Duhamel has made a number of experiments, with a view to determine this point; and it appears from them, that the depth should be about one eighth of the depth of the two balks, or one seventh of the compound beam.

Many artists use an oblique scarfing, instead of Scarfing and dovetailing, as Fig. 8. This practice does not appear advisable; the sharp corner is apt to be crippled. Dovetailing them, as in Fig. 9, seems also injudicious; the pieces are then apt to tear each other up. The experiments of Duhamel appear clearly to favour the method of square tabling, and it has the advantage of acting both ways. The dovetailing appears intended to take a hold of the two pieces, and prevent them from parting. There is a very ingenious method of fixing dowel pins and tree nails in that way, which may be applied to other joints in carpentry. A little split is made in the end of the tree nail, and a small wedge struck in it; this wedge is driven home when the bolt reaches the bottom, expands the end of it, and squeezes it firmly against the side of the hole.

Two beams are often connected side by side, with the intention of resisting strains in the direction of the plane of the joining, or rather with the view of resisting a strain in every direction, as is the case with the parts of a mast, or an axle. The feather and groove, used in flooring, is of the first kind, and it is sometimes employed in joining beams. The feather loosens by the unequal shrinking of the beams, and then it
may slide in the groove. Besides, this form gives a hold only in one way, and is therefore unfit for masts or axles. Tabling the pieces together, or keeping them through in the plane of the joint, would be improper here, so much of the exterior fibres as are cut across by the tabling are unfit for distension, and therefore the compound beam will be weakened against a strain in the direction of the joining. The one piece may also slide on the other in that line, at least so far as to admit of serious bendings, and the form would have no resistance against twisting.

The lateral slide is prevented in mast-making, by dividing the joint along the middle of its breadth, and placing the projecting tablings alternately on either side. (Fig. 10.) Thus a, b, c, are projecting parts, and d, e, f, are depressions, the other piece being formed in the same way, the projections of the one fit into the depressions of the other, viz. a into d, b into e, and c into f, which prevents the beams from sliding on each other, either longitudinally or transversely, and resists twisting completely.

Even this form is not without its defects; for, independent of the jagged appearance of the seam, which is unsightly, and lodges water; that part of the exterior side of the beam which is occupied by the tabling, is not capable of resisting distension; and this, in the case of a round mast or yard, becomes of much consequence, as it occupies precisely the most favourable situation for that purpose. The mast-maker, therefore, perhaps with no other view than to make a fair joint, does not carry his tabling to the exterior side, but leaves two or three inches, of what he calls good wood, keeping the coaks at that distance from the edge of the beam, Fig. 11. This is certainly a good practice; and, of itself, sufficient to prevent the lateral sliding. The coak is thereby placed in that part of the beam which is near the neutral line. It is not subject to strains, for which it is not calculated, yet is sufficient, by its abutment, both laterally and longitudinally, to make a good connection of the pieces.

Another method, called a running coak, is in frequent use in the dock-yards. The coak is continued the whole length along the middle, but the butts project on each side of the middle line alternately, so as to be one-third their breadth within and without each other. This method has some advantages, as the coaks have a hold both by the bottom and one side, Fig. 12.

There is still another method of forming the alternate tabling, which not only gives a smooth seam, but is also better fitted to resist twisting than the running coak. The tables have their full depth in the axis of the joining, but are sloped off towards the outside like so many wedges, and end there in a straight edge. This form has the full strength of its fibres at the exterior side against every strain, and the connection formed at the axis is sufficiently firm to make the parts act together, Fig. 13.

All these forms admit of hooping well; and by making the interior part somewhat full, we may compress the soft heart of the tree so far as to render the assemblage much stronger than an entire tree of equal size.

Timber is also pieced, in order to increase its length; and there are a variety of methods of effecting this, some of them very ingenious. The strongest, and at the same time the simplest method of lengthening a beam, whether it be a post, a tie, or a rafter, is to compose it of several pieces, which are so placed that they may break joint, to use the mason's phrase.

The necessary connection among them can be given in any of the ways we have just mentioned, Fig. 14.

We are thus enabled in ties, to make certain of the cohesion of all the pieces but one; and it is obvious, that the strength increases with the number of pieces.

Besides, the connection among them becomes the more certain, in consequence of the increase of the surfaces of attachment.

Fishing a beam is something of this kind. It consists of clapping a piece of solid wood over a joint, and attaching it firmly to both parts, either by bolts or tabling. (Fig. 15.) A strap is frequently placed over such a joint, connecting the heads of neighbouring bolts. This is merely a fish of iron.

An eminent writer has said, that no tie of the same thickness of timber can be so strong as two pieces laid over each other for a certain length, and bolted together. (Fig. 16.) Now this is certainly wrong, for that very assemblage may be made stronger by dowelling across the joint with a thin key. Neither is the form of Fig. 17. No. 1, so strong as the other mode, where the pieces have a square abutment, and is every way stronger than No. 2. But as a tie, the case is very different.

The bolts are the only means of connection, and as great dependence seems frequently had upon that sort of fastening, it may be worth while to examine it a little more closely. It is clear, that whenever we pass the joint RU, we can have only the tenacity of one half of the beam ASTC. Now, how do we take hold of the other part RUD? It is by means of a bolt, and we hold this by means of the bit beyond it. This piece is only kept in its place by the connecting matter, which attaches it to the fibres. Our only hold therefore, is a thin plate of the connecting matter on each side of the bolt, and parallel to it. The second bolt gives us a hold of more of the connecting matter, but that still acts by means of the same fibres; and the third bolt does also the same thing, which shews by the way the impropriety of placing all the bolts in one line along the fibres, as is frequently done. But besides this, when the part comes to be stretched, the bolts will necessarily yield a little, and then bear only on one side of the holes; the fibres near the junction may be expected to yield; their number resisting an iron bolt is small, and the position of the bolt enables it to act as a lever in crippling them. Accordingly, such bolts quickly work loose, and, in reciprocating strains especially, the assemblage is very apt to give way at once. Placing a strap over the joint to connect the various bolt heads, may prevent the leverage above mentioned, and will be an unquestionable benefit against a transverse strain. But, even with every precaution, the firmness which appears to be produced by bolting, when carefully considered, is by no means so great as is generally imagined. The key placed across the joint of Figs. 18, 19, brings as many fibres as and keys or wedges.
Theory of
Carpentry.

into action as a bolt, and being so much shaken, is not exposed to any leverage, and consequently cannot cripple the fibre in that event. This key need be no thicker than just to take hold of the wood, without tearing it up; the greater distance between these mortices the deeper they must be cut, since the greater will be the lateral adhesion. As to the breadth of the key itself, this must depend on its hardness; and, in order to have it as small as possible, it is common to make it of some much harder substance than the beam, as of oak, or of iron. The latter is said to be apt to cripple the fibre; but perhaps this is more to be ascribed to injudicious driving, for these keys are usually made with a small taper, and, in order to obtain firmness and closeness, the workmen are apt to proceed too far. Every species of connection in carpentry is liable to this defect, and the necessity of guarding against it must be carefully and constantly impressed upon the workman. The joints should be close, and all motion prevented, and the pieces made firmly to adhere, that no corner or single fibre may be unequally loaded; but any thing beyond that is useless and dangerous.

Since, therefore, the apparent firmness of adhesion, produced by bolts and screws, does not communicate any real additional strength, and that an equal adhesion may be produced even by a wooden connection, the ingenuity of the carpenter is left more at liberty; and it may not be improper to inquire, whether stronger modes of adhesion are not to be found than those either of Fig. 17, or 18. It is unquestionable, that if the two surfaces of No. 2. were tabled together, the joint would be greatly stronger, and this can be done with very little, if any loss of wood; nay, the adhering parts near the ends of the joint being so near the edge, and of course so much farther removed from the neutral fibre, would render the assemblage stronger against a transverse strain than even No. 1. The tabling will be more perfect by lengthening the joint, that is, by making it more oblique. But there is a limit to that independent of the waste of timber; for when the distance between the alternate projections is so great, as to tear the fibre ere the connecting matter part, there can nothing be gained by increasing the surface of attachment. Fig 20. exhibits another method of piecing a beam, which will enable it to resist a considerable transverse strain; and, as a tie, it is at least as strong as any such form as Fig. 17. The lower piece is supposed to be oak, and by tightening the key above, its transverse strength is greatly increased. Duhamel has made many experiments on an assemblage somewhat similar to this, and has shown us, that this built beam of three pieces may, in some cases, be much stronger than an entire one. The ingenious carpenter will see, that the principle is capable of being applied in many other situations. As a tie, its chief value consists in taking hold of several plates of fibres. We may clap another such fish on the top, and so double the connection. But we have already said enough on this subject, which would require much more room than we can spare to treat of it completely. Hereafter we shall see, that much more powerful assemblages may be formed by framing. See the article Framing. (A. N.)

**Before we enter upon the consideration of this important subject, we must first lay before our readers a few preliminary problems of a geometrical nature, relating to angles, tangents, arcs of circles, elliptic, parabolic, and hyperbolic curves, circular and elliptic polygons, concentric ellipses, and other subjects which are absolutely necessary to a proper understanding of the art of Carpentry. From these preliminary problems, the reader will be naturally led to the Stereographical Principles of Carpentry, which are also of indispensable use in Architecture, Joinery, and Masonry.**

**BOOK I.**

**Preliminary Geometrical Problems.**

1. From a given point A, to draw a tangent to the arc of a circle BD, Fig. 1.

Join the centre C and the point A; on AC as a diameter, describe a semicircle CBA; draw BA, which is the tangent required.

2. From a given point A in an arc ABC, to draw a tangent, Fig. 2, without having recourse to the centre.

From the point A, with any radius, describe the arc DBE, and with the same radius from B, describe an arc at C; join AEC; make BD equal to BE, and draw AD, which is the tangent required.

3. To describe the segment of a circle, having the chord AB and the versed sine CD given in position, Fig. 3.

Produce DC to E, and make the angle AED equal to the angle EDA; from E, with the radius ED or EA, describe an arc ADB, which completes the segment.

4. To describe a segment by means of an angle, the chord AB and versed sine CD being given in position, Fig. 4.

Fasten two rods DE and DF together at D, so as to make the angle ADB, each rod not being less than the chord AB; fasten the rod GH to the other two so as to keep the angle ADB invariable: Having put a pin at A and another at B, bring the angle at D to A; then move the apparatus so that the rod DE may slide upon the pin A, and DF upon the pin B, until the point D arrive at B, and the point or pencil at D will then have traced out the arc ADB. This apparatus is rather cumbersome; in order, therefore, to perform the operation more conveniently, let the same data be given Fig. 5; join BD, and draw DE parallel to AB; make DE at least equal to DB; form a triangle BDE; put a pin at A and another at D; move the triangle round, keeping the side DE upon A, and the side DB upon D, until the point B arrive at A; and this will describe one half of the segment, the other half will of course be described in the same manner. In many situations it is very inconvenient, and frequently impossible, to find a centre. These two last methods are well adapted for this purpose, particularly the last, as it only requires half the distance at the ends of the chord that the former requires; but should there be no distance, or a very small space at the ends, the following method, by finding points, will then be most convenient.

5. The same things being given to find a number of points, in order to trace the path of the arc, Fig. 6.

Draw AE parallel to CD, and DE parallel to CA; produce DE to F; join AD, and draw AF perpendicular to AD: divide AC and FD each into the same number of equal parts; from the points of division 1, 2, 3, in FD, to the points of division 1, 2, 3, in AC, draw 1 a 1, 2 b 2, 3 c 3; also divide AE into the same number of equal parts; from the points of division 1, 2, 3, draw 1a D, 2b D, 3 c D, and trace the curve A a b c D, which will be the one half. The other half is found in the same manner.

6. To trace the curve of an ellipse through points, the transverse AB, and semiconjugate axis CD, being given, Fig. 7.

Take a slip of paper, the edge of an ivory scale, or a rod of any convenient length, and mark the distance g e equal to the semitransverse CA or CB, and the distance g f equal to the semiconjugate CD.

In DC produced, take any point e, and apply the point e of the slip to the point e; cause the slip to have an angular motion, until the point f fall upon the axis AB at f; then mark the point g on the plane of description, and the point g will be in the curve of an ellipse: in like manner all other points h, i are to be found. If AB and CD were produced, and f made to move in AB, the point g will describe the curve BDA, which will be a semicircle. This last method is the operation of the trammel.

7. The same things being given to find the curve, by another method by points, Fig. 8.

Draw DE parallel to CB, and BE parallel to CD; divide BC and BE proportionally at g and h; make CF equal to CD; draw 1 g h and f b D, and the point h will be in the curve. In the same manner may other points m, n be found. Perhaps to find the points m, h, n, it would be easier to some to divide the lines BC and BE each into the same number of equal parts.

8. The same things being still given to describe the representation with a compass, Fig. 9.

Take half the conjugate CD, which apply on the semitransverse from A to E; divide EC into three equal parts, and set one towards A from E to F; make CG equal to CF; with the distance FG describe an equilateral triangle GHK; produce HG to I, and HG to K; from H, with the distance HD, describe an arc IK; from G, with the distance GK, describe an arc KB, and with the radius IF describe an arc IA; and A D KB will be the curve of the semicircle required.

9. To describe the curve of a parabola, having the double ordinate AB, and abscissa CD given in position, Fig. 10.

Draw AH parallel to CD, and HD to AC; divide AC and AH in the same proportion at e and f;
draw $eg$ parallel to CD, and draw $fg$ D, the point g is in the curve of a parabola. In the same manner all other points $h, i$ are to be found.

10. To describe the curve of a hyperbola, having a double ordinate $AB$, and a diameter DE, given in position, Fig 11.

**Demonstration for the ellipse and hyperbola**, Fig. 12, 13.

Let $AB$ be the diameter, CD the ordinate, AC the abscissa, and $K$ a point in the curve.

Draw $KN$ and $gM$ parallel to $CD$, cutting $AC$ in $N$ and $M$.

Then because of the similar triangles $\triangle BNK, BCG \ldots BN : BC$, $AN : AM$, or $gE : NK : Mg, or CD$

And by construction $\ldots \quad gE : DE, or CA : CG : CD$

Therefore by multiplication we have $\ldots \quad BN \times NA : BC \times CA : NK \quad CD$

By similar triangles $ANK$ and $AMg \quad \ldots \quad AN : AM : NK : Mg, or CD$

By construction $\ldots \quad AM : AC : CG, or NK : CD$

By multiplication $\ldots \quad AN : AC : NK \quad CD$

The property of the parabola.

11. Upon a given straight line $AB$, to describe any regular polygon, Fig. 15.

Produce the side $AB$ to $H$, on $AH$, as a diameter, describe the semicircle $ACH$; divide the semicircumference $HCA$ into as many equal parts as the polygon is to have sides; draw $BC$ through the second division; bisect $AB$ at $K$, and $BC$ at $L$; draw $KL$ at right angles to $AB$, and $LI$ at right angles to $BC$; from $I$, with the distance $IA$, $IB$, or $IC$, describe the circle $ABCD$, &c. to $A$, which will contain the side $AB$ the number of times required.

12. To cut off the angles of a square $ABCD$, so as to form an octagon, Fig. 16.

Draw the diagonals $AC$ and $BD$, intersecting each other at $E$; through $E$, draw $FG$ and $HI$ parallel to the sides; make $EI, EC, EF, EH, EF$, each equal to any half diagonal $ED$; join $IF, FH, HG$, and $GI$, cutting the sides of the square at $P, Q, R, K, L, M, N$, $O$; join $KL, LM, MN, NO, OP, PO, QR, RK$, and $KLMNPQ$ will be the octagon required.

13. To inscribe an octagon in a square $ABCD$, having four of its angles in the middle of the sides, Fig. 17.

Draw the diagonals $AC$ and $BD$, cutting each other at $E$; through $E$, draw $FK$ and $HM$ parallel to the sides, cutting the sides of the square in the middle at $F, H, K, M$; make $EG, EI, EL, EN$, each equal to the half side of the square; join $FG$, $GH, HI, IK, KL, LM, MN, NP, FG, and FG$ $HIKLMN$ will be the octagon required.

14. To cut off the angles of an oblong $ABCD$, so as to form an elliptic octagon, Fig. 18.

Draw the diagonals $AC$ and $BD$, cutting each other at $E$; draw $FG$ and $HI$ parallel to the sides; make $FU$ and $AK$ each equal to $FA$; and join $UK$ and $AU$; make $UM$ equal to $UF$; draw $ML$ parallel to $FK$, cutting $AD$ at $L$; make $FT$ equal to $FL$, and $GP$ and $GQ$ each equal to $FL$; draw $LN$ and $QR$ parallel to $DB$; $PO$ and $TS$ parallel to $AC$; then will $LNOPQRST$ be the elliptic octagon required.

15. In a given oblong $ABCD$ to inscribe an elliptic octagon, Fig. 19.

Draw the diagonals $AC$ and $BD$, cutting each other at $E$; make $IK$ equal to $IB$, and join $KB$, cutting $FG$ at $L$; make $EM$ equal to $LB$, and $EN$ equal to $KB$; $OG, GR, RH, HQ, QF, EP, PI, TO, and OIPFQHRGQ$ will be the elliptic octagon required.

16. Through a given point $K$, to draw the circumference of an ellipse concentric with a given ellipse $ABCD, EFGH$, Fig. 20.

Let $I$ be the centre; take any number of points $A, B, C, D$, $E, F$, $G, H$, in the circumference of the given ellipse; draw the semidiameters $AI, BI, CI, DI, EI, FI, GI, HI$, and the chords $AE, BC, CD, DE, EF, FG, GH, HA$; parallel to these draw $KL, LM, MN, NO, OP, PO, QR, MO$, and $KLMNOPQR$ to $K$ draw a curve, which is the ellipse required.

17. About a given rectangle $ABCD$, to inscribe an ellipse which shall have its axis parallel to, and in the same proportion as the sides of the rectangle, Fig. 21.

Draw the diagonals $AC$ and $BD$, cutting each other at $N$; through $N$ draw $EF$ and $GH$ parallel to the sides of the rectangle; produce $GH$ to $K$, making $IK$ equal to $IA$, or $IB$; join $KA$ and $KB$; from $K$, with the distance $KI$, describe the arc $LI$, cutting $KA$ at $L$; draw $LM$ parallel to $HG$, cutting $AC$ at $M$; join $MO$ and $MI$, draw $AH$ parallel to $MI$, and $AE$ parallel to $MO$; make $NF$ equal to $NE$, and $NG$ equal to $NH$; then $EF$ is the transverse axis, and $HG$ the conjugate, by which the required ellipse may be described.

18. To find the figure of the sines to any given height, Fig. 22.

Describe a semicircle $ABC$, to a given height; divide the quadrant $AB$ into any number of equal parts by the points $1, 2, 3$; make $DE$ equal to $A1$, $DF$ equal to $A2$, $Dg$ equal to $A3$, and $DH$ equal to $A4$; draw the ordinates $ei, f k, g l, HI$, also the
This Figure is very frequently required in architecture. The coverings of cylinders, and domes of every species, are of this form. It may be drawn to any given proportion, by dividing a quadrantal arc into any number of equal parts, and the half base into the same number of equal parts, and taking the ordinates as ordinates in the Figure.

19. To construct a trapezium equal and similar to a given trapezium, Fig. 29.

Let No. 1. be the given trapezium, which divide into two triangles ABC, ACD, by a diagonal AC; make the triangle ABC, No. 2, equal to the triangle ABC, No. 1. (Euclid, book i. prop. 23.) and the triangle ACD, No. 2, equal to the triangle ACD, No. 1; then will the trapezium ABCD, No. 2, be equal to the trapezium ABCD, No. 1.

In this manner may any rectilinear figure be made equal and similar to any other given rectilinear figure, by resolving the given figure into triangles, and constructing these one after the other in the successive order of their contiguity, until all the triangles of the original figure have been constructed in the required figure, and the result will be a polygon equal and similar to the given figure.

20. To construct a rectilinear figure similar to a given rectilinear figure ABCDEFGH, Fig. 24, having one of the sides of the required figure corresponding to a side of the given figure.

Make A b, No. 1, equal to the side of the required figure corresponding to AB, the side of the given figure; draw the diagonals AC, AD, AE, AF, and AG; make bc, cd, de, ef, fg, and gh, respectively parallel to BC, CD, DE, EF, FG, and GH, from one diagonal to the other. By the last problem construct the rectilinear figure abcedfg+a, No. 1, similar and equal to the rectilinear figure abcedfg+a, No. 1; and abcedfg+a, No. 2, will be equal and similar to ABCDEFGH, No. 1.

By means of these problems, it will be easy to adapt a piece of framing to any place required.

21. Given two lines AB, CD, inclining towards each other, to draw a line from a given point A in one of them, so as to make equal angles with both lines, Fig. 25.

Through A draw EF parallel to CD; bisect the angle BAF by AC, and the angles BAC and DCA will be equal.

BOOK II.

Stereographical Principles of Carpentry.

Stereography is that branch of knowledge which demonstrates the properties, and teaches the whole doctrine of regularly defined solids. It explains the rules for constructing the supericies in plano, so as to form the entire solid, or to cover its surface. It also shews how to form any section thereof, or to find any angles or inclinations relating to two or more of its surfaces; or any angles upon any one of its surfaces, formed by a sectional line and adjacent side of the surface, by having the proper data given according to what may be required.

Mr. Hamilton has denominated the principles of perspective by the term stereography, contrary to the usage of other authors. Perspective is only a branch of the doctrine of solids; and all that this branch teaches, is only the methods for finding the sections of pyramids and cones, the eye being considered as the vertex, the original object the base of the pyramid or cone, and the picture to be drawn a section thereof; the term is therefore of too general application, perspective being only a branch of stereography.

The eleventh and twelfth books of the Elements of Euclid belong to stereography; these may be looked upon as the theory of the doctrine of solids, and to them we shall refer our readers for the original properties; but for their practical applications to useful properties in life, it is rather singular that so little has been done in this respect. The present article is entirely new. It is of the greatest importance in the various mechanical departments of architecture. The geometrical principles in masonry, carpentry, joinery, and the other useful branches of the building art, are entirely dependent upon it; in short, the cutting of individual pieces of timber in the art of carpentry, and the formation of separate stones in masonry, is only the application of stereography to practice.

To the acquirement of these arts this branch of geometry is therefore indispensable; and, as it is a key to the whole, no farther apology for its introduction is necessary.

DEFINITIONS OF SOLIDS, AND THEIR PROPERTIES.

A prism is a solid, the ends of which are similar Prisms and equal parallel plane figures, and the sides parallelograms; and if the ends of the prism are perpendicular to the sides, the prism is called a right prism, but if otherwise, it is termed oblique: If the sides and ends are equal squares, the prism is called a cube; and if the base or ends are parallelograms, the prism is called a parallelopiped: If all the planes of the parallelopiped are at right angles to each other, then the prism is called a rectangular prism: If the ends of the prism are circles, the prism is called a cylinder; but if they are ellipses, it is called a cylindroid.

All the sections of a cylinder, or cyllindroid, are either circles, ellipses, or parallelograms, excepting when cut partly through the sides, and partly through the ends, and then they are portions of circles or ellipses.

All parallel sections of a prism are equal and similar polygons.

All sections whatever, except partly through the base, and partly through the sides of a parallelopiped, are parallelograms.

All sections of a cylinder, or cyllindroid, through the curved surface, are either ellipses or circles; and all sections parallel to the axis are parallelograms.
A solid having any plane figure for its base, and its sides triangles, meeting in a common point, is called a pyramid; and this point is called the vertex of the pyramid. A pyramid is denominated triangular, square, pentagonal, hexagonal, &c. If the base be a circle, the pyramid is called a cone.

The axis of a cone is a straight line, extending from the centre of the base to the vertex.

Properties.

All parallel sections of a pyramid are similar figures, except they be parallel to a plane within the pyramid, passing through the vertex.

All sections through the vertex within the pyramid are triangles.

All sections of a cone parallel to the plane, passing through the vertex without the cone, but not parallel to the base, are ellipses.

All sections of a cone parallel to the base are circles.

All sections of a cone parallel to a plane touching the curved surface are parabolas.

All sections of a cone parallel to a plane within the cone, passing through the vertex, are hyperbolas.

The frustum of a pyramid, or cone, is that which is left by cutting away the part which contains the vertex by a plane parallel to the base.

An ungula of a pyramid, or cone, is that which is left by cutting away the part which has the vertex, by a plane not parallel to the base.

A CUNIUS is a solid, the base of which is a rectangle, and the four sides joining the base plane surfaces; two sides, and the other two parallelograms.

The cunoid, or cono-cunius, is a tapering solid, such that the base is a circle, or ellipse, and the vertex a straight line, parallel and equal to the diameter of the base; the curved surface such, that if a plane be supposed to pass through the middle of the vertex and the centre of the base, and a straight line be continually applied while in motion to the circumference and the vertex so as always to be parallel to the plane, until the straight line so applied has gone entirely round the circumference of the base.

Properties.

All sections of the solid parallel to the plane, as well as that in the plane, are triangles.

All sections passing through the vertex are parallelograms.

All sections parallel to the base are ellipses, except one, which is a circle.

If the vertex be in a plane, passing through the centre of the base, perpendicular to the said base, and the straight line drawn from the centre of the base to the middle of the vertex be also perpendicular to the base, the cunoid is said to be right, but if otherwise oblique.

A PRISMOID is a solid, terminated by two dissimilar rectangular ends, and the remaining surfaces joining the ends planes.

A SPHERE is a solid, such that all lines drawn, or conceived to be drawn, from a certain point within the solid to the surface, are equal.

Property.

All the sections of a sphere are circles.

A SPHEROID is a solid, formed by the revolution of a semi-ellipse about one of the axes.

If the spheroid be generated round the greater axis, it is called an oblong or prolate spheroid.

If the spheroid be generated round the lesser axis, it is called an oblate spheroid.

PROB. I. Given the altitude of any three points above a plane, and the seats of the three points on that plane, to find the intersection of another plane passing through the points, with the plane which contains the seats of the three points.

Let A, B, C be the seats of the three given points.

Join any two points A and C; draw AD and CE each perpendicular to AC; make AD equal to the height of the point on A, CE equal to the height of the point on C, and join ED; produce ED and CA to meet each other at I; make CE on the line CE equal to the height on B; draw FG parallel to CA, cutting ED at G; and draw GH parallel to EC, cutting AC at H; join HB, and draw KI, parallel to HB, through KL, will be the intersection required.

In Fig. 1. the distance CF is greater than AD, but less than CE; this makes the point G fall between the points D and E, and the point H between the points A and C. In Fig. 2. CF is greater than CE; this makes the point G fall on DE produced, and the point H on AC produced. In Fig. 3. HG is less than AD, which makes the point G fall between D and I, and the point H between A and I.

These three diagrams are particularly useful in the covering of solids, in the sections of cylinders and prisms, and in the finding of the face moulds for the hand rails of stairs, and in groins where the planes of the angle ribs stand at oblique angles to the plan, and where the section passes through three given points. Fig. 1. and 2. are also useful in the sections of solids, when the angle which the vertical side makes with the inclined side is given.

SOLID ANGLES.

Of the Construction of Solid Angles, consisting of any three Plane Angles.

In these, besides the three plane angles, there are also to be considered the three inclinations of the
planes; so that in a solid angle there are six parts, any three of which being given, the other three may be found. Solid angles are either right angled or oblique: when they are right angled, two of the planes form a right angle with each other; and this is the only case necessary to be considered, as all the cases of oblique solid angles can be solved by the help of those which are right angled. The planes containing the right angle are called legs; the plane subtending the right angle, the hypotenuse; and the three inclinations, angles.

**Prop. II.** In a right angled solid angle are given the two planes ABC and ABD, containing the right angle to find the hypotenuse, and the angle contained by the hypotenuse and the leg-ABD.

In AB take any point A; draw AC at right angles with AB, and ADE with right angles with BD; make BE equal to BC, and BE will be the hypotenuse; from AB cut off AF equal to AD, and join FC, and AFC will be the angle required.

For if the plane ABD be raised upon AB, at a right angle with the plane ABC, and the plane ACF turned up on AC until AF coincide with AD, and, lastly, the plane DBE turned round the line DB until BE fall upon FC; then BE will fall upon BC, and FC will be at right angles to BD, and consequently AFC will be the inclination of the planes.

**Prop. III.** Given one of the legs, and the angle opposite, to find the other leg.

Let ABC be the given leg; make ADC equal to the given angle; from the point C draw CA at right angles with AB; from A, with the radius AD, describe the arc DE, and draw BE a tangent to the arc at E; then will AB be the other leg required.

By these problems, the various levels in roofing are ascertained, as the backing of the hips, and the side joints of purlins and jack rafters; and in hand-railing, the spring of the plank, and the intersection of the plane of the plank with a horizontal plane.

**Prop. IV.** In a right angled solid angle, consisting of three plane angles, are given one of the legs and the adjacent angle to find the hypotenuse.

Let ABC be the given leg; from any point A draw AD perpendicular to AB; make the angle DAE equal to the adjacent angle; from A, with any radius AD, describe the arc DE, cutting AE at E; draw DF and EC parallel to AB; and draw CF parallel to AD, and join F, B, and FBA will be the hypotenuse.

**Prop. V.** In an oblique angled solid angle, consisting of three plane angles, are given one of the sides, and the two adjacent angles, to find the other side.

Let ABC be the given side; in AB take any point A, and draw AD perpendicular to AB; make the angle DAE equal to one of the given angles; draw EK and DL parallel to AB, the former cutting AD at M, any where in CB, or in CB produced take any point F, draw FG perpendicular to CF, and make the angle GFI equal to the other given angle; produce CF to H, and make FH equal to ME; draw HI parallel to FG, IK parallel to BC, and KL parallel to AD; join BL, and ABL is the side required.

The applications of these problems are numerous, in cutting timbers to fit at any angle against another; likewise in oblique stone arches, which have cylindrical or cylindroidal intradoses, in cutting the sides of the bevels of the stone to the given angles. In these, a series of bevels may be found, which will have one side common, while the other side of each is only varied in the most easy manner. If the arch stand in a vertical wall, the constant angle will be a right angle; but if otherwise, it will be acute or obtuse: Thus, suppose AB, Fig. 8, to be the line of an erect wall upon the ground, and CD the direction of the arch; or, let AB be the intersection of any plane, and CD the direction of a prismatic piece of timber, consisting of several sides, to be cut so as to fit against the plane: Suppose ECF, ECG, ECH, &c. to be the angles which the several beds make with each other, in a plane perpendicular to the sides of the arch, or the angles which a series of planes would make at the same intersection, parallel to the sides of the same prism; then CD, CDg, CDh, &c. are respectively the angles which two adjoining sides of the beds make with each other, or the angles which the several arrises of the prism make with the sides of the end to be cut. In like manner, Fig. 9, shows a series of angles when the plane inclines or reclines; each is to be found in the same manner as in Fig. 7. the angles Dg, DCg, DCh, &c. corresponding with EDT, EDG, EDH, &c. In Fig. 8, it will be only necessary to find the angles on one side; but in Fig. 9, they must be found on both sides.

**Prop. VI.** The base and one of the planes of a prism being given, to find the section of the prism oblique to the base, but at right angles to the plane of the side given, the line of inclination being given in position upon the given side of the prism.

Place the base contiguous to the given side of the prism, so as to join to their common side, or line of concourse, or line of junction; take as many ordinates in the base as may be thought sufficient, and produce them to the line of inclination; from the intersected points in the line of inclination draw perpendiculars, which make equal to their corresponding ordinates in the base; and if the points in the base where the lines proceed are the junctions of straight lines, join every two adjacent points by straight lines, and the section will be formed; or, if the points proceed from a curve, a curve must be traced through the points found in the section.

**Examples.** In Fig. 1, the base ABCD being a plane rectangle, the two sides AE and BF of the given CXVI. plane in a straight line with AD and BC, two of Fig. 1. the sides of the base answer the purpose of ordinates, and therefore we have only to complete the section to the length of the inclination EF, and to the breadth BC or AD of the base.

In Fig. 2, the base is bounded by several straight lines; and therefore every two contiguous points in the section are also joined by straight lines.

In Fig. 3, the base is the arc of a circle, therefore the remaining boundary of the section must be a curve passing through the several points: The section here is the segment of an ellipse.

**Prop. VII.** To find the section of a prism, the base and one of the adjoining planes being given, also-
Sectional line on the given plane, and the angle which the common side makes with the line of intersection of the prism.

Produce the line of concourse BA, and the sectional line CD, till they meet in E; make the angle BEF equal to the angle which the section line is to make with the line of concourse; from any point F in EF draw FG perpendicular to EB, cutting EB in G, and GH perpendicular to EC, cutting EC at I; from E, with the distance EF, describe an arc cutting GH at H, and join EH; in the boundary of the base take any point k; draw kl parallel to EF, cutting AB, or AB produced at l; draw lm parallel to the side BC of the plane, cutting CD at m; draw mn parallel to EH; make mn equal to lk, and n will be in the boundary of the section required: In the same manner all other necessary points are to be found.

Examples. In Fig. 4, the base being a rectangle, the determination of the point k corresponding to one of the angles is sufficient; for being joined to the point C in the opposite side, two contiguous sides of the section will then be formed: The whole section will be inclosed by drawing the other two sides parallel to these sides.

In Fig. 5, the base consists of straight lines, and therefore the ordinates are taken from the angles, and the points found in the section joined by straight lines.

In Fig. 6, the base is wholly a curve, excepting the line of concourse; therefore drawing a curve through the points found in the section completes the boundary or inclosure.

**CONIC SECTIONS.**

**Prob. VIII.** To find the section of a cone cut by a plane at any given inclination to the axis, or in a given position to the sides of the cone, Fig. 7 and 8.

Let ABC be a section of the cone through the axis; ABD the half base, and let MN be the position of the axis of the section, in respect to the side AB of the cone; now, to find any point in the curve, take any point D in the circumference of the base; draw DE perpendicular to the diameter AB, cutting it at E, and EC cutting MN at g; draw gh parallel to AB, and gi perpendicular to MN; make EF equal to ED; draw fh parallel to BC, make gi equal to gh, and f is a point in the curve. In like manner all other points k and l are to be obtained, and thus the curve may be completed by tracing it through the points.

In Fig. 7, MN, the axis of the section, cuts the other side BC of the cone; and the section produced from this position is an ellipse. In Fig. 8, the axis MN is parallel to the side CB of the cone; and the section produced is therefore a parabola. In the same manner the hyperbola may be found; it is only fixing upon the position of the axis.

**CUNIODAL SECTIONS.**

**Prob. IX.** To find the section of a cunoid cut by a plane perpendicular to the axis triangle.

Let ABC be the axis triangle, ADB the half base, MN the axis of the section. In the circumference of the base take any point D; draw DE perpendicular to AB, cutting it at E; join EC, cutting MN at f; draw fg perpendicular to MN; make f = E; g = E; h, i, k, &c. are obtained.

**Prob. X.** To find the section of a cunoid, cut obliquely to the axis section ABC, through two given points X, Y, on the sides of the axis triangle, and any point on the surface, the seat of which is being given on the axis section at Z.

Draw CZD, cutting the diameter of the base at D; draw DE perpendicular to AB, cutting the circumference at E; join XY, and draw FZG parallel to XY, cutting AC and BC at F and G; draw FH perpendicular to FG; produce YZ to K; make KH equal to DE, and draw HI parallel to KY or FG. To find any point in the curve, from any point L in the circumference of the base, draw LM perpendicular to AB, cutting AB at M; join MC, cutting FG at o, and XY at n; make HP equal to F0; join pN; make Kq equal to ML, and draw qr parallel to XY, cutting qn at r: then r is a point in the curve. In the same manner all other points s, t, &c. are found.

The following is a general method of finding the sections of all solids, the surfaces of which are formed by straight lines constituted according to any given law. When cut by a plane, the intersection and inclination of which are given to the plane of the base of the solid; also the inclination of the axis, and the seat on the said base, in position to the intersection.

In the consideration of this subject, there are three angular planes concerned. Two of these are perpendicular to each other; and the third joining the other two, forms a right angled solid angle, the last plane being the hypothenus, and the former two the legs. The base of the object, the section of which is required, is given on one of the legs, and this plane is called the original plane, and all lines drawn in it whatever are called original lines. The hypothenus plane is that which forms the section, and is called the plane of projection, or sectional plane. The third plane, which is the remaining leg, is called the directing plane. The directing plane is always parallel to the axis, or principal elevated line of the solid. The section of the solid is likewise called the projection. In finding the projection or section, the sides of the solid angle are all extended on the same plane. The line of concourse of the original and projecting planes is called intersection. As the two sides and hypothenus are in contiguity when spread out on a plane, the side of the original plane, and the projecting plane which join each other, will be separated, that is, what has been called the intersection; to distinguish the one from the other, the side of the original plane which meets the projecting plane is called the intersection, and the side of the projecting plane which meets the base the co-intersection. The intersection of the vertical plane with the original plane is called the director; and the intersection of the plane of projection, and the directing plane, is called the directing line. Thus in Plate CXVII. Figs. 1, 2, 3, 4, ABC is denominated the original plane, ABD, the directing plane, DBC CXVII, the sectional plane, or plane of projection, or project.
If the object, the section of which is required, be a pyramid or cone, and a plane be supposed to be drawn through the vertex parallel to the base, until it intersect the projecting plane, the line of intersection is called the vanishing line.

The inclination of the sectional plane and the intersection, and the seat of the inclination of the object, the section of which is required, being given, the director AB may be any line parallel to the seat of inclination. To determine the directing plane and the sectional plane, proceed in Fig. 3, thus: Let ABC be the original plane, BC the intersection, AB the director. From any point C in BC, draw CA perpendicular to BC, and AB perpendicular to CA. Make the angle ACg equal to the inclination of the sectional plane. Draw AD perpendicular to AB, equal to Ag join DB, and ABD is the directing plane. From B, with the distance BC, describe an arc at F, and from D, with the distance GC, describe another arc, cutting the former at F. Draw BF, and DBF is the sectional plane.

In the projection of solids in general, the nature of the solid, or its elementary construction, must be considered. Suppose the solid to be a pyramid or cone, and a plane to pass through its axis until it meet the directing plane, the original plane, and the plane of projection. Place the height of the pyramid on the line where this plane meets the directing plane, and let this line be called the director of the axis. Let a line be supposed to be drawn from the upper end of the director of the axis to the vertex of the pyramid or cone; this line will be parallel to the original plane, and in the same plane with the line formed on the original plane, by the aforesaid plane passing through the axis. Suppose any number of planes to pass through this line, to any number of points in the base of the solid, to cut the original plane, the directing plane, and the sectional plane; the intersections of the several planes thus drawn, will form parallel lines on the original plane, converging lines from the intersections of the parallel lines to the summit of the directing axis, and lines will also be formed on the sectional plane, meeting the parallels on the original plane at the intersection at one of their extremities, and the converging lines at the points where they meet the directing line at the other extremity. The planes which thus generate these three sets of lines, will cut the surface of the solid in straight lines passing through its vertex. Again, if there be taken another directing axis, and another set of planes be supposed to pass through the line which extends between the apex of this axis and that of the pyramid or cone, and through the several points taken before in the base of the object, three other sets of lines will be formed in the same manner, and will cut the sides of the pyramid or cone in the same intersections as at first; also the last set of lines in the plane of projection will intersect the former in the very same points, as lines drawn from the several points in the base of the object before taken to its vertex. If the section required be that of a prism, draw the plane parallel to the inclination of the prism, instead of planes intersecting each other on the line joining the apex of the pyramid or cone, and the top of the apex line. The following problems, in particular examples, will illustrate these general descriptions and definitions.

Prob. XI. To find the section of a pyramid, placed with one of its sides parallel to the intersection.

Let the parallelogram IFGH be the base of the pyramid, with the sides FI and GH parallel to CB; draw the diagonals GI and FH intersecting at K, and produce FG and IH to the intersection at O and Q, and draw KP parallel to them, meeting the said intersection at P; make Bq, Bp, Bo, respectively equal to BO, BP, BO; produce FI and GH to cut AB at M and N, and draw KL parallel to them, cutting AB at L; draw LR, making an angle with AB equal to the angle which the axis or line from K to the vertex makes with the plane of the base; make LR equal to the length of the said axis; draw RD parallel to AB, cutting BD at D; draw TDU parallel to BE, then LR will be the director of the axis, and TU the vanishing line; draw MM, LL, Nu towards R, cutting BD at n, l, m, and also draw mf, lk, nh g parallel to BE; make Lk equal LK; draw pk, and produce it till it meet TU at S; draw og f S and qhi S, and fg hi will be the projection of FGH, or the section of the pyramid, the base of which is FGH. The reason why mf, lk, nh g are drawn parallel, is, because that any section made by a plane through any line on the original parallel plane to the intersection, will cut the sectional plane also parallel to the intersection.

Prob. XII. To find the section of a pyramid, when Fig. 9, the base stands at oblique angles to the intersection.

Let the rectangle FGH be the base; produce I'H and FG to Q and S; FI and GH to N and P in the intersecting line; through K, draw LR parallel to FG or IH, cutting AB at L, and CB at R; also through K, draw KM parallel to the intersection CB, cutting AB at M; draw MM, making the same angle with AB as the axis makes with the original plane. Draw mk parallel to BE; make mh equal to MK; draw KO parallel to FN, cutting CB at O; make Bn, Bo, Bp, Bq, Br, Bs each respectively equal to BN, BO, BP, BQ, BR, BS; draw rk and ok; draw Lu parallel to MM, and make Lu equal to the length of the axis of the pyramid; draw uD parallel to AB, cutting BD at D; draw VW parallel to BE; produce rk and ok to V and W; draw ag f V, qhi V, also ph g W, ni f W: Then will fg hi be the section of the pyramid required.

From what has been now said, Figs. 4. and 5. will Fig. 4. be understood, and may be described in the same words as in Fig. 1; only it is to be observed, that the different points in a cone are formed in the same manner as the angles, and as many as may be thought necessary for tracing the curve. Fig. 4. shows the section, when the axis of the cone stands perpendicular to the plane of the base; and Fig. 5. for a cone which has its axis inclined to the base.

Prob. XIII. Given the seat D of the vertex, the intersection AC of a triangular plane, also the
Constructive
Carpentry.

**Fig. 5.** Draw DG perpendicular to EF, cutting EF at G, and draw DH perpendicular to DG, make the angle DGH equal to the inclination of the cutting plane; produce GD to I; make DI equal to the perpendicular altitude of the triangle; produce HD to meet AC in K; join KI; draw DB perpendicular to AC; from K, with the distance KI, describe an arc cutting DB at B, and join BA, BC, and BK; make DL equal to DH; draw LM parallel to DK, cutting KI at M; from KB cut off KN, equal to KM, and produce CA to E; draw ENO, cutting BC at O; then OP is the section required.

**Fig. 6.** The seat A of the vertex and base BCDE of a rectangular pyramid, and the intersection FG, of a sectional plane being given in position, and the height of the pyramid in quantity, to determine the lines of section made on the sides of the pyramid by the sectional plane.

Proceed as in the last problem, and find the section of each triangle, which will be the same as the sections of the sides of the pyramid required. It may here be observed, that one triangle HKI will serve for the whole instead of D1K, and the two sides BE and DC, which do not meet HI, must be produced till they meet it, and all the intersections must be drawn to K, as in Fig. 5.

**Fig. 7.** Given the base ABCDEFA of an erect prism, and the intersection HI of a sectional plane, and the inclination of this plane to find the sectional lines on the sides of the prism.

Draw lines GH, GL, and GI, parallel to the sides of the prism, till they cut the intersecting line; draw GK perpendicular to HI, meeting it at K, and GP perpendicular to GK; make the angle GKP equal to the inclination; make GM, GN, GO, each equal to GP; draw MH, NL, OM, GMH, GNL, GOI, are the angles which the sectional lines make with the lines of concourse of the angles.

From what has now been said, Fig. 8. will be plain to inspection. It only differs from the last, in the base being a square.

**Fig. 8.** Any three points being given on the surface of a cylinder, to find an envelope that would coincide with a section passing through these three points, and over the surface of the segment of the cylinder, between the two straight lines drawn on the surface, through the two most remote points parallel to the axis, the seat of the three points, which are the points of the section being given on the base.

This will admit of three different cases. Let Fig. 1. be the cylinder, and let the points be B, D, F; draw BA, DC, and FE parallel to the axis cutting the base at A, C, E; then A, C, and E are the seats of the three points, and ACEFDBA is the portion which requires the envelope.

Now, suppose the cylinder to be cut by a plane ABFE, which will be parallel to the axis, besides the plane of the section BDFGH; then the plane ABFE may cut the plane of the section through the three points at right angles, or the plane ABFE may form an acute angle with the plane BDFA, or any obtuse angle with the said part according to the situation of the point D.

In the general description, it will only be necessary to have the seats of the three points given on the base, and the heights of the points on the cylinder from their seats. Let ABC, Fig. 2, 3, 4, be the part of the base of the cylinder, and A, B, C, the seats of the three points. Join AC; draw CE, Fig. 2, 3, 4, and AD perpendicular to AC; make AD equal to the height of the point above A, CE equal to the height of the point above C, and CF equal to the height of the point above the seat B; join ED; draw FG parallel to CA, and GH parallel to EC or DA, cutting AC at H, and join HB; produce AC to I; divide the curve ABC into any number of equal parts, and extend these parts upon CI; through the points of division in the curve ABC, draw lines parallel to BH intersecting AC; from the points of intersection in AC, draw lines parallel to GH to meet DE; from the points of meeting in DE, draw lines parallel to AC; and from the divisions in CI, draw lines parallel to CE, so as to intersect the other parallels last drawn, the one continually nearer to CI and more remote from CE than the last, and draw a curve EK the envelope required.

Fig. 1. is the case where the rectangular plane makes a right angle with the elliptic section; Fig. 2, that where the angle made by the rectangular plane and the elliptic section is acute; and Fig. 3, the case where the angle formed by these two planes is obtuse.

In Fig. 3. and 4. DME is the orthographical projection of the curve, with which the curve line EK of the envelope would coincide: This is found by drawing parallels to GH through the points of division in the curve ABC, to meet the parallels of AC, as shown by the dotted lines.

Coverings of Solids.

**Fig. 17.** To cover any portion of the surface of a cylinder, cut by any two oblique sections at right angles to an axial plane, given the inclination of the cutting plane to the axis; so that the envelope, or covering, will exactly cover the surface of the cylinder terminated by the sections.

Let that part of the axial plane intercepted by the two oblique sections, and one or both sides of the cylinder, be denominated the seat of the envelope; and suppose the cylinder, or portion of the cylinder, to be cut by a plane at right angles to the axis, the intersection of this and the axial plane will either fall within the seat of the envelope or its plane produced; again, let the arc of the section at right angles to the axis, be called the regulating arc; the section itself, the regulating section; the base of the said section on the axial plane, the primary abscissa; and the regulating arc extended in a straight line, the secondary abscissa; and all lines at right angles to the primary abscissa, terminated by the sides of the seat of the envelope, ordinates.

The method of finding the envelope will then be
as follows: Take any convenient straight line for the primary abscissa as a base, and describe the regulating section; describe the seat of the envelope in position to the primary abscissa; divide the regulating arc into any number of equal parts; extend the parts on any convenient straight line for the secondary abscissa; draw lines through the points of division in the regulating arc, at right angles to the primary abscissa, so as to cut both sides of the seat of the envelope; through the points of division, in the secondary abscissa, draw lines at right angles to the said abscissa; then taking the ordinates of the primary abscissa and placing them from the secondary abscissa on the indefinite peripherals, their extremities will give the points through which the curves or sides of the envelope will pass.

Examples. Let ABCD, Fig. 5. No. 1, represent the quarter of a cylinder ABE, a section at right angles to the axis projected on a plane, orthographically, with its axis parallel to the said plane; let the right angled triangle AFB represent a part to be covered. In this case, AB and BF form a right angle; make ABC, No. 2, equal to AFB, No. 1; then ABC will be the seat of the envelope, AB the primary abscissa, and also a side of the seat of the envelope. Make ABD the regulating section of the quadrangular cylinder; divide the regulating arc BD into any number of equal parts; from the points of division draw lines perpendicular to AB; continue these lines to meet AC; take the equal parts of the arc BD and extend them on the secondary abscissa BC; draw indefinite peripherals to BE; take all the ordinates from the seat of the envelope, beginning with BC, and place them respectively on the indefinite peripherals from the secondary abscissa BC, and through the extremities draw the curve CE, then will BEC be the envelope required.

Let the obtuse angled triangle, $d e f$, No. 1, represent the part to be covered; make AEF, No. 3, equal to $d e f$, and AFC is the seat of the envelope: produce CF to B, and draw AB, forming a right angle with BC. Upon AB describe the regulating section ABD: divide the arc BD into any number of equal parts; from the points of division draw perpendiculars to AB; produce the perpendiculars to meet AC; extend the parts of the arc BD upon BE; from the points of division draw the indefinite peripherals; take the ordinates from the seat of the envelope contained between AB and AF, beginning the first with BC, and apply them respectively as ordinates to BE. Again, take the ordinates in the seat of the envelope contained between AB and AC, beginning with BC, and apply them respectively as ordinates to BE. Through the extremities of the first set of ordinates, draw the curve FE; and through the extremities of the second set, draw the curve CE; then will FCE be the envelope required.

Again, let the acute angled triangle, $g h i$, No. 1, represent the part to be covered: it may be shown in the same words, and by the same letters of reference, that FCE, No. 4, will be the envelope for the surface $g h i$, No. 1.

In the same manner, it may be shown, that $f e h c$, Fig. 6. No. 2, is the envelope for that part $e f g c$. Fig. 6. No. 1, of the semicylinder ABCD, BE being the stretch out of BDA, and AFC the seat of $f g C e$.

Nothing can be more useful in geometrical lines than the method of describing the envelope of any portion of a cylinder. By this method we are enabled to describe the soffits of the intradoses of any arched aperture; to find the exact situation of a line on the curved surface of any rib line that would stand vertically over any given line as a seat, whatever be the form of the line which constitutes the seat. The covering of domes with boards is exactly the same as in Fig. 5. No. 4. The dome, even though spherical, may be supposed to be constituted of a number of cylindroid pieces, each forming an isosceles triangle on the base. In this case, the part to be covered will be contained between two oblique planes, making equal angles with the axis of the cylinder: the quadrant ABD may be considered as a section of the dome through the axis; and the envelope CEF one of the boards, which, when found, is a mould for all the rest. Having a clear understanding of these several diagrams, it cannot be difficult to form an idea how to cover any portion of a cylinder, whether bounded by parallel planes or by any curved section whatever. The falling moulds of the hand-rails of stairs are to be considered as the envelope of certain portions of cylinders.

Pr. XVIII.—To cover the surface of a semicylindroid, contained between two parallel planes, CXVIII. given the regulating section and the seat of the envelope.

Let the regulating section be ABC, and let CDEF Fig. 7. be the seat of the envelope: divide the regulating arc ABC into any number of equal arcs; extend these arcs on the straight line AH: draw lines through the divisions of the arc ABC, at right angles to AC, producing them till they meet EF. Through the points of division in AH draw indefinite ordinates: take the respective ordinates contained between AC and DC, beginning with AD, and apply them successively from AD towards H; and through their extremities draw the curve DH. In like manner, take the ordinates contained between AD and EF, and apply them in the same order on the indefinite ordinates of AH, and draw the curve EG; then will DEGH be the envelope required.

Pr. XIX.—To cover the portion of the surface of a semicylinder contained between two other cylindrical surfaces, which have their axes passing through that of the semicylinder, and to the plane of the said semicylinder, Fig. 8.

The method of proceeding with this is exactly the same as in the former cases, and may be expressed in the same words. It may only be observed, that as the seat is alike on both sides, by finding one half of the envelope the other will be given.

Pr. XX.—To find the envelope for the frustum of a semicone, Fig. 9. Let ABCD be the seat of the envelope; AEB the end of the frustum or regulating section; continue AD and BC till they meet in F, from F, with the radius FA, describe the arc AH; and with the radius FD describe the arc DG: make the arc AH equal to the arc AEB, and draw HGF: then will ADHG be the envelope required.

For, suppose the semicircle AEB turned upon
AB at a right angle with ABCD, and the envelope ADGH bent and turned upon AD, so that the arc AH may coincide in all points with the semicircle AEB, and HG with BC, the arc AH will have AB for its seat, and the arc DG will have DC for its seat: therefore ADGH will be the envelope for the seat ABCD, which is the axis section of the frustum.

Prob. XXI. To find the envelope for the portion of a semicircle terminated by two cylindrical surfaces, which have their axes perpendicular to the plane of the semicircle, and passing through the axis of the said semicircle, Fig. 10.

Let ABCDEFA be the seat of the envelope: join AC, and draw GH a tangent to the arc FED, cutting AF and CD produced at G and H: then, by the last problem, find the envelope A1KGA to cover the frustum of the cone, whose seat is ACHGA: then having marked the equal parts on the quadrant AL, and the same parts on the arc AI, which will be double in number to that contained in AL, draw lines through the points of division in AL, at right angles to AC. From the cutting points in AC, draw lines to the centre M of the cone: likewise through the points of division in the circular arc AI, draw lines again to M: from the points in the arc AB, and from those in the arc FE intersected by the lines drawn to M, draw lines parallel to AC, to meet AM: from the points of meeting describe arcs from M as a centre, so as to intercept the first, second, third, &c. drawn from the divisions in AB to the point M, taken in the same order from A towards B, and from F towards E: through the points thus intercepted, draw the curves AN and FO; and AFON will be the half of the envelope. Make the other half NOPI similar by the same method, or any other; and AFOPINA will be the whole envelope required.

Prob. XXII. To find the envelope of the frustum of a semicunioid, Fig. 11.

Let ABC be the seat of the surface to be covered; let DEC, the section of the lesser end, be a semicircle, that of the greater end a semi-ellipse, and each of the same altitude, or NE equal MF. Produce AD and BC to meet in G. To find any point t, in the envelope, proceed thus: In the semicircumference DEC, take any point p very near to the extremity D of the diameter DC; draw pq perpendicular to DC, cutting it in q; join qG; draw GH perpendicular to AG; on GH make Gs equal to qp; extend the arc Dp; from D, with this extension as a radius, describe an arc at t; from s, with the distance Gs, describe another arc cutting the former at t. In like manner, by taking the point p very near to p, draw pv perpendicular to DC, cutting DC at v; join Gw; make Go equal to ov; extend the arc pw; and from t, with this extension, describe an arc at y; from o, with the distance Gw, describe another arc, cutting the former at y, and y will be another point in the curve. In this manner all succeeding points to the centre j will be found; so that Dty, &c., will be the curve, which will correspond with the semicircle DEC; join st and ty, and produce them to u and z; also produce Gw and Gs to meet AB at n and x; make tu equal to qn, and yz equal to wz; then draw the curve Dty, &c. to J, and the curve Avz, &c. to the middle, and this will complete one half of the envelope; the other half being joined upon the same base, and made equal and similar, will complete the whole envelope ADKL.

To find the envelope of a part of a semicunioid, contained between two cylindrical surfaces, having their axes perpendicular to the triangle passing through the axis of the cunioid, and intersecting that of the cunioid, Fig. 12.

Find the curve line npq, which corresponds to the semicircumference of the semicircle; as in the last problem, the straight line aclm being a tangent, and parallel to the chord on the concave side; make all the distances bk, cg, dh, &c. respectively equal to in, ko, lq, mg, &c.; draw the curve efgh, and it will be the edge of the envelope, which will have enopq, &c. for its seat; and if s be made equal to nq, it will be equal to ow, hu equal to qy, and the curve rstu, &c. being drawn, will give the other edge of the envelope, which will have the arc wuxy, &c. for its seat.

These two last problems are exceedingly useful in all kinds of arched work that is circular on the plan, the intradoses of the archies splaying on the sides and level at the crown, particularly in sash work: but it is to be regretted, that no accurate method for finding the envelope has yet been discovered; every attempt to greater accuracy than the above has been foiled. There is one method, however, that will give the envelope, or vencer, exactly true, by the use of a centre, and describing the lines on its surface the same manner as in plans, then applying the equal distances from the seats to a graduated pole, which is the vertex of the cunioid, that is, by making the distances equal to py, pv, &c. Fig. 11. or by drawing the equal ordinates on the ends of the centre, and joining the level lines, and taking all the distances from their seats.

BOOK III.

Constructive Carpentry.

Constructive Carpentry shows the principles and mode of combining individual pieces of timber into a complete frame, which shall form an essential part of a building.

The knowledge of this configuration depends on the properties of the several solids which are to constitute the whole, and must be sought for in the principles of Stereography, which we have already illustrated. The angular ribs of domes, groins, roofs, &c.; the art of hand railing, sashes, and archivoltas with circular heads upon circular plans, depend principally on the sections of solids. By the coverings of bodies, the under sides of groined ribs and the front ribs of niches are formed to their plans; the falling moulds of winding stairs are adapted to the spiral line of the steps, and the archivoltas of arches to the plans of the apertures. By the angles which the arisces make with the adjacent sectional lines, we are enabled to cut prismatic or pyramidal bodies, so as
to fit any plane surface, whatever angle or angles the arises, or any determinate line of the body, may make with the said surface; as in purlins, jack rafters, &c.

These principles are not only essential to carpentry, but are equally applicable to the constructive parts of masonry; as in the formation of arches, so as to form their surfaces in the face of any wall, and to the surface of any given solid which shall be a centre for the said arch. In plumbing, the sheets of lead for covering domes are formed by the rules for the covering of solids.

Vaulting, Groining, and Arching.

A simple vault is an interior concavity, extended over two parallel opposite walls, or over all the diametrically opposite sides of one circular wall.

The concavity, or interior surface of the vault, is called the intrados.

The intrados of a simple vault is generally formed of the portion of the surface of a cylinder, cylindroid, or sphere, never greater than that of half the solid; and the springing lines of the coussinet, which terminate the walls from which the vault rises, are generally straight lines, parallel to the axis of the cylinder or cylindroid.

When the vault is spherical, the circular wall terminates in a level plane at top, from which the vault springs, and forms either a complete hemisphere, or a portion of the sphere less than the hemisphere.

Conical surfaces are seldom employed in vaulting, but when a conical surface is employed for the intrados of a vault, it should be semi-conic, with a horizontal axis, or the surface of the whole cone with its axis vertical.

All vaults which have a horizontal straight axis, are called straight vaults.

All vaults which have their axis horizontal, are called horizontal vaults.

A groin, is the excavation or hollow formed by one simple vault piercing another at the same height, such that two geometrical solids being transversely applied one after the other; a portion of the groin may have been in contact with the first solid, and the remaining part in contact with the second solid, when the first is removed. The most usual kind of groin is one cylinder piercing another, or a cylinder or cylindroid piercing each other, having their axes at right angles.

A multangular groin, is that which is formed by three or more simple vaults piercing each other at the same height, so that the several solids which form each simple vault be respectively applied, only one at a time, to succeeding portions of groined surface, every portion of the groined surface will have formed successive contact with certain corresponding portions of each of the solids.

A rectangular groin, is that which has the axes of the simple vaults in two vertical planes, at right angles to each other.

An equi angular groin, is that in which the several axes of the simple vaults form equal angles, around the same point, in the same horizontal plane.

The axis of each simple vault forming the intrados of a groin, is the same with the axis of the geometrical solids, of which the intrados of the groin is composed.

When the breadths of the cross passages, or openings of a groined vault, are equal, the groin is said to be equilateral.

Arches are also formed by one simple vault piercing another, after the same manner as groins.

Arches have various names, according to the surfaces of the two geometrical bodies, which form the simple vault.

A cylindric arch, is that which is formed by the intersection of one portion of a cylinder with another.

A cylindroidic arch, is that which is formed by the intersection of one portion of a cylinder with another.

A spheric arch, is that which is formed by the intersection of a sphere with another.

A conic arch, is that which is formed by the intersection of one portion of a cone with another.

The species of every arch, formed by the intersection of two vaults of unequal heights, is denoted by two preceding words, the former of which ending in o, indicates the simple vault, which has the greater height, and the latter, ending in ic, indicates the simple vault of the less height.

When an arch is formed by the intersection of two unequal cylindric vaults, it is called a cylindro-cylindric arch.

When an arch is formed by the intersection of a cylindric vault with a spheric vault, and the spherical portion being of greater height than the cylindric portion, the arch is called a sphero-cylindric arch.

When an arch is formed by the intersection of a cylindric vault, with a spheric vault, and the spherical portion is of less altitude than the cylindric portion, it is called a cylindro-spheric arch.

When one conic vault pierces another of greater altitude, the arch formed by the intersection is called a cono-conic arch.

History of Groins.

The invention of groins must have been subsequent to that of simple vaulting, and has probably origina-
ted from arched passages, when it was necessary to occupy the whole height. At what time they were first introduced in architecture is uncertain; the remains of antiquity shew that they are of very remote date, which, however, cannot be traced beyond the times of Roman power and grandeur. Use or necessity was no doubt the occasion of their invention; but in process of time they were used as ornaments, and became fashionable at the decline of the empire.

They are to be found in the amphitheatre at Rome, formed at the intersections of the radiating and elliptic passages. In the temple of Peace, and baths of Dioclesian, at the same place, instead of massive piers, they are supported upon columns, the most feeble of all supports, and which would be incapable to resist the lateral pressure of the arches, were it not for the auxiliary support of the walls immediately behind them at the sides and angles of the building.

Groins continued to be used at the decline of the Roman empire in ecclesiastic structures; and where-
ever grandeur or decoration was required, they were never omitted. They became the most principal or-
ament of the times, and formed the most conspicuous
features in the edifices in which they were employed.
At first they were used in the same manner as by the
Romans.

In after times the groins were supported upon ribs
which sprung from cylindrical or polygonal pillars,
with capitals of the same form. This produced a ne-
necessary change in the figure of the vaulting, as the
bottom of the ribs rise from the circumference of a
circle, instead of the angles of a square, with its sides
parallel to the walls; and as the spaces between and
over the ribs were vaulted in a twisted or winding
surface, so as to coincide in every part with a straight
line, level between the ribs; the angles of the groined
surface were thus very obtuse at the bottom, but di-
minated continually upwards, and ended in a right
angle, at the summit of the ceiling. Afterwards,
when the pillars were formed upon a square plan,
diagonally placed with regard to the sides of the
building, and decorated with vertical mouldings,
small attached columns, and the number of ribs in-
increased, the first idea of fan work would be presented
at the springing of the ribs. But in this the archi-
tects would soon perceive an incongruity of form in
the surface; as it approached the summit of the
vaulting, the ribs would be formed all of equal radii,
and disposed around to support a concavity which
might be generated by revolving a curve round an
axis which was in the centre of the pillars; and being
accustomed to groins meeting in lines crossing each
other, it was natural to suppose they would at first
permit the ribs to run out and meet each other, which
would then be of unequal lengths. If the differ-
ence between the openings was not very great, the lines
thus formed, by the meeting of the opposite sides of
the vaulting, would not differ materially from straight
lines, but would not be parallel to the horizon, as
they would run upwards towards the centre of the
groin; but this would depend on the angle formed
by two opposite ribs in the same plane. Thus if the
tangents formed at the vertex of the opposite curves
contained an angle of 120 degrees, the apex line
on the ceiling would form a curve, in receding from
the vertical angles of the said ribs, of a very decided
convexity; but in going progressively forward, the cur-
vature would change into a concavity, and then
would begin again to descend. The idea of intersect-
ing the ribs thus disposed in vertical planes around a
common axis, by circular horizontal ribs, was natural;
and this again would generate another idea of sup-
porting the upper ends of the ribs by a circular ring,
centric with the axis of a pillar; and thus being
done from four pillars, would leave a space inclosed
by four convex arcs of circles. Nothing farther was
required to complete this system of vaulting than to
fill up the space, and the whole would be keyed to-
gether. In this manner, by slow and imperceptible
changes, a species of vaulting was invented very dif-
terent from that of the Greeks and Romans. In-
stead of closing the space, if we suppose another ring
forming a complete circumference to be built interi-
Orly to touch the former arcs, and the four triangu-
lar curved spaces closed and wedged together with
masonry, the whole will stand equally firm as if the
middle had been solid; and thus an aperture for light
will be formed the same as in dome vaulting.

The only improvement made by the moderns in
vaulting, is the cylindro-cylindric arches, which are
made in opposite sides of a vault, and when regular-
ly repeated, have a very beautiful effect.

In warehouses, which are loaded with the greatest
weights, and where the walls are placed at a remote
distance, it becomes necessary to introduce many sup-
pports to the floors, which if constructed of timber
are liable to both fire and rot, and thereby exposed to
sudden danger; every precaution should therefor-
be taken to prevent the risk to which they are
thus exposed; at least as far as may appear eligible
in the profits arising from the articles to be depos-
ited making a full compensation for the additional ex-
pense. The end will be fully answered by the intro-
duction of groins, which not only answer the same
purpose as the flooring of timber work and the
wooden posts which support it, but are more dur-
able and a certain proof against both fire and rot.
Though groins are only employed in the lower sto-
ries of buildings, owing to the great expense which
would be incurred by the great thickness of walling;
and the diminution of space which would be oc-
casioned thereby, they may at all times be used in cel-
lars and ground stories, without much additional la-
bour or expenditure of materials.

It has been found that brick groins, rising from
rectangular piers, are inadequate to the weight they
have to support, and incommodious to the turning
of goods round the corners of the piers. An im-
provement has been suggested by Mr George Tapen,
architect, in a small pamphlet lately published, where
he judiciously recommends the piers to be construct-
ed octagonally, and the square angles of the groin
to be cut off equal to the breadth of the side of the
octagonal pier. He gives a very satisfactory reason
to this purpose, that the angles of groins built in
the common way, forming a right angle, are hardly
capable of sustaining themselves, and much less the
load which is required to be supported, owing to the
bricks being so much cut away at the angles in order
To fit them thereto, that they have little or no lap
upon each other. This scheme should certainly be
Carpen-
construc-
Carpentry.
Centering for groins.

According as they are built of stone or brick, or constructed of timber-work, lathed and plastered over.

In the former case, a timber centering is made to form the concavity, and placed in order to support the groin during its erection. The centering consists of several ribs, disposed at three or four feet distance, made to the size of the vault, which has the greatest opening. These ribs rest at their extremities upon beams supported by standards, and are boarded over without any regard to the transverse opening, which is afterwards formed by another set of ribs adapted thereto, and then boarded so as to meet the boarding of the first vault, which, if it be of considerable breadth, must have short ribs fixed upon its surface, in order to sustain the boarding of the transverse opening, and thus the centering will be completed. It is obvious in forming the ribs for each vault, that the outer curve must be the arc of a circle or ellipse within the curve of the vault, and at a distance from it towards the axis equal to the thickness of the boarding. In the making of the ground centre, it will be necessary to find the place of the angles upon the boarding of the large vault, in order to ascertain the place of the ribs and boarding of the transverse vault. This may be done in three different methods. If two straight edges are placed vertically at the angles, and another straight edge or extended line be made to touch the surface of the boarding, and marked at all the points of contact, keeping this straight edge or line always upon the edges of the two vertical straight edges; the defect of this method is, that the place of the angles at the bottom can never be found, as it would require the cross straight edge or line to be of infinite length, and the vertical ones infinitely high. A more eligible method, where there is room, is to fix two ribs in the transverse part, and direct a level straight edge upon the edges of these ribs, so that the end may come in contact with the boards, and mark the boarding in this place; find a number of points in the same manner as may be sufficient for the purpose, and curves being drawn through the points, will give the curves for fixing the ends of the ribs. But the best method is by the following geometrical problem.

Fig. 1. is a cylindrical groin; No. 1. the plan, No. 2. the elevation. Such groins as this frequently occur in lobbies, halls, passages, anterooms, &c.

Fig. 2. is a cylindrical-cylindroid groin; No. 1. the plan, No. 2. the elevation. It is this kind of groin that generally occurs in cellaring; to construct which, a centering must be formed as at Fig. 2. No. 3, 4, 5, and 6. No. 3. shows the cylindroidal part, which is the widest opening, boarded over the whole length; then in order to fix the transverse boarding, as at No. 2. the lines AB, CD, and EF, GH, No. 3. must be drawn upon the boarding for the wide opening, either by the former mechanical means, or by the following geometrical process. No. 5. shows the end of this boarding. If the wide opening be of considerable dimensions, the shallow ribs, called jack-ribs, are fixed between the lines to the height of the cross vault, and made less by the thickness of the boarding, so as to come within this thickness of the height of the groining. No. 4. shows the left hand part completely boarded in; No. 5. the end of No. 3.; No. 6. the end of No. 4., showing the face of one of the ribs of the centering, the thickness of the boarding, the jack-ribs over the boarding, and the posts and ends of the beams that support the whole.

Prob. I. To find the mould or curve for determining the place of the angles upon the boarding of the cylindroid, in order to fix the jack-ribs and transverse bordering of the cylindroid vault No. 4.

Prob. II. Let it be proposed to find the angles of the groin on the surface of the foregoing boarding. In order to prevent confusion of letters, we shall suppose the seal enlarged. Let AEM be half the rib for the cylindroidal part; the bases AM and MN, being at right angles to each other, produce MA to M'; extend the curve AE upon AM', from the equal parts or arcs AB, AC, CD, DE, to AF, etc., f'k', k'k', k'M'; through the points of division draw ordinates; make f'/g, k'/h, k'/l, M'*N, equal to f'g, hi, kl; MN, and through the points g, i, l, N, draw a curve, which, when bent round the bordering at No. 3. from A to I, from C to I, from D to I, from B to I, &c. determines the place of the angles.

Prob. III. To find the form of the end of the boarding of the cylindroidal part, in order to fit it against the boarding of the cylindroidal part, stretch out the parts No. 6, pq, qr, of the arc MR, in the straight line MN, from M to s, from s to p, from p to u, and from u to N; draw the ordinates MA, s'q, p', q', u'N, which make equal to MA, s'q, p', q', u'N, and the thing required is done.

Centering to Gothic Groins.

In one species of Gothic groins, the lines of concourse of the sides of the arches at the summit, cross one another in level lines parallel to, and equidistant from, the sides of the building. The vaulting is supported upon several ribs springing from the head of each pillar, and terminating upon the transverse lines of the ceiling at different equidistant points. The surface of the vaulting lying upon, and between any two adjacent ribs from middle to middle of these ribs, may be considered to be a cunioid, and the ribs may be considered to be sections of the cunioid. The surface of the ceiling between any two adjacent ribs, will therefore have this property, that a straight line or edge applied everywhere level or parallel to the horizon, to two given points on the surface between any two ribs, will coincide entirely with the said surface. From what has been said, it appears that the seats of the joints of the arches between any two ribs, will meet each other in one and the same point in the seats of the summits of the arches. It will readily appear, that if several ribs spring from the top of the same pillar, each from a point in the circumference of a circle, or from an angle of a polygon, that there will be as many portions of different cunioids as there are pairs of adjacent ribs; and consequently the point of concourse of the seats of the joints of each portion will be in the seat of the summit of the arches, where a straight line drawn through two adjacent points in the said circumference...
CARPENTRY.

 Rune meets the seat of the summit of the arches. If several adjacent ribs from the same pillar rise from as many points in a straight line, all the seats of the joints for each, and all the portions, will have the same point of concourse. What has now been said will be clearly seen by the following diagrams, Plate CX.X.

Fig. 1. shows the plan of Gothic groining, where the ribs spring from points in the circumference of a circle, terminating the head of each pillar; and consequently, if the arches have several points of concourse, two of these points will run too far out of the diagram for their centres to be marked.

Prop. IV. To determine the seats of the joints, draw half the sectional curve ABC between two opposite pillars, upon its seat AB; divide the curve AC into as many equal parts as there are to be courses; through the points of division draw ordinates to cut the seat AB; divide BD into the same equality of parts respectively as BA: let e be the next adjoining point to A; produce e F till it meets the seat of the Trumhut; but if the part of concourse run out to a great distance, which is not accessible, produce e D to k; draw n o parallel to DB, meeting the seat of the summit at o; divide o n in the same proportion as BD; draw lines through the corresponding point of division in o n and BD, and produce them till they meet the seat of the diagonal e f; join g e, which produce; but if it is likewise inaccessible, proceed in the same manner, by drawing a line parallel to e f, and dividing the line so drawn in the same proportion as e f; and draw lines also through the corresponding points of division, and produce them to meet the seat g h of the diagonal, and the seats of the joints will be completed for one side. Produce g i to p, and draw lines from the points of division g h to the seat i k of the next rib, tending towards p; produce i l to q, and draw lines tending towards q from the points of division in q s to l m; and the seats of the joints will be completed for one quarter of the groin.

Prop. V. To find any rib, suppose the diagonal rib represented by its seat AB or EB.

Take AB, with its divisions, and place it upon CD, Fig. 3: raise ordinates upon CD, equal in height to those of the half section upon EF, and trace a curve through the extremities, and it will form the angle rib over the seat AB. Any other rib will be found in the same manner.

Instead of the rib Fig. 3. being found from its seat, suppose the rib Fig. 4. to be described with a compass: let the curve EM, Fig. 2. be divided into equal parts, and lines be drawn to meet EL parallel to the base EF, and let lines be also drawn perpendicular to, and meeting EF: let the base GH, Fig. 4. be equal to the seat AB; and H I equal to MN: make the distances on GK, Fig. 4. equal to those on EL, Fig. 2. : from the points of division, draw lines parallel to GH, to meet the curve GI; draw lines perpendicular to GH, to meet it; apply the division to AB and BE, Fig. 2. and these will be the points for drawing the seats of the joints.

Another method for finding points in the seats of the angles and joints is, by dividing all the seats of the ribs in the same proportion as in Fig. 5, which is the same rib with Fig. 2; the parts are taken from PQ, PR, Fig. 5, and applied to ST, SU, Fig. 2, which will give the directing points of the seats of the joints, and also of the remaining ones. Fig. 6. is the rib corresponding to ST, the base being divided, as PQ or ST.

Fig. 7. is an equilateral fan groin. In this the four trinelineal spaces, formed by the four quadrants, and the circle inscribed, are all in the same horizontal plane; the surface within the entire circle is generally horizontal, but may be raised with an arched concavity of any form whatever; the curve of the rib, continued through this circle to meet in the centre, would have no bad effect, and would form a kind of pointed dome.

Fig. 8. is an oblong fan groin. In this diagram, the sides of the transverse arch meet at an interior angle, and the line of concourse terminates by the seat of the horizontal rib, the radii of which is half the breadth of the building; the four tricurvilineal spaces, comprised by the arcs of the opposite horizontal ribs, and the inscribed circle, are horizontal planes, and the inscribed circle may be as in the preceding observation. These are generally filled with fan work. It may be here observed, that the summit lines, AB, CD, EF, GH, will not be straight lines, but curves, which will run higher as they approach nearer to the centre.

Cylindro-cylindric Arching.

Fig 1. is a plan of groining and arching in three aisles. The side aisles, AAA, BBB, are vaulted with cylindric groins: the middle vault and principal aisle, CCC, being higher than the sides, form cylindro-cylindric arches. The principles of construction are shown in the following problem, so far as regards the construction of the angular ribs, for lath and plaster, of the cylindro-cylindric arches. Fig. 2. is a section of the said arch.

Prop. VI. To describe the angular rib of a cylindro-cylindric arch, and to range the under edge, so as to range with the two sides of the said arch, Fig. 3.

Let AB be the side of the groin, corresponding to e c, (Fig. 1.) and BC the side corresponding to e f, the diameter of the vault of the middle aisle, the dimensions here extended to five times that of the plan, in order to prevent the confusion of lines, which would take place in consequence of a smaller scale: let the sides AB, BC, be placed in position, the angle of which is here a right-angle: divide the half arc, standing upon AB, into any number of points, by the points of division, 1, 2, 3, 4, produce the side AB to a, and the side CB to d: parallel to AB draw 1 a, 2 b, 3 c, 4 d, cutting B d, at a, b, c, from B, with the radii B a, B b, B c, B d, describe arcs d h, e g, f b, a e, cutting B h at e, f, g: parallel to B c draw e i, f k, g l, h m, cutting the arc upon the diameter BC, at the points i, k, l, m: parallel to AB draw i n, k o, l p, m q, and parallel to BC, draw 1 n, 2 o, 3 p, 4 G, and through the points n, o, p, G, draw a curve, which will give half the seat of the angle rib: join BG, and through the points n, o, p, G,
draw $Dv$, $Em$, $Fx$, $Gy$, which make respectively equal to $x1$, $x2$, $x3$, $x4$; and draw the curve $Buvxy$, which will give the under side of the angle rib.

Draw $HI$ parallel to $BG$, at a distance from $BG$ equal to the thickness of the stuff, which must be equal to the thickness of the angle rib, together with the waste or greatest recess of the hollow: where the lines $1n$, $2o$, $3p$, $4G$, cut the line $BG$, draw ordinates parallel to $Dv$, $Em$, $Fx$, $Gy$; also through the points, where the lines $i_n$, $k_o$, $l_p$, $m_G$, cut $HI$, draw another set of ordinates parallel to $Dv$, $Em$, $Fx$, $Gy$, and trace a curve through the extremities of each set: the first curve shows the concourse of the two sides, or angular line; the next, the ranging upon the side of the rib which faces the arc $AB$; and the outside one, the ranging upon the side of the rib which faces the arc $B$, or ranges with the large opening. The under edge of the angle rib is first cut out at right-angles to the sides, and the lines are drawn upon each respective side, according to what is here shown. In order to find the place of the angle corresponding to its seat on the plan, take the stretch of the parts $Bv$, $wv$, $wx$, $y$, and extend them in a straight line from $B$ to $Dv$, from $Dv$ to $Em$, from $Em$ to $Fx$, from $Fx$ to $G$; draw the ordinates $Dv$, $Em$, $Fx$, $Gy$, which make equal to $Dn$, $Em$, $Fx$, and draw the curve $Bn$, $mo$, $pr$, $G$, which, being bent under the angle rib, will give the line of concourse.

In practice, it would be better to get out the angle rib in two or three parts, otherwise the waste of stuff would be enormously great: this is shown at the other half. The process is the same as what has been described in the first half.

**On Roofing.**

A roof is that part of a building raised upon the walls, and extending over all the parts of the interior, in order to protect its contents from depredation, and to prevent the injury of the weather, and to admit of greater strength than a level disposition of the timbers, it is in the opinion of the most eminent architects, that the timber should be the higher the point of the arch, or ridge, is where an isosceles triangle, the vertical angle being the summit of the roof. This form is very advantageous in saving timber, as it may be executed with the same scantlings, to span double the distance that the single sloping roof may; or in buildings of the same dimensions, the scantlings of the timbers will be greatly reduced.

The ancient Egyptians, Babylonians, and other eastern nations of remote antiquity, constructed their roofs flat, a practice which is still adopted by the present inhabitants of those climates. The ancient Greeks, though possessing a mild climate, but sometimes liable to rain, would soon find the inconvenience of a platform covering; and accordingly raised the roof in the middle, declining thence towards each side of the building, with a gentle inclination to the horizon, forming an angle from 13 to 15 degrees, or the height from one eighth to one ninth part of the span. In Italy, where the climate is still more liable to rain, the ancient Romans constructed their roofs from one-fifth to two-ninths parts of the span. In Germany, where the severities of the climate are much more intense than in Italy, the ancient inhabitants, as we are informed by Vitruvius, made their roofs of a very high pitch. When the pointed stile of architecture was introduced into Europe, high pitched roofs were consonant to its principles; and therefore formed externally one of the most striking features of the Gothic stile, the prevailing proportion being the equality of the rafters, and the breadth or span of the roof, or the rafters the sides of an equilateral triangle, of which the spanning line was the base. During the middle ages, this form prevailed not only in public, but also in private edifices, from the most sumptuous mansion to the cottage of the labourer; and this equilateral triangular roof continued in vogue till the expulsion of the pointed stile, by the introduction of Roman architecture, introduced by the celebrated Inigo Jones. When the rafters were made three-quarters of the breadth of the building, the proportion was called true pitch, which still prevails in some parts of the country where plain tiles are used; and subsequently, the square seems to have been considered as true pitch. But in large mansions, erected in the Italian stile, roofs of a pediment pitch, covered with lead, were introduced. In the present day, where good tiles are to be obtained in abundance, the roofs may be covered from the pyramidal equilateral Gothic, down to the gentle inclined Greek pediment. In the present practice, the proportion of the roof depends on the stile of the architecture of the edifice, the ordinary height being from one-third to one-fourth part of the span.

There are some advantages in high pitched roofs: they discharge the rain with greater rapidity; the snow does not continue to be so long on their surface; they may be covered with smaller slates, and are not so liable to be stripped by heavy winds as low roofs; but low roofs have less pressure on the walls, and are much cheaper, since they require shorter timbers, and consequently smaller scantlings.

The roof is one of the principal ties to a building, when executed with judgment; as it connects the exterior walls, it also binds the whole into one mass, and secures the work from a state of decay, which would soon ensue from the injuries of rain and frost, so as to rot the timber, destroy the connection of bond in the walls, and cause the building ultimately to fall.
**Prob. VII.** The figure $ABCD$ of the wall plate of a hipped span roof, and the height of the roof being given, to find the backing of the hips, the angles made upon the sides of the purlins by their longitudinal arisines, and the angles made upon the sides of the jack rafters, the roof being equally inclined to the different sides of the building, Fig. 1.

Let the two sides, $AB$, $AD$, and $DC$ of the wall plate be at right angles to each other, and the end $CD$ at oblique angles to $AB$ and $CD$; draw the seat $EF$ of the ridge, in the middle of the breadth, parallel to $AB$ and $DC$; make $AG$ and $DH$ equal to half the breadth of the building; join $GH$, which will be the seat of the common rafters adjoining the hips. Make $EI$ equal to the height of the roof, and draw $IG$ and $IH$, which are the length of the common rafters. Draw $ED$ and $EA$, the seats of the hips; make $EK$ equal to $EI$, and draw $KA$, which gives the length of each hip. Through any point $L$, in the seat of the hip $AK$, draw $MN$ perpendicular to $AE$, cutting the adjacent sides of the wall plate at $M$ and $N$; take the nearest distance from $L$ to the rafter $AK$, and make $LO$ equal to it, and draw $OM$ and $ON$, and $MN$ is the backing of the hip, represented by its seats $AE$ and $DE$. This operation is the same as having the two legs of a right angled solid angle to find the angle opposite to one of the legs, the angle $MON$ being exactly double of the angle so found; for the hipped angle of the roof consists of two equal solid angles. Suppose that the bevel end at $CB$ is inclined at a different angle to the other sides, and let $FC$ and $FB$ be the seats of the hips, draw $FQ$ perpendicular to $FC$, and $FP$ perpendicular to $FB$, and draw $QC$ and $PB$, which are the lengths of the hip rafters. The backings, $SUT$ and $VWX$, are found in the same manner as above, and may be described in the same words.

From $A$, with the distance $AK$, describe an arc, cutting $GH$ at $J$, and join $AJ$, $GJA$ will be the side bevel which the jack-rafters make with the hips; and if a right angle be added to the same angle $GJA$, the obtuse angle thus formed will be the angle which the upper arris of the side of the purlin, placed in the inclined side of the roof, makes with the hip rafter.

Let $a$ be the position of a purlin in the rafter $HI$; in $G$ take any point $b$, and draw $be$ parallel to the inward direction of the purlin $a$; from $b$, with any distance $bc$, describe an arc $cd$, cutting $GH$ at $d$; draw $be$, $ef$, and $dg$, parallel to $EF$, the former two cutting $ED$ at $e$ and $f$; draw $fg$ parallel to $GH$, and join $eg$; produce $be$ to $h$, and $heg$, or $beg$ will be the angle required, according to which side it is applied. This will be found to be the same thing as one of the legs, and the adjacent angle of a right angled solid angle being given to find the hypothemuse. In the same manner, if neither side of the purlin should be parallel to the inclined side of the roof, as at $k$ in the rafter $GI$, the bevel or angle upon each side will be found.

Fig. 2. shows half the angle of the backing of the hips; the length of the common and hip rafters; the bevel of the jack-rafters on their upper sides in an equal inclined roof, without laying down or drawing any more than the necessary seats; and this is all that is necessary when each side of the roof is alike; $AB$ being the wall plate between the hip and the rafter which joins the top of the hip, $AC$ the seat of the rafter which joins the top of the hip, $BC$ that of the hip, $AF$ the length of the rafter which joins the hip, $BE$ the length of the hips, $CHG$ half the backing, $ADB$ the angle which the jack-rafters form with the hips on their upper sides, and consequently, with the addition of a right-angle, the side bevel of the purlin.

Fig. 3. shows the same bevels, excepting that the Fig. 3. side joint of the purlin is found by a different process, thus: From $D$, with the distance $BA$, describe an arc at $D$; from $G$, with the distance $AC$, describe another arc, cutting the former at $D$; join $BD$, and the angle $CBD$ will be the angle in the plane of the roof, made by the lower arris of the purlin, and the joint against the hip rafter.

Fig. 4. is a diagram, showing the lengths of the parts and angles concerned in the roof, in the same manner as above; but the plan of the building, or form of the wall plate, is a quadrilateral, which has neither pair of its opposite sides parallel. The method of executing the roof in this case, is to form a level on the top, from the top of the hips at the narrow end to the other end, as otherwise the roof must either wind, or be brought to a ridge, which will form a line inclined to the horizon; Either of the two last cases is very unsightly.

Besides the angles already mentioned, (see Fig. 2.) AFC shows the angle formed by the upper side of the rafter, and the ridge piece; and the angle $BEC$, the angle which the top side of the hips makes with a vertical line; also, the angle $FAC$, shows the form of the heel of the common rafters; and $EBC$, that of the hips.

It may be here noticed, once for all, that the bevels, or angles, concerned in hip roofing, are no more than the sides or angles of right angled solid angles, consisting of three plane angles. The quantities in degrees may be found as in spherical trigonometry, by considering the plane angles, which constitute the solid angles as sides, and the inclinations of the planes as angles.

**Circular, Elliptical, and Polygonal Roofs.**

A circular roof may be executed with timbers disposed in vertical planes, whether the ribs or rafters &c. roofs are convex, concave, or straight, without any tie between the rafters or ribs, even though the wall were ever so thin; provided that it be only sufficient to sustain the weight of the roof, by joining the wall plate, so as to form a chain, a ring, or endless plate, and by strutting the rafters in one or more horizontal courses, without any danger of lateral pressure, or of the timbers themselves being bent by the weight of the covering; but the same cannot be done with the roof of a rectangular building, for single parallel rafters would not only obtain a concave curvature, but would thrust the walls outwards. Hence, the means of executing circular roofs with safety are simple; but those for straight sided buildings are complex, and require much more skill in contriving, acco-
covering to the utility of the space between the rafters, which may be found necessary in forming more lofty, or more elegant apartments, as in concave or convex ceilings.

A circular roof is that which may be formed by revolving any line round a straight line at rest in the same plane, the two being joined at the top. By this definition, the figure may either be a cone, or a concave or convex surface, or mixed.

Polygona] roofs are those, the horizontal sections of which are similar figures.

An elliptical or ellipsoidal roof is one, the horizontal sections of which are all similar ellipses.

A polygonal roof, with a great number of sides, approaching very nearly to a circle, is stronger than one of fewer sides; the fewer the sides, the weaker will the roof be, and more liable to get out of order. A roof executed upon an equilateral and equiangular plan, is much stronger than one elongated, whatever be the number of the sides.

All circular roofs are, for the same reason, stronger than elliptical ones; the pressure in the former case being equally distributed round the walls, the force of the rafters tending only to keep the circular wall plate in a state of extension.

The roofs of rectangular buildings have generally their sides in plane figures; but those of polygons and circles have a variety of figures, particularly when their plans are equilateral and equiangular:

They have sometimes the sides of their vertical sections straight, sometimes concave, but most frequently convex; and then, as has been observed, they are called domes; sometimes they are undulated, viz. both concave and convex.

Roofs, upon circular and polygonal plans, are also denominated from their vertical axial sections, as well as from their horizontal sections. Thus, if the axial section be a parabola, hyperbola, or semicircle, the roof is denominated a paraboloidal, hyperboloidal, or spherical dome. If the axial section is a figure of contrary curvatures, and the concave part at the bottom, the roof is denominated a bell roof.

Circular roofs are circular roofs, with an aperture through the middle, the axial section being a semicircle, or semielliptic, or a segment.

Covering of Circular Roofs.

Circular roofs may be covered upon two different principles; one is, by supposing the axial section to be divided into a number of small equal parts, and the roof cut by planes through the points of division parallel to the base, and by considering the frustums of the solid as so many frustums of a cone; and the covering of each respective part will be found as in Problem XX. page 521. The other principle is, by dividing the circumference of the base into a number of small equal parts, and supposing axial sections to be made through the points of division, thereby considering the surface of each axial portion as the surface of a cylinder. The covering will be found as in Problem XVII. page 590. The distance between the points of division in the former case, must be less than the breadth of the boards which are to form the envelopes of the covering, in order to make the convex edge of the board; this distance must therefore be less, as the length of the boards is greater. In the latter case, the distances between the points of division may be exactly equal to the breadth of the boards. It is true, that the surface of each part is spherical or convex, and therefore can neither be considered as the frustum of a cone, nor that of a cylinder; but if the distance between the divisions be small, the surfaces will be almost straight in all the axial sections, so that there will be no practical difference, even though the widest boards were used in moderate sized works. The boards which thus form the envelopes must be then in order, that they may comply with the surface of the circular roof to be covered. It is here proper to notice, that when boards are bent, so as to form a surface either concave or convex, that they are much stronger than if the surface were a plane, even though the ribs were the same distance in both; but in order to make the boards bend regularly and truly, the ribs ought to be disposed at a nearer distance at the widest place, which is at the bottom, than the rafters of the common roof. When the ribs are disposed in axial planes, they will come in contact with each other at the top, unless they terminate upon a circular kirb, of a diameter sufficient to prevent their doing so; but as the intervals at the top are always much less than at the bottom, the ribs are sometimes discontinued, in order to reduce the intervals nearer to an equality of breadth throughout the length of each. The execution in this way will save the timber work, and, consequently, lessen the expenses. Sometimes the ribbing of circular roofs only consists of several principal axial ribs, and the intervals filled in with jack ribs, which, if the surface to be covered be spherical, are portions of lesser circles of the sphere, and are disposed in parallel vertical planes.

Prop. VIII. To cover a dome by bending the PLATE boards horizontal, by considering the surface as the CXXIII. surfaces of as many conic surfaces as there are boards. Fig. 1.

The axial section being given, Fig. 1.

Let HAF be an axial section of the dome; draw the axis GA, and produce it to I; divide the curve of the half into the equal parts be, cd, de, ef, the common measure or part being less than the breadth of the rectangular board; produce dc, to cut the axis produced at I; from 1, with the distance Ie, describe the arc en; from the same centre, with the distance Id, describe the arc do; then edon will be the form of the board or envelope to cover the frustum edon. In the same manner, the boards to cover the other frustums will be found. Thus by producing bc, de, ef, the centres k and m for covering the opposite conic frustums bor, se, ep, will be found, the centre for e FH p being inaccessible.

Prop. IX. To cover an annular vault, upon the Fig. 2.

principle of resolving it into conic frustums. The axial section, and inner diameter of the annulus being given, Fig. 2.

Let A bede F be the axial section, FG the inner, and AK the outer diameter; bisect AK by the perpendicular IL, and IL will represent the axis: then, if the points A, b, c, d, e, &c. be the breadths of the intended boards, by producing the chords to the axis,
the form of the envelopes will be obtained, as in Problem XX. page 531.

In these two last problems, the reader will have observed the inconvenience of obtaining the centres of the boards near the base, and the absolute impossibility of obtaining that at the bottom. The methods of finding the forms of the boards where the centres are thus inaccessible, will be shown by the following problem, to which the three following lemmas are a preparation.

Lemma 1. If, in a circle, there be taken any two equal chords $AB$, $BC$, and $AE$ and $BF$ any two parallels; and if the angle $CBF$ be bisected by $BD$, meeting the circumference in $D$, and $AD$ drawn, then $AD$ will also bisect the angle $EAB$. Fig. 3.

Lemma 2. If, in a circle, there be taken any series of equal chords $AB$, $BC$, $CD$, $DE$, and if the angle $ABF$ be bisected by $BK$, meeting the circumference in $K$, and $KC$, $KD$, $KE$ be joined, and $CG$, $DH$, $EI$ be drawn parallel to $BF$; then $KC$, $KD$, $KE$ will bisect the angles $BCG$, $CDH$, $DEI$.

Lemma 3. If there be any two inclined lines $AB$ and $CD$, and if $AE$ be drawn parallel to $CD$, forming an obtuse angle $BAE$, and if the angle $BAE$ be bisected, the bisecting line $AC$ will make equal angles $BAC$ and $DCA$, with each inclined line $AB$ and $CD$.

Prob. X. To find the form of the boards at the bottom of a dome, considering the surface as the surfaces of as many cones as are rows of boards, when the centres of the circular edges of the boards are inaccessible.

Fig. 6. Let $ABC$ be an axal section of the dome, and suppose $fg$ to be the place of the last board on this section; draw the representation of the axis $DB$; produce $DB$ and $g f$ to meet in $E$; from the centre $E$, with the distance $E f$, describe the arc $f l$, the concave edge of the board cutting $DB$ at $l$; join $f l$, and produce $fl$, cutting the circumference $AB$ at $m$; let $gh$, $hi$, $ik$ be the places of the following boards nearer to the bottom; draw $gm$, $hn$, $imu$, $km$, cutting $DB$ at $t$, $u$, $v$, $w$; draw $gp$, $hq$, $ir$, $ks$ parallel to $AC$ the base, cutting $DB$ again in the points $p$, $q$, $r$, $s$; then will $pg$ be half the length, and $pt$ the height of the first board, the centre of which is inaccessible; also $hq$ half the length, and $qu$ the height of the next board; $ir$ half the length, and $rv$ the height of the next; likewise $sk$ half the length, and $sw$ the height of the last.

For draw $fn$ parallel to $DB$, and the angle $n f l$ will be equal to the alternate angle $f l E$; but because $E f$ and $E l$ are equal, the angle $f l E$ is equal to the angle $l f E$; therefore the angle $l f E$ is equal to the angle $n f l$, and consequently the angle $n f E$ is bisected by $fn$; but, by Lemma 2, if there be taken any number of equal chords $fg$, $gh$, $hi$, $ik$, $KC$, and if the angle $n f E$ be bisected by $fn$, meeting the circumference in $m$, and $gm$, $hn$, $imu$, $km$ be joined, and $g x$, $h y$, $i z$, $k$, $l c$, drawn parallel to $f a$; then $gm$, $hn$, $imu$, $km$, will bisect the angles $f g x$, $gh y$, $hi z$, $ik$, $lc$.

It may now be shown as follows, that if any angle $gh y$ be bisected, the angle $gh m$ or $gh u$ will be equal to the angle $B w h$; therefore, if $h g$ and $u B$ were produced, their point of concourse would be the centre of an arc that would pass through $h$ and $u$. For, since $h y$ is parallel to $B D$, the alternate angle $y h u$ is equal to the angle $h u B$; but the angle $y h u$ is equal to the angle $l g h u$; therefore the angle $g h u$ is equal to the angle $h u B$, as was to be shown.

Fig. 1. represents a semicircular dome, boarded with the joints in vertical planes.

Fig. 2. is a segment dome, boarded with the joints in vertical planes.

Fig. 3. is a bell roof, boarded with the joints in vertical planes.

Fig. 4. The manner of finding the form of the Fig. 4. board or envelope, by considering the surface of the dome, as consisting of as many cylindric parts as there are boards. See Problem XVII. page 520. In this, the axal section is considered as the section of the cylinder.

Prob. XL To find the envelope or form of the board, having the axal section given, Fig. 5.

Let $AB$ be the breadth of a board, or the breadth of the envelope; bisect $AB$ at $C$ by the perpendicular $DE$; make $CE$ equal to the length of the arc from the bottom of the dome to the summit, which may be found by calculation; divide the arc $AD$ into any number of equal parts, and draw the sines parallel to $AB$; divide $CE$ into the same number of equal parts, and draw lines parallel to $AB$; make ordinates on each side of $CE$, reversed to the order of the sines, and the curve being drawn on both sides, will form the board.

Fig. 6. shows the manner of finding the envelope Fig. 6. of Fig. 2, in the same manner as in Fig. 4.

Fig. 7. shows the method of finding the envelope Fig. 7. of Fig. 2, without the use of the axal section. In this Figure, $AB$ is the breadth of a board; $A E D F B$ a circular zone, similar to the contour of Fig. 2; the part $E D F$ being flat, corresponding to $e f$ Fig. 2; the arc $A E$ Fig. 7, being similar to $a e$ Fig. 2; and $C G$, Fig. 7, equal to $a e$ Fig. 2. The operation is the same as in Fig. 5, as will be obvious by inspection.

Fig. 8. shows the manner of finding the covering of Fig. 8. Fig. 3, in the same manner as in Figs. 4. and 6.

Fig. 9. is an elliptical dome: No. 1. the plan; No. 9. 2. the elevation; No. 3. the half section of the elevation; No. 4. a section of the plan.

Fig. 10. is a circular dome and elliptic elevation: Fig. 10. No. 1. the plan; No. 2. the section.

Fig. 11. shows the manner of covering the domes in Fig. 11. Figs. 9 and 10, the same as in Figs. 4, 6, 8, by laying down the rotate section, whether on the plan or on the elevation.

The principle of executing niches with spheric heads, depends entirely upon the properties of the sphere; and therefore, since all the sections of the sphere are circles, and those which pass through the centre are equal, and those which are more remote from the centre are less than those which are nearer to it, if a hemisphere be cut at right angles to the plane of its base, its section will be a semicircle of greater or less diameter, as it is nearer or more remote from the centre.

First, let the section be made through the centre at right angles to the plane of the base, then the hemisphere will be divided into two equal portions, each a quarter of the sphere. Each of these quarters will have two planes at right angles, and
each plane will be a semicircle. One of these spheric
portions will represent the head of a niche, the plan
and elevation of which are both semicircles. In this
case the ribs, the ground plan, and the face, will have
the same curvature, and consequently may be drawn
with the same radius.

Secondly, let a hemisphere be cut by a plane at
right angles to its base, but not through the centre,
then will be cut into two unequal portions, the
common section of which will be a semicircle. The
smaller portion will represent the head of a niche,
the plane of which is the segment of a circle, and
the elevation is a semicircle; and because the seg-
ment is a part of the base of the hemisphere, and
the elevation a semicircle upon the same base, and since
the semicircle is remote from the centre, it will there-
fore have a less radius than the segment at right
angles to it. Now, since the under edges of the ribs
of the niche are in the spherical surface, and since these
may be made in planes tending to the centre, the ribs
will all have the same curvature; for they are all
portions of equal circles of the sphere, and conse-
quently may be drawn with the same radius as the
base of the niche, and hence all the sections of a
sphere are circles; And in spherical niches, as the
ribs must be considered as sections of the sphere,
they may be disposed in all positions; and as the
head of the niche is a spherical surface, the under
sides of all the ribs must be spherical; and it is evi-
dent that the spherical sides of the ribs will make
the same angle all round with the plane side. The
heads of niches generally consist of a rib brought
close to the face of the wall, and a number of back
ribs generally fastened to the front rib at the top,
and a horizontal circular plate at the bottom. If
the face of the wall be a plane, the two sides of the
front rib, which join the under or spherical side, are
two parallel planes; but when the wall is cylindrical,
it is necessary that the face of the front rib should
be also cylindrical, and a part of the same surface,
and that the under side be spherical; the opposite
side to the front may be a plane, which may either
be perpendicular to the floor or inclined to it; but
whatever be the position of the plane, the spherical
surface will always form the same angle with the
plane at all points round the ribs in their line of con-
course; so that a bevel constructed with one edge
regular, and the other straight, which coincides at
any point with the spherical surface and the plane
side, will coincide with the two surfaces at any other
point. It is evident, that this plane side, which is
the side opposite the front of the rib, may either be
disposed in a vertical plane, or in a plane inclined to
the floor at many angles; but it is likewise evident,
that there is some one position for the plane, which
will occasion a less waste of stuff in order to make
this front rib, and this position will be found to be a
plane parallel to an inclined plane, which would pass
through the summit of the niche, and face of the
wall, and through the two extremities at the bottom
where the spherical surface rises from the body. The
back ribs may be circles of any radius, not greater
than the radius of the sphere, depending on the situa-
tion of the ribs; but of all the circles of the sphere
for back ribs, the arcs of great circles are the most

eligible, as the spheric portions between the planes
of the sides form the same angle with each of the
planes, whereas if the arcs of lesser circles are employ-
ed, there will be as many different bevels wanted as
there are ribs, and this will occasion not only more
workmanship, but a much greater waste of stuff.

When great circles are employed for the curvature of
the back ribs of a niche, they should be fixed so as
to intersect each other in one common axis, and this
axis ought either to be perpendicular to the horizon,
or parallel to it: the former disposition of the axis,
as it affords a good fixing, in general takes place.

PROOF XII. To find the ribs of a cylindro-
spheric niche, or a spherical niche in a circular wall;
so that the spherical surface may rise vertically from
the body, or that the cylindric surface may be tan-
gential to the spherical surface, given the plan of the
nich and of the wall, Fig. 1.

Let ABGHI be the plan of the wall, BCDEFG
the plan of the niche; now the thing required is to
form a front rib, so as to stand vertically in the cylind-
ric surface of the wall over the arc GH, which is
the seat of the cylindro-spheric line; also to form back
ribs, in order to fasten the lath and plaster.

Let all the back ribs be portions of great circles,
and let these great circles intersect each other in a
vertical diameter; and let the back of the front rib
be a portion of a less circle of the sphere, and the
face to be so excavated as to form a portion of the
surface of the circular wall. In order to do this in
the easiest way, get the front rib out of a parallel
thickness of stuff sufficient to work the face after-
wards, so that the lower ends may rest at B and H,
and the summit of the face of the said rib brought
to the cylindric surface of the wall; then this dispo-
sition gives the rib a reclining position from any part
of the apartment in which the niches are placed. To
determine the radius of the circle according to this
position, and to curve the front surface; let PQR be
the back line of the plane cutting the circular wall
in P and R; the distance between the outer line
PQR and the inner line BFH, is equal to the breadth
of the back ribs, and forms the plate on which they
are to stand; join PR, and from the centre O of
the plan, draw OQ at right angles to PR, cutting it in T;
draw GS parallel to PR, cutting the outer
edge of the plate at S; join TS, cutting the inside
of the plate at Y, and draw UV parallel to TS, at
a distance equal to the thickness of the front rib, cut-
ting OQ at U, and the inner edge of the plate at
V; draw VN parallel to SG, cutting OQ at N;
produce ST and VU to W and X; draw OWX
at right angles to SW.

Take the distances WT, UX, WY, XV, and
apply them in Fig. 2, upon any straight line CE, Fig. 2,
making CF, CO, CD, CE respectively, equal to
them; through C draw AB at right angles to
CE, and draw HI and MN parallel to CE; from
C, with the radius CD, describe the semicircle
AMDNB, and the arc MDN will give the under
edge of the back of the front rib: Again, from the
centre C, with the distance CE, describe an arc
HEI, and this will give the line on the face, before
it is formed to the curve of the wall, for ranging the
spherical or under side.
In order to curve the face of the front rib to the cylindric surface of the wall, divide the quadrant DN into any number of equal parts, as six; and draw ordinates to MN. In Fig. 1. through X draw \( ab \) parallel to PR, cutting CQ at \( a \); make \( ab \) equal to CA or CB, Fig. 2, with the semi-greater axis \( a b \), and semi lesser axis \( a N \), describe the quadrant of an ellipse \( b \) KLMN; transfer the divisions on GN, Fig. 2, to \( a \), No. 1, and draw the ordinates \( c d e \), \( i k l \), &c. to the quarter axis of the ellipse, cutting the line of the wall at \( d, g, k, \&c. \); extend the arc DN, Fig. 2, along the straight line Fig. 3, from \( N \) to \( e' \), from \( N \) to \( h' \), from \( N \) to \( l' \), &c.; draw the ordinates \( NG, e'd, h'g, k'h, \&c. \); and make them respectively equal to \( NG, e'd, h'g, k'h, \&c. \). Through the points \( G, d, g, h, \&c. \) draw a curve, and it will complete the envelope mould, which, bent round the under edge of No. 2, from \( D \) to \( n \), and from \( D \) to \( m \), and a line being drawn by the curved edge, will give the cylindro-spheric line, or line of concourse of the wall and niche; and, by cutting away the waste stuff from the front part, the front rib will be formed.

To form any of the back ribs represented by FN, EM, DL. CK, all tending to the centre O, suppose the rib upon CK to be formed, its thickness is here represented; but we shall suppose the centre of the rib to be the base: draw \( v x \) and \( w y \) perpendicular to CK, from the points where the thickness terminates upon the elliptic curve, till they meet the inside of the plate at \( x \) and \( y \); continue CK until it meet \( ab \); through the points of meeting, and through \( y, \) draw \( z \); parallel to which, draw \( x, \&c. \); then will CX, YZ be the inner edge of the rib, Z and z the outer edge, the dotted line the base, \( y, z, x, \&c. \) and the two sides of the joint at the top. This same rib is shown Fig. 4, 5, 6, at Fig. 4: in the same manner, Fig. 5, 6, and 7, will be found.

Fig. 8. is a bevel, which, being applied with the straight edge of it to the inside of the rib Fig. 2, and the wood cut away towards the front out to nothing on the under edge, at the same angle all round, and brought to its place, will form to the spherical surface of the niche, and to the cylindric surface of the wall.

A pendentive is a portion of a spheric surface, terminated on two sides by two vertical planes or straight walls, and a horizontal plane at the top.

A pendentive is therefore bounded on all sides by three circular lines, two of which are in vertical planes, and one horizontal.

Hence, if an apartment is built upon a square or polygonal plan, and from the interior faces of the walls, concave surfaces, which are portions of the same sphere, and which have one common centre in the axis of the apartment, spring upwards, and towards the axis, until they terminate in a complete horizontal circle, then as many pendentives will be formed as the walls have angles or sides.

If the springing lines upon the walls are semicircles, the pendentives will be portions of a hemisphere, having the angular points in a great circle passing horizontally through the centre.

If the springing lines are segments less than semicircles, the portion of the sphere from which the pendentives are formed, will be a segment less than a hemisphere.

The ichnography or plan of a pendentive ceiling is the triangular spaces formed by a square or polygon equal to that of the plan circumscribing a circle, the radius of which is equal to the radius of a circle which terminates the pendentives.

Pendentives are often employed in ceilings, in place of cylindric or cylindroidic surfaces, as in simple vaults, or in the composition of groins. The whole of the interior of St Paul's cathedral is vaulted with coves of this kind, which support the small cupolas. The beautiful interior of St Stephens, Wallbrook, has its dome supported upon eight pendentives over eight columns, disposed in the angles of an octagon. The ceilings of principal passages in large edifices are sometimes arched with pendentives, supporting rows of small cupolas, or flat circular ceilings.

The apartment which contains the principal stairs is most elegantly ceiled in this manner, whether the plan be square or oblong. If the plan be oblong, spheroid-cylindrical arches may be made in the length of the plan, by which means the pendentives may rise from the sides of a square. When the height will admit, semi-cylindrical vaults will have a more graceful effect than those, the sections of which are portions less than a semicircle. In this case, the pendentives will be bounded by four vertical semicircles, the planes of which are at right angles to each other.

Two of these semicircles will be formed upon the planes of the walls, and the other two by the intersection of the two semi-cylindrical vaults, which will form two spheroid-cylindrical arches.

Though pendentives are usually portions of a spherical surface, they may be portions of an ellipsoid, or of a regular polygonal dome; or of any figure, the horizontal sections of which are circles.

Let \( ABCDA \) be the plan of a pendentive ceiling, and \( GHKLEFG \) the section and interior elevation, the section being made by a plane parallel to one of the sides.

The pendentives are formed of ribs, which must be considered as sections of a hemisphere; the plan \( ABCDA \) must be considered as a portion of the hemispheric base; the springing ribs \( APB, BMC, CND, DOA \), are all semicircles of a diameter equal to the side of the plan, and supposed, in the execution, to be raised perpendicular to the plan. The ribs which form the ceiling are all formed of arcs which are portions of great circles, their planes bisecting each other in a vertical axis; and, as the diameter of the sphere is the diagonal of the plan, half the diameter will be the radius for all the ribs. The interior circle on the plan is the seat of the kirb. The only thing remaining to shew, is the length of the ribs, which are all different.

Prob. XIII. To find the length of the ceiling ribs.

Let it be required to find the length of the rib, the seat of which is \( a b c d a \); draw \( Y f e \) parallel to \( AD \); from \( Y \), with the distance \( Y b \), describe an arc \( b e \); and with the distance \( Y c \), describe an arc \( cf \); on the middle point \( Z \), of the side \( AD \) of the plan, describe the arc \( QR \), which gives the curve of
Carpentry.

Plate CXXV.

Fig. 9.

To Scarf a beam, is to join two separate pieces of timber, so that every superfluity of the one piece shall be respectively in the same plane with every superfluity of the other; or, in common language, that both pieces shall be in the same straight line, and flush on all sides with each other.

Hence it is evident, that if the joints consist of a plane or planes at right angles to two opposite sides of the beam, but not at right angles to the plane of the other two opposite sides, the side of the one piece of timber with which the oblique angles are made, will form the same inclination or inclinations respectively with the plane or planes of the joint, as the opposite parallel side of the other piece will make with the corresponding or coincident plane or planes of the said joint.

There are several methods of scarfing beams, either by the joint consisting of one plane or several planes, sometimes indented into each other.

Fig. 1. shows the method of scarfing a beam by indenting the joint at the ends, the planes of the joint being both parallel and perpendicular to the planes of two opposite sides.

Fig. 2. is the method of scarfing a beam with the coincident parts oblique to the two sides.

Fig. 3. shows the method of scarfing a beam when the joints are both parallel and perpendicular to the two opposite sides, by being banded and indented at the ends, and keyed between the tables.

Fig. 4. represents the method of scarfing a beam with oblique and tabled joints, and keyed between the tables.

Fig. 5. exhibits the method of scarfing a beam with parallel and perpendicular joints, oblique at the ends, by forming the end of each piece into a series of steps.

Fig. 6. shows the method of making a beam of two pieces of timber, when the length of the two parts are no more than the length required; for the whole, by inserting an intermediate piece on one side of it each way, with a double series of steps.

Fig. 7. shows the method of building a beam in two thicknesses, having the parts of each half scarf-

Naked Flooring is the arrangement of the timbers to support the boarding.

Floors are constructed by different methods, according to the bearing of the timbers. When the rooms have small dimensions, the floor generally consists of single joists. When the rooms are large, the floor consists of two rows of joists, the one supporting the other above, and framed at one end into a large beam, called a Girder, which is generally disposed in the middle of the transverse dimension of the space, if there are only two lengths of joistings, with another compartment of joisting upon the other side of it. If there are three compartments of jointing, there will be two girders. The lower supporting row of joists are called Binding Joists; and the upper which is supported is called Bridging Joists. The bridging joists are most frequently notched upon the binding joists, but not to the thickness of the binding joists; so that each edge of the upper side of the binding joists are also notched, leaving the breadth of the rising part equal to the breadth of the notches in the under sides of the bridging joists.

Fig. 8. exhibits the method of building a beam in three thicknesses, as the ribs of a dome such as the Halle du Bled, at Paris.

Fig. 9. represents naked flooring without binding Fig. 9. joists, but with a girder, into which the joists that support the flooring are framed, and the ceiling joists into deep joists which also support the boarding. No. 1. is a section shewing the end of the girder, and the ends of the ceiling joists. No. 2. is a transverse section shewing the ends of the boarding joists, the ends of the strong joists, and the sides of the ceiling joists.

Fig. 10. represents sections of a double floor. No. Fig. 10. 1. shows the ends of the girder, bridging joists and ceiling joists, and the side of the binding joists. No. 2. shows the ends of the binding joists, and the sides of the bridging and ceiling joists.

Truss Girders.

When girders are extended beyond a certain length, Truss girders become bent by their own weight, sagging downwards in the middle; and the degree of curvature will increase in a much greater degree than their lengths. An excellent method to prevent the sagging, without being supported by uprights, or posts from the ground or floor below, is to make the beam in two halves, and insert a truss so, that when the two halves are bolted together, the truss may be between them. In this truss, the two halves of the beam itself is the tie of the truss. To prevent any bad effects from the shrinking of the timber, the truss posts are generally constructed of iron, screwed and nutted at the ends; and, to give a firmer abutment at the ends, the braces are let in with grooves into the side of each half of the beam. The abutment at the ends is also made of iron, and is either screwed and nutted at each of the ends, and bolted through the

ed, as in Fig. 9. In this diagram, as well as in the four first, the joints are strapped across at the settings, and bolted on each side of the joint. The strapping is of great use in preventing the bolts from sinking into the wood.

Plate CXXVI.

Fig. 8.
thickness of both halves, having a broad part in the middle, in order that the braces may abut the whole dimensions of their section; or otherwise the two abutments are made in the form of an inverted wedge at the bottom, and rises cylindrically to the top, where they are screwed and nutted. These modes may be either constructed with one king-bolt in the middle, or with two truss-bolts placed each at one-third of the length from each end. When there are two bolts, they include a straining piece in the middle. The two braces may either be constructed of oak, cast or wrought iron; the latter material is, however, very seldom employed. As wood contracts less in length than most metals, oak is better for the purpose than cast iron; but then the parts of the core must be so much stronger. As to the bolts, wrought iron is indispensable. It is obvious that the higher the girder the parts will receive the less stress, and consequently there will be less risk of giving way by heavy weights, or long bearings.

Fig. 1. is the section of a girder, with two braces and king-bolt.

Fig. 2. is the section of a girder, with a straining piece, two braces, and two truss-bolts, of the most approved form, and certainly the best. No. 1. represents the girder laid open, in order to show the core; No. 2. shows the two halves bolted together; No. 3. shows the edge of a washer; No. 4. the face of the same; No. 5. represents the side of the butamental bolts in the transverse direction of the girder; No. 6. the side of the same in the longitudinal direction; No. 7. represents the transverse direction of the truss-bolts or king-bolt; and No. 8. the longitudinal direction of the same.

Fig. 3. The section of a girder, calculated from its rise to sustain very heavy weights. If the tie beam is very strong, the abutments may be wedged; but then it must be observed, that the wedge ought to be very long, that the laper may be very small, so as to have no inclination to rise, and then the excess of length may be cut off afterwards; however, the bolts represented at No. 5. and No. 6. Fig. 2. are to be preferred.

Fig. 4. represents the end of a girder, with part of the bending joints on each side of it. No. 1. shows the part of the bending joint fitted in, and the manner of cutting the mortice and tenon. The tenon thus formed, with the sloping shoulder with the small projection below the tenon, is said to be ducked; and the mortice cut to receive the tuskings, is said to be housed.

Fig. 5. represents the method of cocking beams upon wall-plates, according to the best method, which precludes every possibility of the beam being drawn from, or pushed farther over the wall-plate, without tearing the rising part away from the wall-plate, or splitting the piece away between the notch and the end, on the under side of the beam. The practice in former times was by a dovetail, the planes of the joint being perpendicular and parallel to the horizontal sides of the beam, two of the said planes being inclined to the vertical sides, at an equal angle to each adjacent side, and forming the dovetail at the bottom, or on the horizontal sections at the end of the beam, so as to be wider at the extremity than at the shoulder. If the timber were with-shrinking, and the joint closely fitted together, this would be an excellent method; but as we are certain that the timber does shrink, a small degree of shrinking will allow a very great draught. No. 3. represents part of the longitudinal direction of the beam, and section of the wall-plate; No. 2. represents part of the longitudinal direction of the beam turned up-side-down, to shew the notching.

Wall-plates are pieces of timber laid on the walls, Wall-in order to distribute the pressure of the roof equally plater, upon, and to bind the walls together. The wall-plates are sometimes called raising plates.

Trusses are strong frames of carpentry resolved into two, or a series of triangles, so as to make the truss act as a solid body, and thereby support certain weights, each at a given immovable point, the truss itself being suspended from two such immovable points. The trusses of roofs are constructed generally of a triangular form, and disposed equidistantly on the wall-plates, in parallel vertical planes at right angles to the walls. The top of the opposite walls are the two points of suspension, and the weights supported by the truss at the immovable points are horizontal pieces of timber running transversely to the planes of the trusses; the horizontal pieces of timber support other equidistant pieces parallel to the upper sides of the trusses; and these last timbers support the covering, or the covering and timber work, to which the covering is fixed. In a truss, some pieces of timber are in a state of tension, and some are in a state of compression; but a piece of timber, which is neither extended nor compressed, is useless. If a quadrilateral figure, or frame, be so constructed, that each two adjoining timbers be made moveable round a point at their intersection, it may be put into an infinite number of forms, because the whole frame will be revolvable about the angles; but if any one of the angles be immovable, the whole quadrilateral frame will be immovable. Two pieces of timber forming an angle, and revol- vable round a point at their intersection, may be made immovable by fastening each end of a bar to each leg, or by taking any two points in the bar, and fastening each point to each leg. Now, if a force be applied at any of the three angular points, the triangular frame will be immovable; but one of the two legs which form the angle will be in a state of tension, and the other in a state of compression, provided that the direction of the force applied does not fall within the angle produced; but if the line of direction of the force applied fall within the angle of the triangle, then both legs are either in a state of tension, or in a state of compression, according as the force applied is pulling or pressing. If one of the sides of the triangle be lengthened without the boundary, and a force be applied transversely to the part so lengthened in the plane of the triangle, this force will bend the side of the triangle, which is in the straight line with the side to which the force is ap- plied; therefore, suppose again a quadrangle or quad-rilateral revolvable about the angles, and a bar be fixed to any two sides forming an angle, viz. a point in the bar to a point in one of the legs, and another point in the bar to a point in the other leg; and sup- pose the two points not to be in two of the angles, or one of the points to be in the side, at some dis-
But if the bar be fixed to two opposite angles, and if the frame be held immovable at one of the angular points where the bar is fixed, and also at one of the other angles at the extremity of one of the legs of the said angle, and a force in any direction in the plane of the figure be applied to this angle where the frame is unsupported, and where the bar is not fixed, the frame will be by this means rendered immovable, and the force by this disposition will not occasion any transverse strain on the sides of the frame. Suppose the frame to be pentagonal, and a bar fixed in like manner to two angles, at the ends of two adjoining sides, two of these adjoining sides and the bar will form a triangular compartment in the figure. If the frame be suspended by two of the angles of the triangle, the three remaining sides will be moveable, at the extremities of the bar, round the remaining angles; but if another bar be fixed to any one of the three angles of the triangle at one end, and to one of the angles of the other three sides, to form another triangle, three of the sides of the pentagonal frame will be made immovable, and the two remaining sides will be so likewise. In like manner, of whatever number of sides the frame consists, by first forming a triangle of two of the sides, and fixing a second bar from any angle of the triangle to one of the other angles of the figure, at the remote ends of two adjoining sides of the frame, there will be formed another immovable side, and another immovable point at the next angle of the frame will be given; if from this fixed point, or any of the other three points, which are the angles of the triangle, the end of a third bar be fixed, and the other end of the bar to one of the remaining angles of the frame, so as to form a triangle with the second bar, and one of the adjoining moveable sides of the frame, or a triangle, with one of the fixed sides of the frame and the adjoining moveable side, and by proceeding in this manner successively, until all the sides are fixed, the frame will be made immovable; so that if any two angles of this frame be supported, and a force or forces be applied at one or each of the angles in the plane of the figure, the whole figure will be immovable. Frames of a triangular form, which have to resist only a simple force, or support one weight, are most simple and best constructed of three sides, the frame being suspended from two angles, and the force or weight to the other. A triangular frame, supporting only one weight, has no occasion for any subdivisions to contain the external space, provided the compressed timber or timbers were inelastic, so as to support their own weight without bending, and the timber incapable of extension. Though a frame should have to support several weights, the external figure may be of any form whatever, provided that the points from which the weights are hung, and the two points from which the frame is suspended, be all immovably supported, by comparing the figure with timber divisions, and thereby forming a succession of adjoining triangles, of which each two contiguous ones have a common side; that is, when two of the angles of each of the adjacent triangles are coincident. It may be proper to observe here, that though it may not be at all times eligible to divide a frame, so that all the compartments will be triangles, yet the succession must not by any means be discontinued, by the intervention of quadrilateral or polygonal figures; but these compartments may adjoin without injury to the truss. The triangle is the most simple of all rectilinear figures; it is also easier constructed, and better adapted to the discharge of rain or moisture in a roof, than any other figure; but in adopting it for large buildings, as several weights must be supported, and as there is only one point from which this weight can be suspended, it becomes necessary to take other equidistant points in the sides, in order to support the covering equally. These points may be made stationary by the former means, of dividing the interior space into a succession of triangular compartments. But if the two upper sides of the frame be of equal lengths, and equally inclined to the horizon, the opposite points may be made to counteract each other, without a concatenation of triangles, by introducing timbers from point to point parallel to the horizon; in this the compartments will be trapezoids, except the upper one, which will be a triangle. These beams may be supported by vertical bolts passing transversely through them from the points where the weights are supported, and the bolts may be nutted below the beams. This mode of securing the points of support depends entirely upon the doctrine of equilibrium; and thus a very little difference from the equality of forces might easily occasion a change of figure, to which the other method, by a series of triangles, is not liable. The securing of the points of support by beams is not confined to triangular frames; but may be applied to roofs having two or several rafters upon each side, so that their lengths and inclinations are equal, and their junctions on the same level. The beauty of every truss is to dispose the timbers in positions as direct to each other as possible. Oblique directions require timbers of large scantlings, and exert prodigious thrusts on the abutments, so as to compress the joggle pieces, and render the truss in danger of sagging. Trusses are variously constructed, according to the width of the building, the contour of the roof, and the circumstances of walling below.

Tie, is any piece of timber in a state of tension, viz. a piece of timber which is acted upon by two forces which have a tendency to a more remote distance.

Straining-piece, is any piece of timber compressed by two opposite forces, which have a tendency to a nearer approach; hence ties and straining pieces are affected in contrary directions. A straining piece requires an inflexible piece of timber; but a chain, or rope, or small bar of iron, will answer the purpose of a tie, provided that it is incapable of any farther extension than being drawn into a straight line.

Tie beam, the timber of the foot of the truss on
the lowest timber connecting the two sides for preventing the lateral pressure of the roof from pushing out the walls, and causing it to press vertically. When the tie beam is placed at the bottom, it is called a footing beam. The tie beam, besides its use in the truss, is necessary in supporting the ceiling floor. The tie beam is generally placed at the bottom of the truss; but in some buildings, in order to get a more lofty story, it is placed in a higher situation; but this disposition of the tie beam is dangerous, if very remote from the wall heads, as the weight of the roof will bend the inclined upper sides of the truss so as to make them concave outwardly. The want of the tie beam, or its not being placed at the bottom, is a great fault in the construction of Gothic edifices, as the roofs in most of these edifices have almost ruined the walls.

Principal rafters, are the two inclined pieces of timber in opposite sides of the roof fastened each to every end of the tie beam, which prevents their thrusting out the walls by the weight of the roof. The principal rafters are generally of equal lengths, and form a triangle with the tie beam when the roof consists only of two sides without a flat, and when the tie beam is laid on the wall plate.

King post, is a piece of timber in the middle of a truss, suspended at the upper end by the principal rafters from the apex of the roof, so that the king post divides the internal space into two equal compartments, each a right angled triangle. The use of the king post is to furnish a general support for the principals, and suspend the tie beam between the ends, so as to keep it from sagging.

Queen posts, are two truss posts, equi-distant from the middle of the truss, the one suspended from the head of the one principal rafter and the end of a beam on one side of the middle, and the other queen post from the head of the other principal and the other end of the beam on the other side of the middle; so that the queen posts divide the internal space of the frame into three compartments, of which the two extreme ones are right angled triangles, and the middle one a rectangle. The use of queen posts is the same as king posts, viz. for furnishing a general support for the principals at different points between the ends, by connecting timbers, and supporting the tie beam between its extremities.

Struts, are oblique pieces of timber, or braces, branching upwards from one, two, or several points in king posts and queen posts, to as many points in the principal rafters, or to as many points in the external frame. Struts are generally disposed in pairs, equally inclined to a vertical line passing through the middle of the plane of the truss, and the directions of each pair tend to the same point in this vertical line. Struts are necessary in large trusses consisting of long timbers, which have to support the covering at various points in the external frame.

Collar beam, is the piece of timber framed between the heads of two queen posts. A collar beam roof is necessary, where there is to be a platform, or wherever rooms are required to be formed in the roof, and to be of greater extension than the distance between the trusses.

Straining sill, is a horizontal piece of timber, disposed between the feet of queen posts, to counteract the efforts of the struts in pushing the queen posts nearer to each other.

Having thus mentioned the several parts of a truss, it may be proper to observe, that all king posts, queen posts, and tie beams, are ties, and therefore a string incapable of farther extension than sufficient to bring it to a straight line, or a chain, or a slender bar of iron, will answer the same purpose, as well as a piece of timber or other such inflexible material. Also, that all collar beams, principal rafters, and struts, are straining pieces, which are therefore necessarily constructed of an inflexible material, such as wood, or a stiff piece of iron. It may be farther observed, that in complex frames, such as centerings to large arches, or bridges, in the act of building, the same timbers, in different stages of the work, sometimes perform the office of ties, and sometimes that of straining pieces, and in the transition of office must be sometimes in a neutral state. The material employed in such situation, must necessarily be inflexible; this is not only to be recommended here, but in every doubtful case, or where it is uncertain whether the part of the truss requires to be a tie or a straining piece; since all, or most inflexible materials, may not only be employed as ties, but as a straining piece also.

Pole plate, is a beam over each opposite wall, supported upon the ends of the tie beams, or upon the feet of the principal rafters.

Purlins, are horizontal pieces of timber, supported by the principal rafters.

Ridge piece, is a beam at the apex of a roof, supported by the king post, or by the heads of the principals.

Common rafters, are inclined pieces of timber parallel to the principal rafters, supported by the pole plates, the purlins, and the ridge piece for supporting the covering, the material of which is sometimes large slates extended from rafter to rafter, and sometimes smaller slates nailed upon boarding, battening, or hung to lath, and these nailed upon the common rafters.

Joggles are the joints at the meeting of struts, king posts, queen posts, and principal rafters; and indeed all the joints of a roof may be termed joggles. The best form of the joggles is, that which is at right angles to the lengths of the struts or rafters, or at right angles to the tenoned piece; but this position cannot at all times be obtained, for the want of sufficient substance of timber; in this case, the joint is either made oblique, or the upper part in a line with the side of the piece which has the mortice, and the lower part perpendicular to the sides of the tenoned piece; or the joint is sometimes made partly parallel, and partly perpendicular to the morticed piece. When the joint is oblique, the force of the tenoned piece in a direction of its length, causes the end to slide upon the abutment towards the side which contains the obtuse angle, but this is in some degree counteracted by the resistance of the tenon on the lower end of the mortice. However, with regard to the stress of the timbers in a frame, the abutting joint is of little importance. M. Perronet, the celebrated French engineer, formed the abutments, and const-
Carpentry.

Plate CXVIII.

Fig. 1.

The timbers of this roof are well disposed, but the iron king post is of little more use than supporting the middle of the tie beam.

The remaining figures in Plate CXVIII. show the various joinings, in roofing, of king posts and principal rafters; of tie braces and principal rafters; of principal rafters and tie beams; of struts and truss posts; of dragon pieces, angle-ties, and wall plates, with the various methods of bolting and strapping these various parts together.

Fig. 4. No. 1. represents the method of joining and Fig. 4, No. 2, the principals meet each other without the intervention of the king post, which is omitted, in consequence of the shrinking of the wood between the joggles.

Fig. 4. No. 2. exhibits the method of fixing the king No. 2, post and tie beam, showing the manner of strapping the same. Fig. 4. No. 3. Shows a section of part of the No. 3, king post through the mortice for the keys, with the manner of wedging the same. Both the mortice and the resisting piece of iron on the upper side of it, are cut with a greater vertical dimension, than what the width of the two wedges are, so that the head of the mortice through the wood goes higher than the head of the mortice through the iron; so also does the bottom of the mortice in the wood go higher than the bottom of the mortice in the iron.

Fig. 5. shows the manner of securing the king post, Fig. 5, principal rafters, and tie beam. No. 1. shows the form No. 1, of the joggle joints, and the manner of strapping the king post and principals, the king post intervening; but it is to be hoped, that this intervention will be relinquished in practical works. No. 2. The manner of No. 2, bolting the lower end of the king post and tie beam, the nuts being double, and their directions, in two planes, intersecting each other at right angles; and also at right angles to the intersection, which is also the axis of the bolt; and the one direction perpendicular, and the other parallel, to the plane of the truss.

Fig. 6. shows the method of hanging the beam, and Fig. 6, supporting it at the foot of the struts. No. 1. The two rafters, suspending a double or branched rod for supporting the lower ends of the struts.

Fig. 7. represents the method of securing the lower end of the principal to the one end of the tie beam. No. 1. The two parts secured together by means of an eye bolt. No. 2. The manner of cutting the tenon. In this, the principal is thinner than the tie beam, so that the end of the tenon forms the outer abutment, and the part on the inside of the rafter at the bottom, the

Fig. 3. represents the truss of the roof of the Royal Hospital at Greenwich. The design was by Mr James Stewart, author of the Antiquities of Athens. It was executed by Mr Samuel Wyatt, about the year 1785.

The distance of the trusses is about 10 feet 6 inches; each truss contains about 198 solid feet of timber.
inner or second abutment; both these abutments being at right angles to the rafter.

Fig. 8. represents another method of securing the rafters and tie beam. No. 1. The two joined together.

No. 2. The end of the beam showing the socket.

Fig. 9. shows the method of joining the struts and king post when there is a deficiency of wood at the joggles. This also shows the method of forming the dovetail on the tenon which goes into the beam.

Fig. 10. shows the method of joining the wall plate at the angles. No. 1. The horizontal projection, showing the diagonal tie and dragon piece which contains the socket for the feet of the principal rafters. No. 2. The elevation of the high rafter framed into the dragon piece. No. 3. Shows one side of the wall plate with the sockets.

As all timber will shrink unless it has been seasoned for a considerable time, and, as the time which it requires to season must depend greatly on the thickness of the timber; so the timber in all large roofs, constructed with king posts and queen posts, will also shrink; and as the timber is large, the time required must be very long, and perhaps even then not to be depended upon. It has been found, that roofs have sustained very considerable injury by the shrinking of the timbers, in causing them to sag and press down the other parts of the building connected with them, which ought to have been supported by the roof, and by this means not only destroying the interior ceilings, by producing large fissures in the plaster of the partitions, particularly at their junctions with the exterior walls, but also destroying the appearance of the exterior. Now it has been found, that timber contracts very little in the length, even less than many of the metals, and that the evil chiefly arises from the shrinking of king posts and queen posts between the joggles. To remedy the defect, it is here proposed to have neither king posts nor queen posts, and, instead of them, to substitute long rods of iron, which will perform the office of tie braces, by suspending the tie beam, either in the middle or in two equidistant places, by one or two iron bars depending from the apex of the roof; and by pitching the lower ends of the struts upon the one or each of the places on the tie beam, supported by the iron bar or bars; the upper ends of the said struts supporting the principal rafters between their extreme points at the required points where they are loaded by the weight of the covering, and again by suspending other rods of iron from these points to the tie beams; and thus a series of equidistant fixed points of any required number, supporting both rafters and tie beam, will be found, as may be judged necessary, and without the smallest danger of shrinking, and at less expense than truss posted or joggle posted roofs, strapped or bolted to tie beams.

The iron of the straps and bolts in common truss roofs, are of considerable expense; the trouble of boring, fitting in bolts, or wedging straps, is very great; and the making of king posts and queen posts with joggles still greater, and the timber out of which they are made increases the expenses; so that all these sundries taken together, would be more expensive than rods nutted and screwed.

with struts and tie braces, calculated to span from 40 to 50 feet, according to the strength of the timbers and iron braces.

Fig. 2. represents the design of a roof constructed with struts and tie braces, calculated to span from 60 to 80 feet, according to the strength of the timbers and iron work. The tie braces are here, and in the last roof, supposed to be screwed and nutted above the rafter, and below the tie beams.

Fig. 3. shews a truss posted roof, with a king post and a pair of side posts on each side of the king post, calculated to the same extent as the last roof; but, from the number of joggle pieces between the struts, a very small degree of shrinking in each will loosen the struts, and consequently deprive them of their office of supporting the rafters and tie beam. This circumstance cannot take place in any of the former figures; and it may be farther observed, that the straps and keys which are used in this design, will go a great way towards the expense of the long iron screw bolts; and it may here be again repeated, that the trouble of forming the truss posts with square abutments at the joggles, the fitting of the iron straps, and the cutting of the mortices for the wedges, is much more trouble than the boring and screwing of the bolts. The expense of the materials of the straps and keys, and of the timber of the truss posts in this roof, would exceed that of the bolts and nuts in the last roof.

Fig. 4. exhibits a design for a roof, which may admit of an arched ceiling. The peculiarity of this roof is, that the ties extend to the lower extremities of the principals, and rise in the middle, so as to give greater elevation to the vaulted ceiling. This roof was designed and executed by Mr. Revelley in the church at Southampton, about the year 1797, and perhaps was the first construction of the kind in this country. The two ties are halved together at A; but the parts AB, AC perform only the office of ties, or are in a state of tension; while the parts AE and AD perform the office of struts, or are in a state of compression. The king post AF, or an iron bolt, is a necessary part of this construction, and cannot by any means be dispensed with.

On Domes.

Having now given some of the best forms of common roofs, we shall next proceed to domes, and show how they may be constructed under various circumstances.

If the dome be spherical, and have no lantern to support the ribs, it may be constructed of boards in two or three thicknesses, with the longitudinal joints of the boards tending to the axis of the dome, and intersecting the spherical edges, and the abutting joints intersecting the sides of the ribs which tend to the said axis. Let us now suppose the thickness of a rib to consist of three boards, and suppose the circular pieces, which are to compose the ribs, to be all prepared of equal lengths and breadths; take one of the lengths, suppose for the left hand piece at the bottom, and lap the next higher length, which is the middle piece, two thirds upon the lower piece; take another length for the right hand piece next higher,
and lap this two thirds on the middle piece, so that the right hand piece will lap one third upon the left hand piece; between the ends of this third screw, spike or pin the three boards together; the middle board will want a third, the right hand board two thirds to make it complete at the bottom. These parts being supplied and fixed, lay another board at the higher end of the right hand board, the end of another to abut upon the higher end of the middle board, and the end of a third board to abut upon the upper ends of the left hand board; then there will be three plies of boards, which must be fastened together between each pair of heading joints, which are three in number. Proceed in like manner with every succeeding three boards as with the last three, until you arrive to the top, and the deficiency must be supplied as at the bottom. In this manner, every rib in succession must be constructed until they are all finished. Each rib ought to be fitted to the curvature of the axial section of the dome drawn on a floor, and the three thicknesses fixed together throughout the whole length before it is removed. If, in addition to the fixing, the joints be strapped, it will add considerably to the strength, and will not be much inferior to the strength of a solid piece. In large domes of this construction, it becomes necessary to discontinue the ribs, otherwise an unnecessary quantity of timber would be employed; and it should be observed, that the greatest intervals must be so regulated in their dimensions, as not to be greater than what would make the horizontal ribs for the boarding, when fixed, sufficiently strong.

Fig. 5. is a dome of this construction. No. 1. the elevation; No. 2. an ichnographical projection. In this design, the ribs are only once discontinued, but in large works they may be twice or several times discontinued. The wall plate and kirk at the top, are framed in the same manner as the ribs.

As all domes are best boarded with their joints in vertical planes tending to the axis, horizontal pieces must, in this case, be strutted between the ribs, and their outer sides formed with the spherical surface. A dome constructed in this manner, might also be made to support a heavy lantern, provided the strutting pieces were supported together.

In the above manner, was the timber dome of the Halle du Bled at Paris, constructed by Moulineau, which is supposed to be the first of the kind.

If the boarding of the dome is required to be bent with the joints in horizontal planes, and the dome have no lantern, a very good method is to construct it with several horizontal ribs, disposed at equal angles round the axis, as their common vertex. According to the above method, between every pair of such ribs place other ribs, the curvature of which will be portions of less circles of the sphere, unless one stand in each interval, and its plane bisect the inclination of the vertical planes of the two adjacent principal ribs: dispose of these ribs in equidistant parallel planes, and fit their upper ends upon the sides of the principal ribs. This disposition of the ribs will be a considerable saving of timber, besides what it would have been had all the planes of all the ribs tended to the axis.

Fig. 6. is a design for a dome constructed in this manner: No. 1. the elevation, and No. 2. the ichnographical projection.

If the dome is required to have greater height on the exterior side of the building than can be given by employing ribs built as above, the curved part of each rib may be supported upon a vertical truss, and the inter-curves of the ribs fixed to the under sides of the truss; and if a lantern is required, the better method is to place the lantern in its situation, and then to place the ribs; the curved parts which form the exterior and interior domes, will be fixed more accurately after the ribs are put up. In each of these trusses it will give much less stress to the timbers, if one of them inclines upwards its whole length from the wall plate to the lantern, as these timbers in every truss will support the lantern of themselves, being only compressed in a direction of their length, and it should be observed, that the abutting parts on the lantern should never be on the middle of the sides, but upon the angles of the posts, and that small beams or interstices ought to be framed between the posts opposite the abutting places. These inclined timbers having a tendency to bend by the weight of the lantern, will hardly require any other trussing than what is sufficient to keep them from sagging by their own weight; and it is evident that they can only support the lantern when it is properly balanced. The lantern will therefore not be proof against the variable force of the atmosphere; a gust of wind would soon put it out of its place. If the trusses consist of two triangles, a piece of timber may be made to reach from the lower end of the lantern to the middle division of each truss; and these braces will render the lantern secure from atmospheric power. It is evident that the disposition of these pieces and the upper trussing timbers must be made to accommodate the curvature of the exterior and interior domes. The trussing might have been done without, provided the slanting timbers which support the lantern were strudled in horizontal equidistant rows, and the exterior curve might have been supported by radiating pieces.

Fig. 7. shows the lantern, and one of the trusses on each side of it. The pieces AB, AB, are two of the inclined pieces supporting the lantern; and the pieces CD, CD, secure the equilibrium against wind, or sudden impulse.

Though any elevation might be given to a dome by this last method, and the timbers might even be made so secure as to support a lantern of stone of considerable ponderosity, yet, as this material is liable to decay, and would therefore be subjected to frequent reparations, a vaulting of stone may be carried from the cylindric walls upwards, in the form of the frustum of a cone, with its axis vertical, and the lantern built upon the top of this vaulting. If the exterior dome is to be formed of timber-work, the ribs may be constructed in three thicknesses, as in the Halle du Bled, or in single pieces scarfed together, and supported by posts and beams, which mutually support the extremities and bearings of each other.

The dome of St Paul's cathedral, designed by Sir Christopher Wren, is of this construction. The in-
terior, or lower dome, consists of 18 inches brickwork, and several courses of whole brick, bonding the entire thickness of the spheric arch, at five feet distance. This dome, as we are informed, was turned upon a centre which supported itself without any standards from below; and this centering remained for the use of the painter. The interval between it and the dome was twelve feet. This dome is hooped with a double chain of iron at the base, to prevent any risk by its lateral pressure. A cone of eighteen inches brickwork supports the exterior dome, the beams being tied to stone corbels by iron cramps, which are well bedded in lead, and bolted to the beams. The stairs which lead to the golden gallery at the top of the dome, are carried up between the trusses, or between the brick cone and the external dome. The boards are bent from the base upwards to the bottom of the lantern, having their joints in planes tending to the axis. The repandous sides of the exterior dome are framed of segments of circles, which would meet, if produced in a point on the axis. The brick cone supports a lantern of Portland stone, of 21 feet diameter, and near 64 feet high. The diameter of the dome is 104 feet, and there are 32 trusses in its circumference.

Fig. 8, shows the elevation of two opposite trusses; the sections of the brick dome and cone:

A. One side of the section of the interior dome.
CD One side of the section of the brick cone.
EF Repandous side of the exterior dome.

The hammer-beams are marked by the small letters a, b, c, &c.; and the posts by the numbers 1, 2, 3, &c.

The struts are all five inches by eight: the scantlings of the other timbers, denoted by the small letters and numbers, are as follows:

The curve ribs of the dome are 10 by 11½ inches at the bottom, and 6 inches square at the top: the purlins which support the boarding are 4 inches square.

Fig. 9, shews part of the brick cone, one of the stone corbels, with part of a hammer-beam connected therewith by means of an iron strap bedded into the stone with lead, and bolted to the hammer-beam.

The construction of this dome and truss is, upon the whole, very judicious, and the timbers are well disposed.

Centerings to Arches of Bridges.

Center, in carpentry, is a frame of timber constructed for the purpose of supporting the stones or bricks of an arch or vault during the erection.

The center, therefore, serves as a foundation to build the arch, and is taken down, or struck, at the completion of the work.

The centre of a large vault, as that of a bridge, is constructed of trusses disposed equidistantly in vertical parallel planes, and boarded over, so that the convexity of the boarding may coincide with the internal intended concavity of the arch. The distances of the ribs may be disposed at from 3 to 8 feet, according to the strength of the boarding and the ponderosity of the arch. In very large works, a bridging is laid for every course of arch-stones, with blockings between, to keep the ring-stones at regular distances; but the ring-stones do not always rest upon these bridgings; planks are sometimes put between, that they may be cut away afterwards, and separate the centre and the intrados from each other, in order to ascertain whether there are any settlements in the arch, and to repair the damages and put the arch in a state of equilibrium.

The principle of trussing having already been given under the department of Roofing, little more requires to be said than a few observations upon the forms of trusses applicable to centering.

The river is not navigable, the trusses may be constructed with a beam at the bottom. In this case there is no difficulty; the forms for the trusses of roofs may form the grand or principal part of the truss for the centre; but when the river is navigable, the centre requires as large an opening as is consistent with its strength, in order that the vessels may pass under it, and the disposition of the timbers will require much greater skill of the carpenter.

The general principle of construction is a series of triangles, of which every two is connected by a common side.

Let ABCDEFG, Fig. 10, be the curve of the arch which requires a centre. Let the points A, B, C, &c. be connected so as to form the equilateral polygon ABCDEFG, and join AC, CE, and EG; the timbers thus disposed will form three triangles, which may be looked upon as so many solids revoluble about the angular points A, C, E, G; suppose now these to be in equilibrium, the smallest force on either side would throw it down, and therefore without other connecting timbers, it would be unfit for the purpose of a centre.

Let ABCDEFG, Fig. 11, be the curve of an arch which requires a centre; first form the equilateral polygon ABCDEFG, with the timbers AB, BC, CD, &c. and fix the timbers AC, CE, EG, as before, which will form three triangles, moveable round A, C, E, G. Let the timbers BD and DF be fastened, and thus the whole will be immutable, so that, if supported at the points A and G, and a force be applied at any other of the angles B, C, D, or F, the timbers will be all in a state of tension, or in a state of compression, and the whole may be looked upon as a solid body. For since the sides and angular points of a triangle are fixed, when the triangle is supported at two of the angles, and a force applied to the other, let us suppose the triangle ABC to be supported at the points A and B, and the point C, and the other
CARPENTRY.

Carpesium, CAR.

CARPESIUM, a genus of plants of the class Syngenesia, and order Polygamiia Superflua. See Botany, p. 297.

CARPET, in the manufacture of cloth, is a species of woollen stuff, made of variegated colours, and used for the floor cloths of rooms.

The manufacture of carpets, we may reasonably conclude, originated in Asia, from whence most of our knowledge of the manufacture of cloths of almost every description appears to have been derived; and to this day, the finest and most expensive of the ornamental kinds are distinguished by the name of Turkey carpets. They are now, and have long been, manufactured both in France and Italy, and those used in Britain, of internal manufacture, are equal both in fabric and design to any imported. In England they are generally called Wilton carpets, from the county which is the chief seat of that and the other finer branches of the woollen manufacture. Some manufactures are, and have been long established in Scotland, of which Stirling and Kilmarrock are the chief seats, but they are generally confined to the coarser and low priced kinds.

Carpeting possesses this peculiar property, differing from almost every other kind of cloth, that it consists of two distinct webs, woven at the same time, and firmly joined together by the operation. Hence arises that common effect, that on the two sides of a carpet the form of the pattern is the same, but all parts may be constructed all in the same plane, and the pieces BD and DF may be halved upon the pieces CA and EG; but the utmost care must be taken to secure the several pieces concouring at each of the angles, by bolting or iron straps, as much dependence can be put in any such joint without iron; but perhaps the best method of any is to halve the thickness of the pieces AC, CE, EG, at the points C and E, and also the pieces AB, BC, CD, DE, EF, FG, at the points B, D, F; then bolting the ends A and C of the pieces BA, BC, the end C and E of the pieces DC and DE, and the ends E and G of the pieces FE and FG, and then fixing double braces BD, DF, that is, fixing BD upon one side of the truss, and another upon the other side of the truss opposite to it, also fixing DF upon one side, and another opposite to it.

Fig. 12. represents the manner of constructing a Fig. 12. centre according to the principles of Perronet, the celebrated French engineer, but the disposition of the timbers, forming only a series of quadrilaterals, gives nothing but immutability of figure. It can, therefore, only derive its stiffness from the resistance of the joints.

Having thus given a general account of the principles of Centering as connected with the article Carpentry, we must refer our readers to the article BRIDGE for its application, and other practical remarks in the construction.
Double Cloth Carpets.

If we suppose these to be composed only of two colours, the principle of weaving them may be very easily explained. It is only necessary to raise the warp of each web alternately for the passage of the shuttle, the upper web being entirely above when the under web is woven, and vice versa. A representation of the carpet draw-loom, will be found in Fig. 1. Plate CXXX., which is a transverse section of a carpet loom, showing that part which is called the harness. The manner in which this is done, in the real loom, are four leaves of heddles, two being allotted for each web; but as these differ in no respect from common heddles, excepting in the length of the eye, they are not represented. The form of the eye which is common both to the carpet and damask draw loom, will be seen by examining Fig. 5. In draw looms of every kind, there is no sinking of any portion of the warp, as in plain cloth; the general body of the warp is therefore placed low, and the threads under which the shuttle is to pass are raised, all the others remaining stationary. The harness part of the loom is moved by a boy or girl, placed to assist the weaver, by moving the harness whilst he inserts the woof, and works the front mounting or heddles. Fig 4. A represents the frame work of the loom; B is a box or frame of pullies, over which the cords of the harness pass, and are then made fast to a piece of wood, which the weavers call a table, and which will be seen at E. From the tail of the harness the simples descend, and to the end of each is attached a small handle, called a bob. These handles being disposed in pairs, and their regularity preserved by means of a perforated board, it is only necessary to pull every handle in succession; the weaver, at the same time, working the treddles with his feet exactly as in any other loom. The treddles are four in number, the fabric being that of plain or alternate cloth, and two treddles allotted for each web. The harness part of the carpet draw-loom is furnished with mails, or metallic eyes, to avoid friction, and two threads are drawn through each eye. The design of a carpet is drawn upon cross ruled paper, exactly in the same way as every other species of fanciful loom work, and is transferred from the paper to the mounting, by rules so entirely similar to those used for damask and all the branches of ornamental weaving, that a very short description will be abundantly sufficient. It may, however, be of use shortly to advert to the general principle upon which the particular application of the harness to the weaving of carpets depends; for a little consideration of general and elementary principles must, in every art or science, prove of the greatest utility to those who wish afterwards to qualify themselves for an extensive knowledge of their particular application. Suppose that two webs then, are so mounted, that every alternate thread of the one may be raised, so as to form an ample passage for the shuttle, without at all depressing the other. Then suppose another web placed above the former, at such a distance that it will exactly touch the summit of those threads of the former which are raised. Then if the threads of the latter web are sunk, while the others are raised, the two would be entirely incorporated. But if this be only partially done at particular places, only those parts immediately operated on will be affected by the action of the apparatus employed. Supposing the carpet is to consist of two colours, as green and yellow, and that on the upper surface, as stretched in the loom, yellow flowers or ornaments are to be represented upon a green ground; then all those species of design paper, which are coloured, may be supposed to represent the yellow, and those which are vacant the green. Then counting the spaces upon the paper, omit those which are vacant, and cord those which are coloured, and the effect will be produced. But as the two webs are to be raised alternately, whatever is cored for the first handle must be passed for the second, and whatever is passed for the first must be cored for the second. Thus the handles being placed in pairs, one will produce the flower, and the other the ground. Fig. 2 and 3, are profile elevations of the carpet draw loom. Fig. 2, represents a section of the harness; the box of pullies being at B, the perforated board or regulator at C, and the suspended weights at D. In Fig. 3, the box or frame of pullies is at B, the board by which the simples are regulated appears at F, and the handles or bobs at G. In both figures, the portion of the frame work of the loom which is visible, is distinguished by the letter A.

Turkey and Wilton Carpets.

These carpets are merely woollen velvets, with various colours, and their principle is, in every respect,
entirely the same. To form the pattern, or design, the manner of applying the cords is entirely similar
to the damask draw loom. Where the filling is
afterwards to be cut, it is common to introduce
grooved wires, which serve as guides to the knife, and
these may be cut out as soon as a sufficient quantity
of cloth has been woven, to secure the warp from be-
ing entirely cut away from the cloth. A very great
variety of hearth rugs, bottoms for chairs, stools, and
other kinds of ornamental furniture, are woven upon
this principle. For lobby and stair carpets, many
are woven merely as plain cloth, the warp being of
variegated woollen yarn, so very closely set together,
and confined in the reed, as totally to cover and con-
cel the wool. In this case, the woof may be of
slack turned hempen cordage, very thick. This not
only forms a very stout and durable fabric, but from
the coarseness of the hemp, gives the whole fabric
the appearance of a narrow stripe, not dissimilar in ef-
cfect to corduroy.

It seems somewhat singular, that no attempt should
have been hitherto made to apply mechanical power to
the weaving of any of the various and extensive branches
of the woollen manufacture, while so many attempts
have been made, hitherto without much success, in
the cotton and partially in the linen. The recent in-
vention of the cotton machinery has, no doubt, given to
those employed in that manufacture, a greater acquain-
tance with the application of mechanical agency; and
the beneficial effects of the rapid succession of improve-
ments, must have greatly weakened that dread of innova-
tion which operates so strongly on the human mind,
especially where antiquity and long established usage
have thrown a sort of veil of respect, and almost vena-
tion, over what has passed through many successive
generations, almost without alteration. The very
circumstances of any art being long practised with
little variation or improvement, seems to warrant a
presumption, that it has already approximated as
nearly to perfection as can be reasonably expected;
and this sort of reasoning is certainly entitled to very
considerable consideration before rash innovation is
attempted. Every department, however, of the woollen
manufacture, seems to present to the judicious speculator a field for further improvement, and facilities
for its accomplishment, beyond any of the other
branches of the cloth manufacture. The raw ma-
terial of itself presents very great advantages. It
is not only long and stout in the fibre, but powerfully
elastic. Hence it is admirably fitted to oppose that
reaction to the power of machinery, the want of
which is the most powerful obstacle in the cotton,
and still more so in the flax. When, to these con-
iderations are added, that of its requiring no aid of
chemical preparation, the most powerful objections
to every kind of weaving by machinery hitherto at-
tempted are at once removed, and the mechanic has
nothing to impede him, provided he judiciously ap-
plies the mechanical powers in the most efficient and
simple form. These considerations have induced the
author of this article to pay some attention to what
appeared to him an object, not only of immense nation-
al importance, but which has most unaccountably been
totally neglected. In Plate CXXX. Fig. 6; 7, will be
found a plan for the construction of a carpet draw loom,
every operation of which is performed entirely by me-
chanical power, and which, instead of requiring a man
and boy, performs every function of both. Conse-
sequently it would only require a casual superintend-
ance; and perhaps a few boys, under a careful and juri-
dicious overseer, might be sufficient for a manufactory
of twenty or thirty looms. Only that part is repres-
ented which is peculiar to this particular species of
weaving; the other parts, which drive the shutter
and shift the boxes, being not necessarily different
from any of the plans given under that de-
partment of the article Cloths MANUFACTURE, which
are woven, has been, and may be, regarded as the for-
ter, nor from the plan given for shifting the boxes
from that described and represented for check and
pullicate lays under the article Check. The novelty
and originality of this plan, is chiefly in that part
which is adapted to move the harness automatically,
and even this is so very similar to what has long been
successfully applied to moving the keys in the com-
non barrel organ, as hardly to come under the de-
scription of a novelty merely speculative. The pro-
posed loom, in order to afford the utmost possible
room for every part of the apparatus, and also to be
erected with a due regard to economy of expence,
reaches entirely from the floor to the joisting of the
shop. This no caps and few cross rails are at all
necessary, and the whole framing consists of five
strong upright posts, with only four rails for fixing
and supporting particular parts of the machinery.
It is obvious, that for an operative weaver renting
merely a loom-stance, and subject to frequent remo-
vials, a plan of this kind would be liable to serious ob-
jection; but it is hardly presumable that any com-
pany or individual would embark capital in an exten-
sive manufactory driven by mechanical power, with-
out having previously secured the permanency of si-
tuation, for at least a considerable term of years.
Hence economy in constructing machinery, when not
injurious to its strength and efficiency, becomes a
very important feature in the plan of erection. Fig. 6.
is a transverse elevated section of the loom, imme-
diately in front of the harness; the following de-
scription of which, it is hoped, will enable any person
conversant with the common modes of carpet weav-
ing, to ascertain the scope of the projected improve-
ment. In this figure, the two back posts strongly
secured to the floor and to the roof, are represented
at AA; the frame or box of pulleys at C; the per-
fornated, or regulating board for the harness, is at
DD; and the suspended weights which lighten the
harness appear below at EE. An additional post,
perticular to the power loom, is represented at F.
This post serves to secure that part of the harness
which is called the tail at B, in the same way as the
table does in the common carpet draw loom, and be-
low at G; serves for one end of the axis of the bar-
rel G, which raises the harness, and supersedes the
use of a draw-boy by revolving, upon its own axis.
The other end of G may rest either upon a vertical
or horizontal post, which is not represented. On
the end of the barrel is a ratchet wheel, which may
either be placed to the right, as in Fig. 6, or to the
left, as in Fig. 7. If the former be adopted, the
atchet H may be driven merely by a stud in the

Plate
CXXX.

Fig. 6, 7.
Construction of the Barrel.

To those who are conversant with the principle of the construction of barrels for organs, chimes, and other automatical engines, that which is necessary for a carpet draw-loom, will not appear very difficult; but for the use of mechanics who may wish to understand the principle of this machine, it may perhaps be proper to enter a little more into detail. The barrel may be hollow, and built of thick and well seasoned planks, upon rings of cast iron, wedged, or otherwise firmly fixed upon the axis, which may be either of malleable or cast iron; but the former is certainly preferable in every respect. When the cover is firmly joined by glue and countersunk screw-nails, it is to be very truly and straightly turned; and where it can be conveniently done, this operation will be better performed in the bushes or centres in which it is afterwards to revolve than elsewhere. When this has been done, it is only necessary to ascertain the places for the projecting pins; and these will be much firmer and less liable to accident, if screwed, than if driven into the cover or circumference of the barrel. In order to ascertain with precision the proper diameter of the barrel, regard must previously be paid;

1st, To the extent or number of changes required in the pattern to be formed. This will be easily found by referring to the design, as in mounting the common carpet draw-loom; for if the pattern is the same, just as many sets of forks or pins will be required for the power loom as there are bobs or handles for the common loom.

2dly, The range which is required to open the shaft each time to a sufficient depth; and this may be found by attending to the principles upon which the agency of the barrel upon the mails of the harness depends. Let us suppose, for example, that the depth of shed formed by the harness requires that the mails should be lifted three inches. Then as this is to be effected by the deviation of the tail part from the straight line, and that as one extremity of the harness only is moveable without entering into all the nicety of trigonometrical calculation, it may be assumed that the lashes will descend to raise the mails in the ratio of 2 to 1, or nearly so. If then the barrel must move six inches at every shift, a very large diameter indeed would be required for a very moderate range of pattern; and yet this, where it is practicable, will be far the easiest and cheapest method. Taking, therefore, the shift of the barrel at six inches each, a barrel six feet in diameter would only work a pattern of about forty changes. But in more extensive patterns, the barrel must be extended to a size, which would be totally impracticable. Means must therefore be used to counteract this inconvenience, and fortunately these are simple and obvious. It is obvious, that in the way in which the lashes are fixed in the common carpet-loom, they are well calculated for their purpose; for a child will find little inconvenience in pulling a handle six inches down, but would find his strength totally inadequate to raise a great number of weights suspended to the harness, were the mechanical power against him. Upon this obvious principle it is plain, that a few small blocks placed above the barrel, to invert the power and increase the range of the mails in rising, will at once do away the inconvenience, and consequently it will be easy to reduce the size of the barrel, and increase the range of the weights in whatever ratio may be found practically convenient. Where the agency of water or steam is employed, the loss of power can be an object of no consideration; and no judicious mechanism can be at a moment’s loss to construct them with any number of sheaves suited to his purpose. It is simply the apparatus employed to shorten the range of the weight which moves a common roasting jack. A few levers also might be very easily so disposed as to produce exactly the very same effect. For a cheap and simple practical substitute, large glass beads, with a proper number of smooth holes, and the cord rubbed with black lead, would do very well.

In the profile elevation, Fig. 7, not only the general appearance of the loom will be exhibited in a different point of view, but also some parts not shewn in Fig. 6, and between both every thing of consequence will be found. A recapitulation of the whole reference letters will therefore be sufficient for what appears in Fig. 6, and a short description for those which do not. AA are two of the upright posts extending from the floor to the roof, and firmly secured to both. B is the post for the barrel, and is here supposed to be fixed at the top to a cross rail, nailed or screwed to the roof. C, D, and E do not appear, being behind the post B. F is the end of the axis of the barrel appearing through the upright post, and G the barrel itself, the ratchet being here placed to the left hand. H is the catch by which the ratchet is pulled. I the lower part of the
lashes fixed like the samplers of a common draw-loom, the lashes forming a small curve, in order to ensure a constant pressure against the barrel. \( K \) and \( V \) the wheel and pinion, by which the barrel is moved round. \( L, M, Q, \) and \( P \) do not appear, the view being the opposite side of the loom. \( N \) shows one of the heddles, the wipers which move them being concealed by the wheel \( K. \) \( Q, \) the lashes. \( R, \) the pulleys which support the four leaves of heddles omitted in Fig. 1, and the heddles themselves appear at \( S. \) \( T \) is the lay and reed, at \( U \) are the rods for the two warps, and at \( V \) the double cloth. The two beams are at \( a b \) and the tension of the web is preserved by two inverted balances, the lighter weights being at \( X, \) and the heavier suspended on levers at \( Y W. \) The levers acting as steelyards, the tension may be increased or diminished at pleasure, merely by moving the weights.

It has been deemed unnecessary to specify particularly any way of moving the web from one beam to the other, because three different plans will be found, which are in actual use in the representations and descriptions of power-loomos, given under the article Cloth Manufacture; and either of these may be applied to this loom with equal facility as to any other. It is, however, necessary, in order to complete the automatic properties of the loom, either that one of these, or some efficient substitute for them, should be adopted. The shuttle and lay motions being also common to all power-loomos, are therefore totally omitted here.

The above description will probably enable an intelligent mechanic to comprehend the principles of the invention; but in this, as in all new discoveries, much improvement is always to be expected and acquired by actual trial. Its obvious utility, even as a first sketch, may render it of service to those who find it their interest to prosecute this manufacture. (J.D.)

CARRACCI. See Carracci.

CARRÉ, LOUIS, a celebrated French mathematician, was born at Clos-Fontaine, near Nançay, in Bré, on the 26th July 1663. His father, who was a respectable farmer, having intended him for the church, young Carré prosecuted the study of theology for three years; but, in consequence of his refusing to take orders, all his pecuniary supplies were withheld, and he was obliged to quit the university and seek for employment. In this situation, he was engaged as amanuensis to the celebrated Father Malebranche, under whom he acquired a knowledge of mathematics and metaphysics. After having filled this situation during seven years, he employed himself in teaching mathematics and philosophy at Paris. In this new employment he had several pupils of the fair sex, for whose talents he seems to have entertained a very uncommon, and rather an extra-

vagant degree of respect, when he estimated female genius as higher than that of the other sex. The language of Carré being rather unpolished and ungrammatical, one of his fair pupils offered to give him lessons in French, in return for his philosophical instructions. Carré cheerfully accepted the offer, and often acknowledged himself greatly indebted to the instructions which he then received.

The subject of metaphysics now occupied all the leisure hours of Carré, and his mathematical studies were almost completely forgotten, till the 4th February 1699, when M. Varignon admitted him as one of his eleves in the Academy of Sciences. This new office drew his attention to mathematics, and in the year 1700 he published, in quarto, a complete work on the integral calculus, entitled, Une Méthode pour la mesure des surfaces, la dimension des solides, leur centre de pesanteur, de percussion, et d'oscillation. This work reached a second edition, in which several errors were candidly acknowledged and corrected.

On the 15th February 1702, M. Carré was admitted Associate Mechanician, and on the 18th August 1706, he was promoted to the situation of Pensioner; the emoluments of which enabled him to devote himself entirely to his studies, but particularly to the various branches of mechanics and natural philosophy. He composed treatises on a great variety of physical subjects, all of which we bequeathed to the Academy of Sciences, though it does not appear that any of them have been published. In the forty-eighth year of his age, he was attacked with dyspepsia, which at last brought him to the grave, on the 11th of April 1711.

The following is a list of the papers which he published among the Memoirs of the Academy of Sciences:

CARRIAGE.

Carriage, a general name given to all vehicles used with wheels, for the conveyance of any weight, goods, or passengers; but now more commonly applied to those for the latter purpose, such as coach, chaise, &c. In this sense carriages are of undoubted antiquity. They are frequently mentioned under the name of chariots in the Old Testament. Chariots were in use in Greece, particularly at the Olympic games.

The Romans used carriages of different kinds, and under different names. The arceus is mentioned in the 12 tables; the lectica followed; then the carpentum, and still later the carruca, which last was considered a first-rate machine, and often highly ornamented with gold and precious stones. After these, covered carriages of various kinds were used as appendages of Roman pomp and grandeur, until the manner of thinking which prevailed under the feudal system banished them for a time. Indeed so early as the reign of Julius Caesar, carriages were even let to hire in Rome, as appears from Suetonius, who, speaking of that emperor, says, Longissimas viae incredibili celeritate conficit expediteus, meritoria rea, centina passuum nullia in singulos dies.” (See Suetonius, lib. i. cap. 57.) In latter times, it would be difficult to say at what precise period, of what kind, or in what nation, carriages were again introduced. Historians appear to have taken little interest in them, as few have mentioned them at all, and those few but slightly; nor ought we to be surprised at this, when we consider the low state of mechanical arts, the little intercourse between neighbouring powers in mercantile matters, and the necessity, in feudal times, of princes having their lords and vassals trained up in the use of arms, and, of course, not indulged in any thing bordering upon luxury or effeminacy. In this state of things there was hardly an opening for carriages, as kings, lords, and commoners, all rode on horseback; and even the women and the clergy had no other mode of conveyance, except on mules or asses. Indeed so strong was the prejudice against carriages, that edicts were published prohibiting their use, at the same time that they were sometimes allowed, by special favour, to invalids, and women of the highest rank. No wonder then that historians should not accurately detail the introduction of carriages, which their princes beheld with a jealous eye, considering them as fit only to enervate their vassals, and of course weaken their own power; and which it is hardly possible they could divine, should, at some future period, become not merely of utility, but of absolute necessity; affording the chief means of internal intercourse between place and place to the inhabitants of almost the whole civilized, world, and their manufacture furnishing employment to thousands.

It would appear from an ordinance of Philip the Fair of France, issued in 1294, for suppressing luxury, that carriages were known at that time in Paris, as the citizens’ wives were therein forbid the use of carriages (carr.) About the end of the 13th century, when Charles of Anjou made his entrance into Naples, the queen rode in a carriage called at that time caretta, the outside and inside of which were covered with sky blue velvet, interspersed with golden filies. The Emperor Frederick III. seems to have used a close carriage in his journeys to Frankfurt in 1474-5. The Electress of Brandenburg, and Duchess of Mecklenburgh, and some others, displayed elegant carriages in 1509. In 1550 there were in Paris three coaches, said by some to have belonged to the queen, to Diana de Poictiers, and to Rene de Laval, Lord of Bois Dauphin, who was such a corpulent and unwieldy nobleman as to be unable to ride on horseback. Others say the three first carriages belonged to Catherine de Medicis, Diana Duchess of Angouleme, who died 1619, and Christopher de Thou, first president of the Parliament. Henry IV. was assassinated in a coach; and he appears to have had one only, from a letter he writes to a friend, in which he says, “I cannot wait upon you to-day, because my wife is using my coach.” (Varietes Historiques, p. 92.)

Roubo, in his voluminous Treatise on Joiner Work, has given drawings of carriages, such as were used in the time of Henry IV. From these drawings we see, that there were neither straps nor springs in use at that period. From the same work it would appear, that the coach in which Louis XIV. made his public entry, was hung upon straps without springs; and there are also given several drawings of carriages with springs. (L’Art de Menuisier, Carrossier, par M. Roubo le Fils; See Description des Arts et Metiers, fol. 1770, vol. x. p. 453.) In 1562, the Elector of Cologne had several carriages. In 1594, the Margrave John Sigismund had, at Warsaw, 36 carriages, with six horses each, (Suite des Memoires pour servir a l’Hist. de Brandenburg, p. 63.) where, the royal author adds, “the common use of carriages is not older than the time of John Sigismund.”

In The Triumph of Maximilian, a work executed in the years 1516, 1517, and 1518, the curious reader will find plates of various carriages or cars, some drawn by horses, some by stage, some by camels, others impelled forward by means of different combinations of toothed wheels, worked by men. Of one of the most remarkable of them, we have given an exact copy, in Plate CXXI. and we are inclined to think that the idea of the walking crane may have been taken from this vehicle.

Amongst other things described of the marriage of the Emperor Ferdinand II., it is said by Count Kevenhiller, that “the bride rode with her sisters in a splendid carriage studded with gold, her maids of honour in carriages hung with black satin, and the rest of the ladies in neat leather carriages.”
In 1523, a law was enacted in Hungary to prevent the use of carriages. There was also a curious document published by Duke Julius of Brunswick, in 1588, forbidding his vassals the use of carriages, which is in substance as follows: "As we know from ancient historians, from the annals of heroic, honourable, and glorious achievements, and even by our own experience, that the respectable, steady, courageous, and spirited Germans were heretofore so much celebrated among all nations, on account of their manly virtue, sincerity, boldness, honesty, and resolution, that their assistance was courted in war, and that in particular the people of this land, by their discipline and intrepidity, both within and without the kingdom, acquired so much celebrity, that foreign nations readily united with them; we have for some time past found, with great pain and uneasiness, that their useful discipline and skill in riding in our electorate county and lordship, have not only visibly declined, but have been almost lost, (and no doubt other electors and princes have experienced the same among their nobility); and as the principal cause of this is, that our vassals, servants, and kinsmen, without distinction, young and old, have dared to give themselves up to indolence and to riding in coaches, and that few of them provide themselves with well equipped riding horses, and with skilful experienced servants, and boys acquainted with the roads; being not able to suffer any longer this neglect, and being desirous to revive the ancient Brunswick mode of riding, handed down and bequeathed to us by our forefathers, we hereby will and command, that all and each of our before-mentioned vassals, servants, and kinsmen, of whatever rank or condition, keep in readiness as many riding horses as they are obliged to serve us with by their feiü or alliance, and have in their service able, experienced servants, acquainted with the roads; and that they have as many horses as possible, with polished steel furniture, and with saddles proper for carrying the necessary arms and accoutrements, so that they may appear with them when necessity requires: We also will and command our before-mentioned vassals and servants, to take notice, that when we order them to assemble, either altogether or in part, in times of turbulence, or to receive their feiü, or when on other occasions they visit our court, they shall not travel or appear in coaches, but on their riding horses," &c. (Lunig. Corp. jur. feud. Germ. ii. p. 1447.) Nor was Duke Julius the only great lord that attempted to suppress the use of carriages, for Philip II. Duke of Pomerania Stetten, tried the same thing in 1608.

All these orders, however, proved ineffectual; for about the end of the 16th century, emperors, kings, and princes, began to employ covered carriages in journeys, and afterwards on public solemnities, there-by setting an example, which, in the course of the 16th century, was generally followed.

Early in the beginning of this period, covered carriages appear to have been used by women of high rank, while yet the men considered it as unbecoming to indulge themselves in such a luxury. Ambassadors appeared in coaches for the first time in 1613, at the imperial commission held at Erfurth. (Ludolf. Electa juris publici, v. p. 416. Von. Mosers Ho-

frecht, ii. p. 397.) The wedding carriage of the first wife of the Emperor Leopold, a Spanish princess, cost, with the harness, 38,000 florins. (Kink, Leben k. Leopold, p. 607.) The coaches used by that emperor, are thus described by Kink: "In the imperial coaches, no great magnificence was to be seen; they were covered over with red cloth and black nails. The harness was black, and in the whole work, there was no gold. The panels were of glass, and on this account they were called the imperial glass coaches. On festivals, the harness was ornamented with red silk fringes. The imperial coaches were distinguished only by their having leather traces; but the ladies in the imperial suite were obliged to be contented with carriages, the traces of which were made of ropes." Twiss says, that coaches were seen for the first time in Spain, in the year 1540. In 1681, there was a magnificent display of carriages in Hanover, belonging to the Duke Ernest Augustus, who had fifty gilt coaches, with six horses to each. (Lunings Theatr. cer. i. p. 289.) In the beginning of the 17th century, there were elegant coaches in Russia. (Essai sur la Bibliothèque de l'Academie des Sciences de St Petersburg, par J. Bachmiester, 1776, Svo. p. 36.)

Carriages appear to have been very early in use in England. For it is said in the life of St Erkenwald, who died about the year 685, "Quadam vero die, verbi Dei paula, commissa sihini gregi, ministatura, dum ..." (Kink, p. 348.) As early as 1601, we have records of the same kind. (See Sir William Dugdale's History of St Paul's Cathedral, vol. Appen. p. 3.) In Brook's Catalogue of Kings, Princes, &c. p. 67, he says, speaking of William, third Earl of Derby, "this William dyed of a bruise, taken with a fall out of his coach, in the yeare 1523, the 28th of King Henry the Third." We find in Stowe's Summarie of the English Chronicles, p. 287, the following notice taken of carriages: "This yere Walter Rippon made a coche for the Earl of Rutland, which was the first coche that ever was made in England since to wit, in anno 1564. The said Walter Rippon made the first hollow turning coche, with pillars and arches, for her Majesty; being then her servant. Also, in anno 1584, a chariot throne, with four pillars behind, to beare a canopie, with a crowne imperiall on the toppe, and before two lower pillars, whereon stood a lion and a dragon, the supporteris of the armes of England." Stow, in his History of London, (vol. p. 70.), says, "The oldest carriages used by the ladies of England, were called whirligotes, and that they were in fashion but for a short time." And Anderson, in his History of Commerce, (vol. iv. p. 180.), says, "That coaches were first brought to England, in 1580, from Germany, by Fitz-Allan, Earl of Arundel." And in 1598, the English Ambassador came to Scotland in his coach. (Scott's History of Scotland, p. 551.) Anderson says, coaches began to be in common use in England in 1605. In 1610, one Henry Anderson, an inhabitant of Trail Sound, or Stralsund, in Pomérania, offered to bring from that country to Scotland, coaches and waggonets, with horses to draw, and servants to attend them, provided he was secured in the exclusive privilege of keeping
them. Accordingly, a royal patent was granted to him, conferring an exclusive privilege for fifteen years of keeping coaches to run betwixt Edinburgh and Leith. (Privy Seal Record, Book 79, p. 225.) It would appear from this, that it was only for these towns that coaches were then intended. Coaches and six were introduced into England in 1619, by Villiers, Duke of Buckingham, (Northumberland Household Book, p. 448; Wilson’s Life of James, p. 130) this was considered such a piece of vanity, that the Duke of Northumberland appeared immediately afterwards with eight horses in his coach by way of ridicule.

The first coach that was seen in Sweden, was taken there the end of the sixteenth century by John of Finland, upon his return from England (Dalin, Geschichte des reichs Sweden, ubersetzt von Dahnert, iii. p. 390 and 402). Public carriages were first introduced to let for hire in France in 1650, by Nicholas Sauvage. These carriages took their name from the residence of the proprietor, who lived in a house called Hotel St Fiacre, and were thence called fiacres. Others followed Sauvage in this employment, and obtained licences for letting carriages upon paying a certain sum of money. Among others, Charles Villerm paid into the king's treasury 15,000 livres, for the exclusive privilege of keeping coaches for hire within the city of Paris. Shortly after this coaches were kept, such as the hackney coaches of the present day, standing at certain places in different streets, to go from one part of the city to another. The name fiacre became soon applied solely to them; the appellation of Carrosse de Remise being given to those that were kept at the proprietors houses, and let out to hire for a certain time. And in 1662, carriages with four horses were kept for the purpose of carrying people to the different palaces at which the court might be. These went under the name of Voitures pour la Suite de la Cour. Regulations were established by the police to secure the safety of public carriages, and marks affixed upon them whereby they might be known. A full history of the Parisian fiacres, and the orders respecting them may be seen in Continuation du traite de la Police, Paris, 1788, fol. p. 435; and also Hist. de la Ville de Paris, par Sauval, i. p. 192. Coaches to let for hire were first established in London in 1625, amounting at that time to twenty. These stood at the principal inns, and were called hackney coaches, from their being first used to go betwixt London and Hackney. Ten years after they became so numerous, that Charles I. issued an order limiting their number. In 1637, there were in London and Westminster fifty coaches. In 1652 their number had increased to two hundred. In 1654, there were three hundred. In 1661, four hundred were licensed at six pounds per annum. In 1694, they were limited to seven hundred. In 1715, to eight hundred. In 1768, there were one thousand; in 1802, they were increased to 1100; and they are now considerably above that number. Hackney coaches were first established at Edinburgh in 1673, at which time there were twenty. (Arnot’s Hist. of Edinb. p. 597.) In 1679, at the rebellion, the hackney coach horses of Edinburgh were employed to draw the royal artillery. (Maitland's History, p. 338; Wodrow’s History, vol. ii. p. 52.) In 1753 they had decreased to fourteen, and in 1778 to nine. (Arnot’s History, p. 598.) Since that period, however, in consequence of the improvements in the various streets, whereby their use has become more general, the great enlargement of the city, and the increasing wealth of the inhabitants, their numbers have been gradually increasing, till now there are very nearly one hundred hackney coaches. Fiaces were first introduced at Warsaw in 1778. In Copenhagen, about the same time, there were one hundred hackney coaches. (Hauers Beschreibung von Copenhagen, p. 173.) There were in Madrid at that time from four to five thousand gentlemen’s carriages; (Twiss’s Travels through Spain and Portugal.) In Vienna, three thousand gentleman’s carriages, and two hundred hackney coaches. In 1683, coaches with wheels were forbidden at Amsterdam, being considered destructive to the pavements; (Handvesten van Amsterdam, ii. p. 739,) but about 1775 their number had increased so much, that there were twenty-five thousand coach horses in the seven united provinces.

The following statements of the number of carriages in England, Scotland, and Wales. in 1807, the progressive increase or decrease for the twenty years preceding, with the number of carriages actually made in 1804, 1805, 1806, and 1807, may be interesting to our readers. They are taken from the Appendix to the Report from the Committee on the Acts now in force regarding the use of broad wheels, and on the preservation of the turnpike roads and high ways of the kingdom, printed by order of the House of Commons, 2d May 1809; and are therefore completely authentic documents. We also subjoin a statement of the number of four and two wheeled carriages charged with the duty in Scotland, from 25th March 1747, when the duty commenced, until the present time; distinguishing, as far as possible, the private from the public carriages; and also the number of taxed carts from 1798, the period from which the duty upon them commenced.

An account of the number of Wheel Carriages in England and Scotland respectively, distinguishing Gentlemen’s Carriages, Stage Coaches, and other Carriages let to hire, for the year 1806, ended the 5th April 1807.

* Error of two in the printed Report.
Carriages have improved in their construction, and increased in variety, in a greater proportion than in numbers. The improvement in their construction may be imputed to the distribution of labour in building them, to the long experience of the workmen in their several departments, to the emulation naturally arising amongst the people employed in their manufacture; but chiefly to mechanics having become more a study, and of course better understood amongst all ranks of society than formerly. Carriages have been, like every other invention of man, improving slowly but gradually; and even now, when for beauty, elegance, lightness, and strength, human ingenuity would seem to be exhausted, experience leads us to look forward to something more perfect than we have yet seen; and we are warranted to expect this from the various improvements appearing from all different quarters, in almost every separate department of coach-making. We shall conclude this article with a list of patents granted for the several improvements in wheel carriages within the last ten years; and to which we refer our readers, if desirous of more information than our limits enable us to afford.

The variety in carriages is so great, that it is almost impossible to enumerate them, arising in a great measure from the increasing wealth of the people enabling them to gratify their improved taste; but more particularly, we should imagine, from a desire in the makers to raise their own reputation by attracting the notice of the public with a name that had not been before heard of, although the carriage they produced under such name, differed very immaterially from others that had been long perfectly well known. We shall content ourselves by giving the names of those most generally known and used, with a very short description of each, leaving out of view the varieties hinted at above.

An Account of the number of Four and Two Wheeled Carriages in Scotland charged with duty from 25th March 1747 to 25th May 1812, and of Taxed Carts from 5th April 1795 to 25th May 1812.
Carriages may naturally be divided into two classes: four-wheeled, and two-wheeled. The chief of these are,

Coach.—A close-bodied carriage, made generally to hold six people, sometimes only four people in the inside, one half sitting opposite to the other, face to face; a window in the door on each side, and a large one, or two small ones, in front, having four wheels, and drawn by one or more pairs of horses, driven by the coachman from a coach box in front of the body. When the driver rides on horseback they are called post coaches. Under this description may be included all mail and stage coaches, which have nothing particularly to characterize them but their uncommon strength. See Plate CXXXII. Fig. 1.

Vis a vis, made after the fashion of a coach, and in every respect like it, but only to hold two people within, sitting opposite, as the name indicates. It is drawn by two horses a breast, and driven as a coach.

Landau, made exactly to resemble a coach, with the same accommodation, but having the top or roof, upper part of the sides, and back, to open and fold down to the front and back, leaving to the passengers a free view of everything around; drawn and driven as a coach.

Landau Barouch, made in all respects like the landau, but_curved away with an inverted sweep in the under part and front of the body, by which means there is no space for an inside box under the front seat. This carriage is also drawn and driven as a coach. See Plate CXXXII. the dotted line in Fig. I.

Barouch. The body is made the same with the under part of the landau barouch, (sometimes like the under part of a coach body,) not having any frame work above the elbows of the passengers, and of course no glasses. On the back half of the body is put a roof similar to the roof or hood of a two-wheeled chaise, to fold up or down at pleasure, and a leather cover made to go over the cushion of the front seat at such a height, only, as to admit the feet of the persons who sit on the hind seat being put up between the cushion and leather cover. When this leather cover is not used, one or two people (according to the size of the carriage) can sit upon the front seat. These carriages are sometimes made with doors, and sometimes with leather only, to fill up the space left to enter at.

Barouches are drawn by one or more pairs of horses, and driven sometimes from a coach box, and sometimes the front part of the body is formed into a seat for the driver.

Post-chaise, a close-bodied carriage, made to hold three people in the inside, looking all forward, with two windows in front, and one in the doors on each side, with four wheels, and drawn by one or more pairs of horses. The driver rides on horseback.

Chariot, exactly the same with a post chaise; only accommodated with a coach-box for the driver.

Landeaulet, made similar in every respect to a post-chaise, but with the advantage of a moveable roof, like a landau, which folds back so as to leave the passengers quite free. This may be put up and down by the people inside of the carriage at pleasure. See Plate CXXXII. Fig. 2.

Phaeton, an open bodied carriage, made to hold two or three people looking all forward, with four wheels, drawn by one or more pairs of horses, with or without a folding leather roof to cover the seat part, and a leather cover to enclose the knees of the passengers, called a knee flap. This carriage may be driven by the person sitting inside, from a coach-box, or the driver may ride postilion.

Carriole, an open bodied carriage, similar in the body to a phaeton, drawn by two horses a breast, having two wheels, and either with or without a roof, as above. It is driven by the person who rides in the carriage.

Two-wheeled chaise, an open bodied carriage, also similar to that of a phaeton, but drawn by one horse, with two wheels, having a leather roof, knee flap, &c., and driven by the person who rides in it.

Gig, an open carriage similar to the last mentioned, but without a roof, driven in the same way. See Plate CXXXII. Fig. 3.

There is a great variety of carriages besides these, such as, in four-wheeled carriages, berlins, Calash's, Chaise Marine's, Sociables; and in two-wheeled carriages, dog-carts, buggies, tandems, mail carts, Tillinghurghs, Irish cars, Windsor chairs, &c. and coach and chaise bodies, have of late been constructed upon two wheels; besides many others, which may be considered more as modifications of those already described, than as different carriages in themselves.

List of Patents granted for Improvements in Carriages, from January 1802 to July 1812.

CARRICKFERGUS.

Scaric-fer- gus.

in the west excepted. The entrance into it is bold, being about five miles wide, and having from 12 to 20 fathoms depth of water, which grows gradually shallower till you advance opposite the town, where it is from 5 to 8 fathoms deep in the middle of the road. It grows narrow by degrees from the mouth to the bridge of Belfast, where it is not more than three-fourths of a mile broad, and from 9 to 13 feet deep at full tide; (See the article BELFAST.) From this shallowness, Comol Pool is used as the harbour for ships trading to that town, in which 20 vessels may ride afloat at low water, though within a cable's length small banks lie around them almost dry. In this bay there are few rocks or shoals, except a reef of rocks running out into the sea for three or four hundred yards from the north side of it, called the Briggs; and, except some foul ground and a dangerous sunk rock on the county of Down side, lying between the Copeland islands (on one of which is a lighthouse) and Donaghadee, called the Deputy Rock, there is also, a little south-west of Carrickfergus, one shoal, on which lie 8 fathoms water at ebb tide, in the middle of the bay. The entrance into the castle is between two towers, or half moons, mounting several pieces of cannon; and over the gateway is a portcullis, and apertures for throwing down stones, and otherwise annoying the enemy. In the inner yard is a high square tower, the walls of which are nine feet thick; the lower part is bomb-proof, and serves as a magazine. In 1794, the castle was repaired, and 27 pieces of ordnance mounted on the batteries; since that time it serves as the principal magazine to the northern district. The garrison, however, seldom exceeds fifty or sixty men. The salary of the governor is about 500L. per annum. At the head of the main street stands the county of Antrim courthouse, a handsome building, where the assizes of that county are held twice a year; and adjoining to the court-house is the county prison. The market-house stands near the centre of the town, and is a tolerable building. The market is held every Saturday. The custom-house stands near the quay, which, although built within these few years, does not deserve the name of a public building. The quay, however, has been lately much improved. There are only two houses for public worship, an established church, and a Presbyterian meeting-house. The church is an ancient building, dedicated to St Nicholas, having in the north aisle an old monument of the Donegal family. The east window is of stained glass, representing John baptizing in Jordan. There are two free schools, one of which is solely supported by E. D. Wilson, Esq, the present respectable mayor, and the other by the gentlemen of the town and neighbourhood. The town has been a corporation since the days of Queen Elizabeth, who granted the charter to Arthur Chester, then governor, which was afterwards confirmed, with many additional privileges, by James I. The government of the town is vested in a mayor, recorder, sheriffs, aldermen, and burgesses; and the corporation, under the act of union, returns one member to the imperial parliament. In 1316, after a long blockade, the town and castle surrendered to the Scottish forces under Edward Bruce; and in the Carrickfergus month of April 1642, it was taken possession of by 4000 Scotch auxiliaries under the command of general Monroe, who retained possession, till he was surprised and made prisoner by general Monk in 1648. In the beginning of the next year, general Monk was made prisoner by Lord Inchiquin; and, in the latter end of the same year, the town and castle surrendered to Sir Charles Coote. On the 12th, August, 1689, Duke Schomberg arrived in the bay with ninety vessels, having about 10,000 troops on board, and disembarked the next day at Grooms Port near Bangor. On marching to Belfast, the enemy retired to Carrickfergus, where several regiments were instantly detached with cannon. The place was summoned in form; but not agreeing in the terms, batteries were raised. On the 22d, trenches were opened, and the siege carried on in form till the 26th, when several breaches being made, and all things ready, for an assault, the garrison surrendered, obtaining leave to march to Newry, where the Duke of Berwick, natural son of James II., commanded. On the 14th of June 1690, King William landed here, attended by Prince George of Denmark, the Duke of Ormond, and many other noblemen of distinction. On the 21st February 1760, Commodore Thurat arrived in the bay with the following ships, Belleisle 44 guns, Le Bland 32, and Terpsichore 26; being part of a large fleet intended for the invasion of Ireland by the French. Thurat proceeded to land his men, which amounted to about 1000, at Kilraat, and instantly marched to attack the town of Carrickfergus, the garrison of which consisted of about 180 men of the 62d regiment, commanded by Colonel Jennings. The garrison made a vigorous resistance from the town wall and gardens, and afterwards retreated into the castle. The French then formed into three grand divisions, and attempted to force the castle gate, but were beat back with considerable loss. The garrison having now expended all their ammunition, Colonel Jennings was reluctantly obliged to surrender, and obtained honourable terms. During the heat of the engagement, "a French soldier observing a child who had run playfully into one of the streets amid the fire of the contending parties, grounded his musket, carried the infant to a place of safety, and, returning to his comrades, resumed the combat." Such a humane action deserves to be recorded, whilst we regret that the name of the generous individual is unknown.

The enemy's loss is supposed to have been about 40 killed, among whom were three officers, and between forty and fifty wounded, amongst whom was General Colbert, the commander in chief. The garrison had only two killed and three wounded. Thurat was desirous of landing at White-house, and surprising Belfast; but to this plan the general objected, fearing to be harassed by leaving a garrison in his rear. The French evacuated the town in great confusion on the 26th of the same month, and were captured on the 28th by Commodore Elliot off the Isle of Mann. Carrickfergus is situated about 9 miles North East of Belfast, and 89 from Dublin. West Long. 5° 48', North Lat. 51° 36', (o)
Carrier. 553

Carrier.  

CARRIER, a species of pigeon, which has received that name from being employed in conveying letters from one place to another. It is the Columba indicaria of Linnaeus, and is thus characterised "cere broad, carunculate, whitish, eyelids naked." But this description is too indefinite to enable ordinary observers to recognise the species; we may therefore remark, that the carrier is of a larger size than the greater part of pigeons, being 15 inches in length from the point of the bill to the extremity of the tail, and sometimes weighing 20 ounces. Its shape is more symmetrical from the length of neck and closeness of the feathers; and the breadth of the chest added to these two, are considered not only indications of the use, but of the qualities of the individual. The colour is not a distinguishing mark, the carrier being black or dun, blue, and blue-pyebald, the two latter of which are most esteemed by pigeon fanciers from their rarity. The cere of this bird is very large, extending over half the upper chap of the bill in a white, tuberous, furfuraceous flesh, called the wattle, hanging down on both sides next the head, and terminating in a point about the middle of the bill. On the appearance of this several properties are supposed to depend, which has given birth to cruel operations on the bird. As the wattle of a good carrier should be broad across the bill, and rise high at the head, a method has been contrived to impose on the less skilful, by artificially elevating the hind part with cork fixed in by wire, in such a manner as scarcely to be perceptible. The eyes are surrounded by the same furfuraceous substance, extending to about the diameter of a shilling; and the wider it is, the more the carrier is valued. But the best birds are said to have three peculiarities in the appearance of the bill, three in the wattle, three in the head, and as many in the eye: though some concentrate them in one each, to which are added the length and slenderness of the neck, and the length of the body. We are unacquainted with the country of which the carrier is indigenous; but it is said to have been imported into Britain, where it is now completely naturalized, from Bussorah.

Though the superstitious partiality with which pigeons in general have been viewed, may perhaps be traced to passages in Scripture, the qualities of the carrier were prized before the Christian religion was known, and in countries where it was never recognised. It is the peculiar property of this bird to find its way through the air from incredible distances, over which it has been conveyed head-winked, or in a covered basket, back to its usual abode, which has taught mankind a mode of transmitting intelligence by its aid. The Greek and Arabic poets, in their figurative language, alike represent the interchange of amatory billets by pigeons; and Martial describes one as an ominous messenger of welcome tidings.

Acea per tacitum delapsa sedenis in ipso
Pluuit Arcteullae blandia columba sinus.

* * *

Tace a Sardois, tibi foliis exulcis oris
Fraute rescreris, nuncia venit avis.

Lib. viii. Eleg. 32.

But we are distinctly told by Ælian, that Tauro-

VOL. V. PART II.

themes, a victor in the Olympic games, communi-
thed his success to his father by means of a pigeon, to
which a purple ligament was affixed. Pliny also nar-
rates, that a correspondence was carried on by means
of pigeons, at the siege of Modena. Quin et inter-
nunciae in magnis rebus fuere epistolas annexas car-
num pellicis obliuione. Mutinens in estra Consul-
tum Decimo Bruto mittenre. "Of what avail," he
adds, "were centinels, circumvallations, or nets ob-
structing the river, when intelligence could be con-
voyed by aerial messengers." More recent instances
are given of the utility of pigeons, in communicating
information to the besiegers or besieged during times
of warfare. It is said that while an army was be-
sieging Tyre, in the Crusades, intelligence from a
distant quarter was suspected, from a pigeon being
frequently observed hovering over the city. By some
means the besiegers obtained possession of the bird,
removed a billet attached to it containing useful in-
formation, and replaced it with deceitful intelligence.
The pigeon was again liberated; and having convey-
ed the false information, the besiegers were enabled
to render themselves masters of the place. In other
cases correspondence has been intercepted, whereas the
bird, terrified by the sight of a hawk, has sought the
earth, and thus fallen into the hands which it was
most important to avoid.

In more modern times, the carrier has been employ-
ed to convey intelligence, which required immediate
communication, to the Turkish government, which
practice subsisted in the time of Sir John Mandeville,
who travelled in the 14th century, and is alluded to
by Baumgarten, who was at Alexandria in 1507. At
a later period, there was a regular chain of posts,
kept up by high towers, between 30 and 40 miles as-
sunder, provided with pigeons, and sentinels stood
there, constantly on the watch, to secure the intelli-
gence communicated to each, and transmit it along.
The notice was inscribed on a thin slip of paper, en-
closed in a gold box of small dimensions, and as thin
as the paper itself, suspended to the neck of the bird:
the hour of arrival and departure were marked at
each successive tower, and, for greater security, a du-
plicate was always dispatched two hours after the
first.

It was not uncommon, in the course of the 18th
century, for the English merchants at Aleppo to ob-
tain intelligence of the arrival of their vessels at Scan-
deroon by the same means. Whatever could be com-
prised in few words, was written on a slip of paper,
and fastened to the pigeon, which immediately took
flight. It was usual to send down the pigeons from
Aleppo, that they might always be ready at the port,
and no delay ensue. Maillet, the French consul in
Egypt, relates, that a merchant of Aleppo, having
accidentally killed one of these feathered messengers,
was the first to learn that a scarcity of galleys prevail-
ed in England, and profiting by the intelligence,
he made a speedy transaction, by which he gained 10,000
crowns. This practice of employing pigeons, in Syr-
ia, has been discontinued.

We are not aware that the carrier pigeon, and
its kindred species, have been used in Britain for the
regular conveyance of written intelligence. But
some years ago there were instances, and perhaps no

uncommon, of a pigeon being let fly at the moment of an execution at Tyburn, whereby the relatives of the unfortunate criminal might be warned of his fate. In the latest times, they have chiefly been converted to use, in announcing the issue of wagers between places far asunder; and, considering the rapidity of their flight, certainly they are not unsuitable messengers. Nevertheless the carrier pigeon is not the only bird which the ingenuity of mankind has entrusted with being the bearer of information. The swallow has been thus employed, though not in a systematic manner; and the ancients relate that one of the kings of Egypt had a crow so well trained, and which had been so useful to him, that after its death he preserved it in a tomb.

The carrier is naturally endowed with the faculty of returning to its usual place of habitation; but certain precautions have been observed to render its mission more secure. It is only used during the time of incubation, or while it has unfledged young; besides, a kind of training is adopted, whereby lesser distances are passed over in its return, before the full flight is required. The Turks take a pigeon, on gaining its ultimate strength, and first carrying it half a mile in a basket, allow it to fly; it is next carried a whole mile, and so on, increasing the distance to twenty or thirty miles. The same was done between Aleppo and Scanderoon, and, at last, when judged to be sufficiently trained, those which had young were sent down to the port. When the pigeon was allowed to escape, its feet were bathed in vinegar, with the design of keeping them cool, and to restrain the bird from alighting in quest of water, by which the billet which was fastened under its wing might be injured, or the journey prolonged. But it was necessary that there should be no great interval after removal from its young, and if a fortnight elapsed, the return of the pigeon could not be relied upon.

Immediately on escaping, the carrier towers to an immense height, and then commences its progress with inconceivable rapidity. Though it be difficult to ascertain the velocity with which a bird cleaves the air, it has justly been assimilated to the flight of an arrow from the bow, and some have ventured to hazard conjectures on the subject. Mr Cartwright, who lived so long in a desolate region, computed the rate at which certain wild ducks flew, to be 95 miles an hour; the celebrated Spallanzani found by experiment, that a swallow flew from Bologna to Modena, which are 20 miles distant, in 13 minutes; and he affirms that the common swift can fly 60 miles in a quarter of an hour. We do not know that the carrier is endowed with such incredible speed; but Damiiri, an Arabian author, maintains, that it can traverse a space equal to about 450 miles in a day. Maillet says that, when fairly in flight, it does not occupy above half an hour in ten leagues; and D'Arvieux, in calculating the distance between Scanderoon and Aleppo at 40 leagues, observes, that pigeons pass from the one to the other in three or four hours. However, when employed by the English factory of the latter place, they have been known to perform that flight in two hours and a half. A well authenticated experiment is described, where a pigeon being let fly from St Edmund's Bury in England, reached

London in the same time, the distance being 73 miles. Most probably the rate of flight is not less than 30 miles an hour, and perhaps considerdly more. See Bochart Hierozoicon, tom. iii. col. 15, 16. Leyden, 1692. Ellian Varia historia, lib. ix. cap. 2. Plinius Historia Naturalis, lib. x. § 24. (c)

CARRON WORKS, the name of an iron foundry in Scotland, on the most extensive scale, situated by the side of the river Carron, about three miles above its junction with the river Forth, and about two miles north from the town of Falkirk, in the county of Stirling and parish of Larbert.

These works were projected by the late celebrated and enterprising Dr John Roebuck, who, after visiting many situations in Scotland for the purpose of erecting an iron work and foundry, at last fixed upon the present site. They were established by a company, with Dr Roebuck at their head as the acting partner, in the year 1760.

The company are chartered, having an original capital of £150,000 divided into six hundred shares of £200 each, which are now in comparatively few hands. These shares sell at present at an advance of thirty per cent., and the company divide upon the purchase sum about seven per cent. each year, payable half yearly. Besides the above increased capital, there is a very great undivided and accumulating capital, consisting of landed, mineral, and heritable property, with an immense stock of all materials requisite for carrying on a concern so very extensive; for as a foundry, it is indeed the most extensive in the world, though, as to the making of pig iron, it is on a small scale in comparison with several iron works in Great Britain.

One primary object in placing these works where they are, appears to have been that of having the full command of the river Carron, for driving the heavy machinery, requisite for an iron work, together with the facility of water carriage for the raw materials and manufactured articles.

As the river Carron flows but a short way through a champaign country, and as its source is not very distant, it is on that account suddenly swelled with heavy rains, and as suddenly reduced by a short continuance of drought. This circumstance rendered it absolutely necessary to collect the river Carron into a large reservoir immediately adjoining the works, though even this was found, from the intermitting of the river, quite insufficient for the purposes of the work. To correct this defect, a very powerful steam engine, upon the common construction, is employed to raise the water after having passed over the wheels, and is discharged into the reservoir again. This machine raises the water about 35 feet high, by means of four very large pumps, and is capable of lifting 40 tons of water each minute, which flows from it like a river, to be again used at the water wheels. From the great extension of the works, even this vast auxiliary power was found insufficient, and of late a very powerful steam engine for blowing, made by Messrs Watt and Bolton, has been erected, capable of blow-
Caron Works.

It has two regulating cylinders, which support, by the compressed air, floating pistons of no less than 15 tons weight each, which produce a regular uninterrupted blast.

The machinery driven by water is chiefly employed for blowing into the blast furnaces and cupolas, for the boring mills, forge hammers, plating mills, and polishing mills, also for grinding fire clay, and charcoal.

There are five blast furnaces, which produce nearly 200 tons of pig iron each week, in which coal, viz. mineral charcoal, only is used. Of air furnaces and cupolas there are about 20 capable of melting, for foundry purposes, double that quantity of metal. Here all kinds of ordnance are cast, such as mortars, cannons, and cannonades, of every caliber, not only for the British government, but for all the European powers. They are all cast solid in a perpendicular direction, and are afterwards bored to the requisite caliber, with machinery moved by water. From long habit, and the constant attention paid to this department, the pieces of ordnance made here are of the best kind, and of the proper texture of metal, being greatly consolidated by a heavy pressure of liquid metal poured in a perpendicular direction. In former times all the ordnance made here were tried with the full disorder by being sent from the works, but they are now only proved by water forced into the chamber by a very powerful compressing engine, a method of proof which is reckoned much better than the former. The cannonade gun, so well known in the navy, invented in Ireland by General Melville, was perfected at Carron, (from which it derives its name,) by the joint aid of several scientific gentlemen. Mr Gascoigne, (afterwards Sir Charles Gascoigne,) the then manager, had an active hand in this improvement.

Immense quantities of shot and shells are also made here, besides every article in the foundry line, such as engine cylinders and materials, pipes, boilers, ovens, vats, pots, grates, machinery of all kinds, and in short articles of every description so universally known by the name of Carron goods. From the minute attention paid to the manufacture of all articles made here, they are in general so well executed that the name Carron, upon cast iron goods, gives them a kind of sterling stamp.

Smith work, particularly all the varieties of the heavy kind, is also executed here on a great scale, and in the best manner.

All the various machinery employed at Carron, is plain, substantial, and well finished, without the least aim at finery; a principle of the first importance, and worthy of imitation in all such concerns.

From the great extent of this foundry, the fire blast furnaces cannot supply the consumpt of pig iron, so that it is estimated that the company buy annually a quantity of iron equal to the produce of other five furnaces; the consequence of which is, that they are constantly in the market for iron, both in Scotland and Wales. Only a small quantity of malleable iron is made for their own particular uses.

Upwards of 2000 people are employed at the works in the various departments, so that it may be estimated that at least 6000 souls depend upon the Carron company immediately for subsistence.

With respect to the raw materials used at the works, the coals are supplied by two large collieries adjoining the works, which are brought direct from the pit mouth to the furnaces, by means of improved cast-iron rail ways. The main seam of coal is about four feet thick, partly of slate, and partly of cubical coal, being the only coal in these collieries hitherto wrought for making iron. A plan has been here adopted of working by means of sliding rods and pumps, under dip of the engine levels, to a greater extent than has been practised in any part of Scotland; a mode to which the company have paid great attention, and upon which they have very much improved. The sliding rods are moved by the engine above ground, and by this mode collieries have been revived by the same engine pit and machinery, which were considered as exhausted in the common mode of working. The consumption of coals is no less than 200 tons each day; from which we may easily conceive not only the magnitude of the works, but also the great annual excavation of the coal fields by such an expenditure of fuel.

It is somewhat remarkable that none of the iron stone, used at the furnaces, is found in the immediate neighbourhood; the chief supply of it is brought from the westward down the great canal, which passes within a mile of the works, and from the coast of Fife: all of it is of the common argillaceous iron stone, yielding from 25 to 30 per cent. of iron; only a small quantity of the Cumberland rich iron ore is used in the furnaces occasionally, for giving the metal a peculiar texture. The lime-stone, used as a flux in the furnaces, is also brought from the coast of Fife. All the fire-bricks used for lining the furnaces are made at the works, from a clay which is found immediately under a thin coal in one of their collieries, and which resists the action of fire.

As the quantity of ordnance stores, and the various articles made at this work, are immense, the company keep from 15 to 20 vessels in their employment, for carrying their manufactures to London, Liverpool, and other ports, and for bringing iron-stone and lime-stone to the works, the greater part of which vessels are their own property.

Till within these two years all the cartage for the works was done by single horse carts; but the improved rail-ways have superseded that mode. It is remarkable, that all the carts employed at this extensive iron work had wooden axles, which the carters preferred: the reason assigned for this was, that in the deep cut roads, the concussions were not so severe upon the horse as if they had been of iron.

This great work is under the direction of one manager, and the whole is conducted with the greatest order, attention, and economy, and no where in Scotland are the wages of workmen more moderate. Here societies are formed by the workmen, and patronized by the company, for the relief of those in distress, or who are superannuated—a system highly beneficial in all large works.

In a commercial view, these works are well situ-
On approaching Carron, every stranger is struck with the very great stock of coals, iron-stone, and lime-stone, and with the various horrid instruments of war, scattered or piled up in every direction, while, at the same instant, the car is assailed by various discordant sounds, such as the impetuous rushing of water, the creaking of boring mills, the varied clanking sound of ponderous hammers, with the loud and constant hissing of the blast furnaces, in the midst of which the eye is arrested by large fields of burning coals, producing a smoke which at times almost obliterates the light of the sun, and which, in the night, highly illuminate the atmosphere to the distance of many miles; while, in another direction, the metal is pouring in streams of liquid fire, throwing off starry confections of light. These various operations, with the numerous workmen going about in busy confusion, produce a "tout ensemble" quite unparalleled and astonishing.

CARROTS. See Agriculture. Index.

CARRISTARES, William, an eminent Scotch clergyman and statesman, was born on the 11th of February 1649. From his father, who was minister of Cathcart, in the neighbourhood of Glasgow, he received the best education which the country could afford. He was placed under the care of Mr Sinclair, a Presbyterian clergyman at Ormiston, who kept a large and genteel academy. There he acquired that taste for literature by which he was afterwards so much distinguished, and formed those connections, which he continued to maintain, with some of the first men in the kingdom. From this academy he went to the University of Edinburgh, where he made great progress in the scholastic philosophy of the times, and ultimately applied, with a professional view, and with considerable success, to the study of theology. But his attention soon began to turn from divinity to politics. The situation of the country, and the complaints of the people, operating upon a mind naturally generous and ardent, determined him to co-operate with those who were seeking a redress of grievances, and to devote his services to the cause of civil and religious freedom. His father, apprehensive of his engaging too deeply in that opposition to the court measures which was then going on, sent him to the University of Utrecht, under the pretence of affording him the best opportunities of completing his studies. But this measure of precaution had an effect the very contrary of what it was intended to produce. Young Carstares got a letter of introduction from his father to a physician in London, who happened to be one of those who kept up a correspondence with Holland; and who, on finding that he was well acquainted with Scotch affairs, and might be of great service to the Prince of Orange, gave him a letter of recommendation to the prince's physician. Through this medium he was soon introduced to the Pensionary Fagel, and next to William himself, from whom he received every mark of confidence and favour, and with whom he now laid the foundation of that friendship which subsisted between them till death. After residing for some time at Utrecht, and attending no less to political business than to literary pursuits, he returned to his native country, at once possessed of all the secrets of the Dutch court, and confirmed in those principles of liberty which he had originally embraced. He obtained license to preach the gospel according to the Presbyterian form, to which, both from conviction and education, he was strongly attached. But seeing no prospect of being useful as a clergyman in Scotland, he resolved to go back to Holland, where he was sure to enjoy those privileges which were withheld from him at home. As he intended to go by London, he was employed by Argyle, and the other Scotch patriots, to treat with the English ecclesiastics; and accordingly he had several conferences with them, and engaged in negotiations with the malcontents everywhere, for the purpose of securing a union of counsel and of efforts in the common cause. He engaged in the Rye-house plot, deeming it perfectly justifiable to take up arms for the assertion of those constitutional rights which had been violently invaded, and which remonstrances and complaints had failed to recover; but at the same time expressing the utmost abhorrence of the proposal which had been made to gain that object more effectually, by the assassination of the King and the Duke of York. On the discovery of this plot, he was apprehended and thrown into prison, where he remained for eleven weeks. At length he petitioned the Court of King's Bench for his habeas corpus; but, instead of obtaining it, he was, contrary to his own desire, and to the maxims of criminal justice, sent down to take his trial in Scotland. As soon as he arrived in Edinburgh, he was put into irons. For several weeks he continued in that painful situation, urged all the while most earnestly by one of the secretaries of state to divulge what he knew, and encouraged to do so by the promise of a pardon. This method not succeeding, he was subjected to the torture—a mode of extracting evidence which still existed in all its vigour; but, though it was inflicted with great severity in presence of the privy council, he bore it with the utmost firmness, and persisted in maintaining an unbroken silence. At length, a milder and more insidious treatment was resorted to, which had the effect of subduing, in some measure, the stubbornness of his virtue. On condition of his answering certain questions that were put to him, he was not only assured of receiving a pardon for himself, but also of never being produced as a witness, or having any of his statements brought forward as evidence, in the trial of any other person. He stipulated, besides, that these engagements should be confirmed by a re-
CARSTARES.

After being released from imprisonment, he was permitted to retire to Holland, where he arrived about the beginning of the year 1685, and was soon appointed chaplain to the Prince of Orange, and minister of the English Protestant congregation at Leyden. He was now more than ever both able and willing to serve the Prince. Accordingly, he was much with him, informed him accurately of the state of affairs in Britain, gave him complete insight into the temper and character of the principal men by whom public affairs were conducted in that country, made him acquainted with the dispositions and views of such of the British mal-content as resorted to Holland, and at last accompanied him, in the capacity of domestic chaplain, in his ever memorable expedition to England in 1688. At the revolution which then took place, he was always consulted by William, and gave his advice with so much frankness, and at the same time with so much wisdom, that he continued to possess the confidence of William, who, though he appointed him his chaplain for Scotland, and annexed to that office the whole revenue belonging to the Chapel Royal, yet signified to him that he required his constant attendance upon his person, assigned him apartments in the palace when in England, and, when abroad, allowed him L. 500 every campaign, for camp equipage. Mr Carstares was instrumental in procuring a loyal address to his master from the Presbyterian clergy of Scotland, which was very acceptable to the Prince. On the other hand, he was instrumental in procuring for his native country the establishment of that form of church government, to which he himself and the great body of the people were so partial; and this object was not attained without some difficulty, as the King was anxious that the same ecclesiastical regime should prevail in both parts of the island. But he agreed with his Majesty in disapproving of the act which was passed for abolishing the right of patronage, because he feared that it might lead to dangerous consequences, and be attended with an abuse of that power which it lodged in the hands of the people. He also gave an advice to William, which shewed that his zeal for royal authority was beginning to encroach upon his attachment to public liberty. His advice was this, that the King should be extremely cautious in giving up any branch of his prerogative, —a danger to which, as he alleged, William was the more exposed, because he had been raised to the throne by the voice of the people. In 1698, an act was passed in the Scottish parliament, obliging all persons in office not only to take the oath of allegiance to the King and Queen, but also to subscribe an assurance, declaring that William was king de jure, as well as de facto. The Presbyterian clergy refused to sign the declaration, and applied to the privy council for redress; but they thought proper to withhold the indulgence, and, under sanction of the King's authority, which they procured when Mr Carstares happened to be absent from court, either to require every representative to the General Assembly to obtemper the act, or, in case of disobedience, to dissolve the assembly in his Majesty's name. The clergy sent up a memorial on the subject to Mr Carstares, who immediately waited on the King though at a late hour,—awaked him out of his sleep,—represented to him the unjust nature and dangerous tendency of that measure which his government in Scotland had adopted,—and prevailed upon him to countermand the order that had been given, and to dispense with the oath to which the ministers objected. This act of William's administration had the effect of making him very popular in Scotland, and restored Mr Carstares to the good opinion of his countrymen, who had, on several accounts, begun to suspect the sincerity or the ardour of his attachment to their cause.

Mr Carstares continued to have the chief direction of Scottish affairs; and he conducted himself with such ability, prudence, and uprightness, that William's confidence in him increased with the duration of his services, notwithstanding the many attempts that were made by his political enemies to lower or supplant him in that monarch's estimation. He had a difficult part to act; but the difficulties of his situation were not too much for his wisdom and vigour to surmount. He equally checked the hostility of his foes, and secured the affection of his friends; and was so impartial and disinterested, that though he could only gratify the views of some, he commanded the respect of all. At the death of William, which could not fail to afflict him most sensibly, he was just as poor as when he first entered into that prince's service,—a circumstance highly creditable to him, since he had such fair and excellent opportunities of securing for himself an independent fortune.

In the succeeding reign, Mr Carstares's connection with public business was but limited, though he was of too much consequence to be entirely overlooked. Queen Anne, unsolicited, appointed him her chaplain for Scotland. He was also made principal and primarius professor in divinity of the university of Edinburgh; and, in the same year, became one of the ministers of that city. The duties of his pastoral office he discharged with equal ability and success; and though he had been long out of the habit of preaching, his discourses were very much and generally admired. His close attention to politics did not seem to have injured his literary attainments; for we are told that his first oration after his introduction into the university, which was delivered before a numerous and respectable audience,
exhibited so much profound erudition, so much acquaintance with classical learning, and such an accurate knowledge of the Latin tongue, that his hearers were delighted; and the celebrated Dr Pitcairn declared, that when Mr Carstares began his address, he could not help fancying himself in the forum of ancient Rome. As Principal of the university, he was very attentive to its interests and prosperity. The salaries of the professors being extremely small, he procured an augmentation to them out of the bishops' rents, in consequence of an application to the Queen and her ministers, with whom his influence was still very considerable. The same boon was, through his means, extended to all the other universities of Scotland; and, to shew the generous spirit by which he was actuated on this occasion, he refused to appropriate any part of the gift which had been obtained, to the increase of his own professional emoluments.

The first General Assembly which met after Mr Carstares became a minister of the church, chose him for their moderator; and this honour he enjoyed no less than four several times in the course of eleven years,—a fact which shews clearly the acknowledged superiority of his talents, and the great extent of his influence. This influence, indeed, enabled him to preserve his interest with the court, because it enabled him to secure the acquiescence of the clergy when it was of real importance to possess it, and when it could not otherwise have been obtained. One striking instance of this occurred in the case of the union, which could not have been accomplished if the clergy had opposed it, and against which they were actually disposed and prepared to remonstrate. Mr Carstares prevented them from carrying their design into effect; and for this eminent service the Queen took the opportunity of his being in London in the year following, to thank him in person, and at the same time to bestow upon him one of those few silver medals in commemoration of the union, which she had ordered to be struck off for her particular friends.

Though the union took away from the church of Scotland much of that importance which it had hitherto possessed in the eye of administration, and through, since it was no longer formidable to them, they no longer felt any great deference for its claims, yet Mr Carstares, by his personal exertions, contrived to uphold its respectability, and to preserve to it some portion of weight in the government of the country. His views, however, were much obstructed by the violent spirit and intemperate conduct of many of his Presbyterian brethren; and he had the double and painful task of first exposing himself to their censure by resisting their prejudices, and then of vindicating to the Queen and her ministers those very proceedings which he had formally condemned before they were adopted. When the bills for the restoration of patronage, and the toleration of the Episcopal clergy in Scotland, were brought into Parliament, he was one of the representatives sent up to oppose them. The opposition, which he seems to have carried on with sincerity, was unsuccessful. It was fortunate, however, that he had gone to London on this occasion, as it afforded him an opportunity of preventing measures which went directly to the material injury, if not the complete destruction, of our Presbyterian church. It was actually proposed, by some members of administration, to discontinue the annual meetings of Assembly, or, if they should be convened, to prorogue them as soon as they were constituted: and it was even in contemplation to bring a bill into Parliament for the purpose of taking away the only pretext of holding them in future. Mr Carstares prevailed on the government to refrain from these unjust and oppressive measures, on condition of his undertaking to use all his endeavours to allay those ferment which the late acts of the legislature had excited. In these endeavours he succeeded so well, that the Queen and her ministers were perfectly satisfied; and so high did he stand in their regard, in consequence of his prudent management, that they required him to name the person who should be appointed commissioner, and to dictate those instructions which he should think seasonable in the existing circumstances of the country.

Mr Carstares was extremely zealous for the Protestant succession in the House of Hanover; and said and did every thing in his power to forward that object. Of so much importance were his services deemed, that George I., two years before his arrival in England, signified, by a letter from his secretary, his acknowledgments to Mr Carstares for the part he had acted, and continued him his chaplain for Scotland; an office, however, which he did not live long to enjoy. In the month of August 1715, he was seized with an apoplectic fit, which carried him off about the end of December following, in the 67th year of his age. His body was interred in the Greyfriars church yard, Edinburgh, where a monument was afterwards erected to his memory, with a suitable inscription in Latin. By the university, the church, and the country at large, his death was sincerely lamented. They had good reason; for he had been to all of them a useful servant, and a distinguished ornament. King William declared, in presence of several of his courtiers, "that he had known Mr Carstares long; that he knew him well; and knew him to be an honest man." See McCormick's Life of Carstares, prefixed to Carstares' State Papers. (r)

CART. See Agriculture, chap. vi. sect. iv.

CARTES. See Descartes.

CARTESIAN TEMPERAMENTS OF THE MUSICAL SCALE. That the versatile genius of M. Descartes early led him to the consideration of the musical scale, is well known; but that his speculations on this subject proved not less abortive and inapplicable to the art, than his vortices and other parts of his philosophy were to the phenomena of Nature, has not, we believe, been any where shewn.

According to the "Animadversions" of Lord Brouncker "on the Musical Compendium" of Descartes, it appears, that two different systems of musical intervals, but constructed on similar principles, were recommended by that author to the adoption of musicians, viz. one wherein a ratio, whose common logarithm is .9754132, (a semitone, the smaller of Descartes, or interval =45.97715°±/.45m.,) is 10 times added to itself, leaving a difference, or wolf, flat, or
in defect, on the twelfth or resulting semitone, of about $\frac{1}{4}$ of a major comma, or more exactly

$-12.2182\delta$; the other, wherein the log. $9714813$

(orf the larger semitone of Descartes, $\pm 1.875642$

$+\sqrt{5}$) is 11 times repeated, leaving a semitonic wolf about $\frac{1}{4}\delta$ of a major comma, or more exactly

$+10.56952\delta$, sharper than the other semitones of this

These systems have been supposed by some persons to approach very nearly to the equal temperament, or isotonic system, which is, however, far from being the case; and they appear so very inapplicable to practice, that we shall dispense with calculating the beats of the 12 several fifths in each of these systems, according to our usual practice, and rather devote the room they would occupy, in explaining some of the most material properties of all systems constructed on similar principles to the above, viz.

wherein \textit{eleven semitones are equal}: In which case, the most favourable situation for the resulting temperament of wolf seems to be between G$^\#$ and A$^\#$, and yet here it will be found, that only the five keys, C, D$^\#$, A, B, and C$^\#$, can have their Vths, IIIrds, and 3rds, unaffected by this semitonic wolf; that D, E$^\#$, and E, are the only remaining keys that can have their IIrds and 3rds so unaffected; and that F, with a 3rd unaffected, is the only remaining key that can have either of its concords uncontaminated by the semitonic wolf of such a system. And it must not be imagined, that the above are the anomalous keys; and that those which include the resulting semitone, may be made, by a proper apportionment of the wolf, more harmonious than the above keys that exclude it, since it will be found on trial that G, F$^\#$, and G$^\#$, are the only three keys that can have the advantage of a semitonic wolf so contrived, in their Vths, IIIrds, and 3rds, in each case; and that F is the only remaining key where the Vth and IIrds can be taken to include the semitonic wolf, situated as above. And thus it appears, that in these Cartesian systems, on one of the above suppositions, no key bearing one sharp or one flat in its signature, and many others not much less frequent in use, can be made tolerable; while, on the only other supposition that can be made, (as to the value of the semitonic wolf as affecting the concords, the fifth in particular,) the natural keys (C and A) with most others in frequent use, must be sacrificed to others less frequent in their occurrence; disadvantages which do not attend the more rational system of \textit{eleven equal fifths}, instead of semitones, as shown by Mr Farey, in his account of \textit{regular Duodecime Systems}, in the \textit{Phil. Mag.} vol. xxxvi. p. 40. But we shall proceed to give a few theorems relating to Cartesian systems: Putting \(w\) for the semitonic wolf, or difference between the resulting semitone and all the eleven others, and \(r\) for the temperament or imperfection of the fifth resulting therefrom, though not included therein, and in terms of the small interval schisma or \(\Sigma\), (see Plate XXX. in Vol. II.)

First, \(w = \frac{1}{4}r - 1.715409\delta\), whence the semitone may readily be calculated if the fifth be given; and it appears also, that when \(w\) vanishes, or the fifth is to be perfect, the resulting semitone is 1.715409 \(\delta\) less than the other semitone. Second, \(r = 1.0066552\delta + \frac{1}{4}w\), whence, having the semitonic wolf, or semitones themselves, (because VIII - 12 semitones = \(w\),) the temperament of the fifths may be laid: and also it appears, that when \(w\) vanishes, 1.0066552 \(\delta\) results as the isotonic fifth temperament, (see \textit{Phil. Mag.} vol. xxxviii. p. 436.) Third, V - \(r\) being the value of each of the 5 fifths, where \(w\) does not enter, V + \(\frac{1}{4}r\) - 1.715409 \(\delta\) will be the value of each of the 7 quint wolves or fifths, (or D, E$^\#$, E, F, F$^\#$, G, and G$^\#$ in the above case,) wherein the semitonic wolf enters, as will be evident by equating these two classes of fifths, when \(-r = -1.0066552\delta\) will result, as above. Fourth, We have 7.5770452 - \(r\) for the sharp temperament of the 9 major thirds, where \(w\) does not enter. Fifth, 5.8616362 + \(\frac{1}{4}r\) will be the value of the 4 major tierce wolves (or F, F$^\#$, G, and G$^\#$,) wherein the semitonic wolf enters, which may be proved as above. Sixth, 7.770452 + \(r\) is the flat temperaments of the 9 minor thirds where \(w\) does not enter: And, Seventh, 9.3924542 - \(2r\) will be the value of the 3 minor tierce wolves, (or F$^\#$, G, G$^\#$,) wherein the semitonic wolf enters; the equating of which last temperament and wolf, will prove \(r\) in them to be equal to the isotonic temperament in such case, as before.

The above temperaments and wolves of the principal concords in the four last theorems, are very differently related to each other from what they are in regular douzeaves, as will appear on comparing them with the 13th, 16th, 14th, and 17th of Mr Farey's \textit{Corollaries}, in vol. xxxvi. p. 374, 375. of the Magazine above quoted.

On the whole, it appears that semitonic systems of this kind, by having six more quint wolves than are necessary, and some of them falling in the most material keys, as G, F, D, &c. are unworthy of further attention, except as an exercise for the musical student, when enquiring into the very curious nature and constitution of the Scale, which they can never too much explore, and which the seven theorems that we have calculated and given above, will be found greatly to facilitate. See our article \textit{Temperament}. (5)
CARTHAGE.

CARTHAGE, the chief city of Africa Propria, is situated in longitude 10° 40' east, latitude 36° 40' north. The materials we possess for composing a history of the Carthaginians, bear no proportion to the importance of the subject. Every page of ancient history contains some reference to this remarkable people, some circumstance with which they were directly or indirectly concerned; yet are we almost wholly ignorant of their internal polity, and of all the secret springs which gave energy to their exertions. We find them bearing a part in the most important transactions of the civilized states, pushing their maritime discoveries and their system of colonization into the remotest regions, and at last striving with Rome herself for the mastery of the world: Yet of their resources we know scarcely any thing, except from analogy and conjecture; and of the events of their domestic history our accounts are meagre and unsatisfactory. The information we possess is for the most part derived from the casual notices of the Greek and Roman historians, few of whom had the opportunity, some, as it appears, not even the inclination, to give fidelity and accuracy to their narratives. It is our business, therefore, to put together the fragments which (without a metaphor) lie scattered throughout the ancient historians: from these something like a continuous narrative may be formed; though still we must content ourselves with a partial and imperfect knowledge of many important points.

According to Procopius, (De Bello Vandal. lib. ii. c. 10.) the whole district of Africa, from Egypt to the Pillars of Hercules, was first peopled by the tribes that fled before Joshua from the countries of Canaan; and it seems unquestionable, that the system of colonization which had been begun by the great Phoenician cities, received a very powerful impulse from the revolution which that conquest produced: an impulse which was felt, not only on the northern shore of Africa, but throughout all the countries of Europe. It is impossible to reconcile the various and contradictory accounts of the foundation of Carthage, in any way but by supposing, that they may have reference to the different stages of settlements made on that part of the African coast; and this supposition is strengthened by the authority of Sallust, (De Bell. Jug. c. 18.) Petavius has bestowed great pains on this most difficult point of chronology. He enumerates (lib. ix. cap. 62.) all the statements which he had been able to discover. The opinion he adopts is, that it was founded about the middle of the ninth century before Christ. This nearly falls in with Sir Isaac Newton's conclusion; and Blair, whose Tables we follow throughout, coincides with it, placing the building of Carthage ante Christ. 869. We are perhaps justified in assuming this date as sufficiently exact, since it tallies very closely with the period at which the Phoenicians began to obtain naval ascendancy in the Mediterranean. The division of the seas had been obtained by the Lydians, the Thracians, the Rhodians, the Phrygians, and the Cyprians; the people of Phocicia had now, in their turn, succeeded to it, and they maintained it in undisputed possession for upwards of 200 years. To this period we may, without hesitation, refer the adventures of Elisa or Dido; who, as Justin informs us, quitted Tyre at the head of a numerous colony, to avoid the oppression of her brother Pygmalion. After touching at Cyprus, where she obtained an addition to her numbers, she proceeded to the African coast. A Phoenician settlement had been previously established at Utica, by which they were gladly received; the natives, too, welcomed their arrival, being eager to avail themselves of the commercial advantages which the arrival of the strangers held out. A negotiation was speedily entered upon for an allotment of land; the artifice which Dido is said to have practised in obtaining the allotment, is well known: She covenanted for as much land as the hide of an ox would inclose; (quantum loci bosini tergo circumdare poterint;) then cutting the hide into shreds, she claimed as much as she could surround with them. The site of the infant colony was well chosen. A bold projection of the African coast marks almost exactly the central point of the southern shore of the Mediterranean. A noble bay, formed by the promontories of Juno and Apollo, supplies all the advantages of a sheltered and capacious roadstead. At the bottom of this bay stretches a peninsula, 360 stadia, or about 45 miles, in circumference, connected with the mainland by an isthmus of the breadth of little more than three miles, (25 stadia.) Upon this isthmus Dido laid the foundation of her new town.

It may not, perhaps, be unseasonable to give by anticipation, in this place, a description of the town as it existed at the period of its greatest splendour. Several writers have left us minute accounts of its situation and appearance at the beginning of the second Punic war; by comparing and contrasting these accounts, we may be enabled to form some idea of its extent and magnificence.

The city consisted of three parts: Byrsa, or the

* There are some slight differences amongst the ancient geographers respecting the extent of the country which was called Africa Propria. Mela (lib. i. c. 7.) describes it as containing all the countries situated between the river Ampasga and the borders of Cyrenaica: But this would include part of Numidia and Regio Syrtes, which must be considered as distinct from the proper territory of Carthage. Its true limits seem to have been, the river Tunes on the west, the frontier of the Garamantes and the deserts of Libya Interior on the south, and the Mediterranean with the Lesser Syrtis to the north and east. It was divided into two provinces, Regio Zeticana to the west, and Byzacian or Emporia to the east.

† The name Dido appears to have been only a characteristic appellative, signifying, according to Servius, a 'virago'; but Sochart shews, that it meant a 'wanderer.'
CARTHAGE.

Cartage.

Description of the town of Carthage at its greatest splendour.

Citadel; Megara, or Magaria; and the Cothon, or port. The quarter called Byrsa is said to have been twenty-two stadia in circumference, and was situated in the centre of the city: its highest point was a steep rock, on which stood a temple of Asculapius.

This part of the town was thought to have been built by Dido herself; its name is a Greek corruption of the true Punic or Phœnician word Bosra, or Bostra, i. e. a fortress or citadel. The name of the second division of the town, Megara, or Magaria, may also, according to Bochart, be traced to the Phœnician, in which language it signifies houses or a town. It was situated so as to encircle the Byrsa.

The name of the third quarter, Cothon, has also been derived from the Phœnician word which expresses an "artificial harbor." The entrance to the port was seventy feet broad, and was contrived so that it might be shut up with chains. The harbour was double; the outer part appropriated exclusively to the use of merchants, the inner fitted for the reception of ships of war. In the midst of the inner harbour was an island, which, as well as the harbour itself, was lined with large quays, in which were distinct receptacles (nagia) for laying up 220 ships of war: over these was a range of store-houses, for the necessary articles of naval equipment. The entrance into each of these docks was adorned with pillars of the Ionic order, so that the harbour and the island had the appearance of a magnificent gallery (παρεκτήσις).

The merchants' harbour was completely separated from the arsenal, and had a distinct communication with the town, (Appian, de Bell. Punic.) As to the extent of the city, Livy intimates, (lib. li. in epitom.) that it was twenty-three miles in circumference;—the number of inhabitants was roundly estimated at 700,000. This is the number given by Strabo, (lib. xvii.;) and if we consider, that Carthage united "extensive commerce and meddling empire," the circumstances which Hume expressly mentions, (Essay xi.) as the obvious causes of the growth of large cities, it may perhaps be thought, that this statement is not so much overcharged as some of those which have come down to us, of the populousness of ancient nations.

At no period of their history did the Carthaginians lose sight of their Canaanish origin. Plautus (in Poenulo, act. v. sc. 3.) expressly alludes to it; and St Augustin says, that the tradition was even in his days preserved. Their language appears to have been formed by a mixture of Hebrew or Phœnician with the peculiar dialect used by the more ancient inhabitants of Africa. Hence the epithets in Plautus of migidlyths and bisulcattianum. (Poen. act. v. sc. iii.) But some authors have imagined, that the Libo-Phœnicians were a people distinct both from the Carthaginians and Libyans, in the same way as the mixed race bordering on the respective frontiers of Syria and Phœnicia were called Syro-Phœnician.

The government of Carthage was, at its origin, probably monarchical. Justin expressly assigns the regal character to Dido, (lib. xviii. c. 7.) A very short time, however, could have elapsed before it was changed into a republic: Its exact form cannot be ascertained. Aristotle, in a minute but somewhat obscure account, describes it as a mixed government, (De Repub. lib. ii. c. 11.) consisting of an aristocracy, and of what he calls politeia; by which word, as he himself explains it, (Eth. Nicom. lib. viii. c. 12.) he means an oligarchy,—a government in which wealth formed the only title to office. * Polybius says, that the monarchical, the aristocratical, and the democratical forms were all united in it. But Isocrates (Isocrates in Niccol. vol. i. p. 96.) seems to have had a more practical view of it, when he says, that the civil government was oligarchical, and the military monarchical; that is, in modern language, the legislative an oligarchy, and the executive a monarchy.

For though the appointment and the functions of the Suffetes give to the constitution something of a monarchical air, the principle of the whole was oligarchical; all offices were elective, and all elections had reference to property. We will proceed to give some account of the constitution in its three branches.

The chief magistrates, two in number, called Suffetes, † were elected annually from the noblest families, and always supposed to be chosen for their wealth and talents. Their province was to assemble the senate, (Liv. 34. 62.) in which they presided, in order to propose the subjects of deliberation, and to receive the suffrages. If the suffetes concurred with the senate, the decision was final; if otherwise, the matter was referred to the people, (Arist. ubi supra.) It will be evident, that the suffetes answered in some degree to the kings of Lacedemmon, and to the consuls of Rome; consequently, in some authors, we find them indifferently called either kings or consuls, (Justin, xxxi. 3.) But they differ from the former in as much as they were elective; and from the latter, as they were confined to civil affairs. It is not ascertained by whom the suffetes were elected, probably by the people, as an office similar to theirs existed in all the towns of note throughout the Carthaginian dominions.

The senatorial dignity was elective, as appears from Of the the senate, though it is not known in whom the election lay. There does not appear to have been any specific qualification, as birth, riches, and individual merit are, in their turns, mentioned as supplying sufficient claims. We are ignorant of the number which composed the senate, though probably it was very large; for Justin mentions, (lib. xix. c. 27) that on one occasion a hundred were selected to investigate some alleged misconduct of their generals. In this great council, every thing relating to peace and war, negotiations and alliances, in a word, all affairs of consequence, whether foreign or domestic, were debated, and for the most part determined. There was, however, in its constitution one provision, which is obviously anomalous to every principle of good government. The decision of the senate was not final, unless the vote were unanimous, and received the sanction of the suffetes.

* The authors of The Universal History observe, that in the apregaphenia men were supposed to be divided into the rich, the poor, and the virtuous; in the Dasileher only into rich and poor.
† This name is evidently borrowed from the Hebrew דודש, saphetim, the appellation of the judges of Israel.

VOL V. PART II.
Hence the people, by degrees, acquired an overpowering influence. The consequences were, as might be expected, fatal: For, during the second and third Punic wars, every thing was referred to the populace; while in Rome, on the contrary, the senatorial influence was in full vigour; and thus, as Polybius remarks, (book vi.) the Romans, even after their severe defeats, by means of their good government, recovered, and were finally victorious.

The centumvirate consisted of an hundred and four persons, elected from the senate; they seem to have had extensive power, though confided, as Aristotle (ubi sup. see also Alexander ab Alexandro, lib. iv. c. 11.) intimates, chiefly to affairs of a judicial nature. They were, as we have seen above, (Justin,) appointed, in the first instance, for the purpose of inquiring into the conduct of their generals in an unsuccessful expedition; and though their power afterwards was considerably enlarged, this seems to have been their principal business. Aristotle compares them to the Ephori at Sparta; but it will appear, that the tribunal which we shall next consider has a better title to this comparison. The quinquevirate consisted of five men, selected from the centumvirate, possessed almost of despotic authority. Their privileges are imperfectly known, but they seem to have been almost unlimited. They had cognizance of all affairs, whether of a public or of a private nature, and appear to have constituted a court of appeal in the last resort for all causes. It is not certain whether the office was perpetual. They not only had the power of filling up the vacancies in their own body; but we learn from Aristotle, that they chose those persons who composed the tribunal of the centumvirate.

The principal offices in the executive government of Carthage were, the praetor, the questor, and the censor; titles which seem to have been given by the Roman historians, from the analogy of their duties to the same officers in their own constitution.*

Remains of the code of laws. Of the system of Carthaginian legislation very considerable traces remain; and those are important, not only as they throw light on the manners of the people.—Diodorus mentions a law of a very long duration, that those children alone who were nobly born should be sacrificed to Saturn. This had fallen into disuse, but was revived on an occasion of great public emergency, (Diodorus, lib. xx.) when two hundred children of the best families were offered at once to stone for the neglect. Some other laws regulating the popular superstitions are preserved. Indeed it is most singular, that of the very few fragments that remain to us, there is not one but is calculated, in some degree, to confirm the belief that Carthage must have been immersed in the most degrading barbarism. Even so late as the time of the elder Dionysius, we find that a law was made, (Justin, book xx. c. 5.) prohibiting every inhabitant of Carthage from learning either to write or to speak Greek. However, this absurd law must have been in a very short time either repealed or neglected, as Hannibal seems to have been eminently skilled in that language.

Accounts are preserved of several very peculiar Punic customs which prevailed among the Carthaginians. In any great public calamity, the city was hung with black; this took place more than once. Its inhabitants fed on the flesh of dogs till the time of Darius Hyestaspe, who interfered to prevent the continuance of this practice, and stipulated that their compliance in this point should be a condition of his entering into alliance with them; as also, that they should cease to offer human sacrifices, and that they should burn instead of burying their dead. The magistrates in office, and the soldiers in the field, were forbidden to drink wine. The generals were held personally responsible for the success of their undertakings, and several instances are recorded in which they were punished for their failure with death. The populace and senators had distinct baths; this is mentioned by Valerius Maximus (lib. ix. c. 5.) in proof of the extreme arrogancy of the senate; but he gives no further particulars relating to it. Like the Greeks and Romans, they had no public inns, but strangers were entertained in private houses; and, like them, they paid uniform respect to soothsayers of all descriptions.

It would appear that the religious worship of the Religious Carthaginians was taken entirely from the Phoeni- cians; but as their frequent intercourse with the Greeks, especially those of Sicily, induced them to adopt many of their religious ceremonies, and even some of their deities, and, as the Greek and Roman writers invariably apply the names of their own deities to the gods of foreign nations, the subject is involved in very great obscurity.

The principal deity worshipped at Carthage, as Diodorus informs us, was Chronus, who, according to Quintus Curtius (lib. iv. c. 3.) was the same with Saturn. Though the Punic name of this deity is not known, there seems good reason to conclude, from the similarity of rites, and other circum-stances, that he was the same as Moloch, or Milochem, the famous idol of the Ammonites, Canaanites, and other neigbouring nations. (Lev. xviii. 21. xx. 2, 3. 4.)

The deity next in estimation was Urania, called, in the Phoenician, Belis, or Belther. It is not easy to determine whether she most resembled the Venus or the Juno of the Greek mythology. St Austin seems to have considered her as the first, but Virgil distinctly asserts that she was the second. (See Æn. i. and Ævus not. in loc.) Of the subordinate deities little is known, and that little is unsatisfactory. The most celebrated was the Tyrian Hercules, whose

* Aristotle argues, that the different powers in the Carthaginian constitution must have been very nicely adjusted, and states, in proof, its very long continuance without a deviation into tyranny on the one side, or anarchy on the other: however, he himself notices, that the propensity for colonization, which seems always to have existed amongst the Carthaginians, may, in a great degree, account for this, though it cannot be considered as a remedy applied and enforced by the laws. With his characteristic acuteness, he detects the fault of the Carthaginian constitution, and foretells its baneful effects; remarking that the legislature is compelled to regard property rather than merit; μὴ πρὸς ἀρχιτέκτοναι, αλλὰ πρὸς θησαυρῶν τοὺς ἀρχηγείους.
worse extended over the coasts of Africa as far as Cadiz, where he had a temple: he was supposed to preside over gold and silver, and all sorts of treasures. Asklepius, also, was a very popular deity, and had a temple on the summit of the Byrsa. A list of several other names is given, but little is known concerning them; some are supposed to have been celebrated persons, to whom divine honours were paid. In the preamble to a treaty made with Philip of Macedon, (Polyb. lib. vii.) there is an enumeration of many deities; among the rest the Aesculapius, or genius of Carthage. We cannot determine who is meant by this title: it is sufficient only to notice the fact, and to add, that the heathen world looked upon these demons as intelligences of a middle nature between gods and men, as beings to whom the administration of the affairs of the world was committed.Originally, the Carthaginian language was the same as the Phoenician or Hebrew; and notwithstanding some little variations, caused by the distance from the mother country, and the incorporation with the neighbouring nations, it ever continued in substance the same. An attempt has been made in modern times, to trace in the Maltese dialect the remains of the ancient Punic, and with some appearance of probability. As to the visions of the antiquarians of our own day, they are much too fanciful, and founded on much too narrow a basis, to detain us with a consideration of them.

Literature and science appear, during every period of their history, to have been at a very low ebb among the Carthaginians. Even the names of their writers have perished with their works. However, it should be remembered, that the Romans exercised the most severe cruelty, in destroying not only the public archives, but almost every thing which the Punic writers had produced, which bore any appearance of general literature or history. But though this is sufficient to account for the total disappearance of the works of Carthaginian writers, we are not authorised to conclude, on the other hand, that they ever were very numerous, or very celebrated. In fact, it does not appear that the Carthaginian at any time were a refined or a literary people. In the first ages of their history, their character is stained by traits of the grossest barbarism; and this was afterwards modified, rather than subdued, by commerce and its attendant luxury. Plutarch represents them as uniformly of a morose and saturnine disposition, utterly averse to any thing which had the appearance of wit, raillery, or refinement. They seem to have been deeply tinctured with all the worst vices of a trading nation.

* For an account of this deity, and his name, Melcarites, see Newton's Chronology, p. 110, 111.

† The great Hannibal is said to have been skilled in the Greek language, and to have written a history of Manlius Vulso's proconsulship in Asia.

Magro, another celebrated general, wrote a treatise on agriculture, in 28 books. Cicero speaks of him with praise: (De Oratore, lib. I. 249.) Varro relates that they were translated into Greek by Dionysius Ulicensius; and Columella, that the senate, by a public decree, directed the translation of them into Latin.

Ptolomy, though born at Agrigentum in Sicily, is spoken of as a Carthaginian historian. Polybius complains greatly of his want of fidelity. To Hume and Hanno, both Carthaginian commanders, the ancients were indebted for the best accounts of the western shores of Europe and Africa.

Cicero, the successor of Carneades in the philosophical chair at Athens, was a Carthaginian by birth: Cicero speaks highly of him. (Acad. Quest. lib. iv. 90. Tusc. Quest. lib. ii. 44.)

The Carthaginian purple differed from the Tyrian; it was of a deeper tint; the Tyrian was of the colour of an unripe

They were tyrannical and cruel; sordid, and proverbially faithless; and though we must be inclined to receive with caution the accounts which their implacable enemies, the Romans, have left us, yet the whole tenor of their history is so uniform in this representation of them, that we are compelled to believe it, or to suppose the historians guilty of incredible malice, united with the most successful ingenuity. In turning to the brighter parts of their character, we are first attracted by their acknowledged skill in the mechanical arts. This, in all probability, they derived from their Tyrian ancestors; and we require no further proof of their very great excellence, than the fact that, even at Rome, any singular invention, or curious piece of workmanship, was called, by way of eminence, Punic. Thus we find Valerius Maximus (lib. vii. c. 5.) speaking of the Lectuli Punicani, Plautus of the Laterae Punicae, and Cato (de Re Rustica) applies the epithet to a great number of things.

Their army was composed entirely of mercenaries. Polybius (lib. vi.) gives a most sensible and eloquent enumeration of the evils of this system; and the acute historian of the Roman republic remarks, "That the Carthaginians were among the few nations of the world who had the ingenuity, or rather the misfortune, to make war without becoming military; and who could be successful abroad while they were liable to become a prey to the meanest invader at home." Hannibal stands almost a solitary example of a Carthaginian possessing superior knowledge in military science; only a short time before, his countrymen had been compelled to have recourse to the Grecian skill and discipline.

Their marine was most deservedly celebrated. Marine. Polybius (lib. vi.) does not hesitate to prefer it to that of any other nation in the world. The extreme attention which was paid to it, may be inferred from the description of the naval arsenal which we have given above. There are no means of ascertaining exactly the number of ships at any time actually fitted for service; probably the Cothon was capable of receiving their whole navy.

In commerce and navigation they were, beyond all question, unrivalled. Their mariners were perfectly acquainted with all the ports of the Mediterranean. To the East their discoveries were extended as far as any other nation, and to the West they seem to have penetrated farther than their rivals presumed to follow them. In addition to their own export of staple manufactures, utensils, naval stores, and the purple dye which is so celebrated, they appear to have possessed the carrying trade of the

Constitution of their military force.

Navigation, and commerce.
The site of the infant colony appears to have been admirably chosen, and the new city flourished so rapidly, that Jarbas, a native prince, was induced to make himself master of it. He desired that ten of the most noble Carthaginians should be sent to him as ambassadors; to these he proposed himself as the suitor of Dido, and having induced them by threats and promises to enter into his views, he dismissed them. By an artifice they procured from Dido a promise to comply with their wishes; but she, to avoid the fulfilment of the contract, and the imputation of slighting the memory of her first husband, Sichaeus, devoted herself to a voluntary death. This is Justin's account, and it evidently differs not a little from that which Virgil has given us. Much discussion has been employed to reconcile these differences; and Sir Isaac Newton (Chronol. p. 65.) seems inclined to favour Virgil's statement, from the idea that he might have had access to the archives of Carthage; and the arguments he brings forward, seem to render the statement that Dido and Aeneas were contemporaries, more probable than that which is learned in general are willing to allow. However, the reasoning is far from conclusive, and we shall be content in this, and in all other instances, to follow the chronology of Blair, who places the destruction of Troy 408 years before the first Olympiad, (B.C. 1184,) while he brings the foundation of Carthage about 300 years later (B. C. 869.)

How long the monarchical form of government continued at Carthage, we have no means of ascertaining, nor are we acquainted with any of the circumstances which befell the infant state. There is a chasm in the history of the Carthaginians of no less than three hundred years. Their progress in this interval could not have been slow; for from the first notice we have of their existence as a people in the ancient historians, (Herod. in Clit. Thucyd. lib. i. p. 11.) we find them in alliance with the Tuscans, bringing forward a fleet of 120 sail, and combating with the Phœnicians, who had settled in the island of Corsica, in their progress from Asia to the southern shores of France. (B.C. 539.) The Phœnicians were victorious; but Herodotus intimates, that the victory was in the end greatly detrimental to their interests. At about this period also, the Carthaginians, as Justin informs us, (lib. xxi. c. 7.) engaged in war with the neighbouring African princes, in which they were victorious by the skill and bravery of their general, Maleus, or as Vossius would correct it, Malchus. Under the command of the same general, they made, for the first time, a descent on Sicily, and Sicily, subjugated a great part of the island. This event supplies a convincing proof, that they had now begun to be animated by that spirit of enterprise which afterwards rendered them so remarkable. Elated by their success in this instance, they proceeded to carry their victorious arms into Sardinia; though it appears that at the same time they were agitated by domestic discussions, and wasted by a most destruc-

ve sort, which is not to be attributed to the republic or her allies.

Having thus noticed what is most important and peculiar relative to Carthage, its domestic policy, and external relations, we resume our summary view of its history:—premising, that of those circumstances which are not important either in themselves or their consequences, our sketch will be slight and rapid, in order that we may be enabled more fully to describe events of superior importance.

The site of the infant colony appears to have been admired and chosen, and the new city flourished so rapidly, that Jarbas, a native prince, was induced to make himself master of it. He desired that ten of the most noble Carthaginians should be sent to him as ambassadors; to these he proposed himself as the suitor of Dido, and having induced them by threats and promises to enter into his views, he dismissed them. By an artifice they procured from Dido a promise to comply with their wishes; but she, to avoid the fulfilment of the contract, and the imputation of slighting the memory of her first husband, Sichæus, devoted herself to a voluntary death. This is Justin's account, and it evidently differs not a little from that which Virgil has given us. Much discussion has been employed to reconcile these differences; and Sir Isaac Newton (Chronol. p. 65.) seems inclined to favour Virgil's statement, from the idea that he might have had access to the archives of Carthage; and the arguments he brings forward, seem to render the statement that Dido and Aeneas were contemporaries, more probable than that which is learned in general are willing to allow. However, the reasoning is far from conclusive, and we shall be content in this, and in all other instances, to follow the chronology of Blair, who places the destruction of Troy 408 years before the first Olympiad, (B.C. 1184,) while he brings the foundation of Carthage about 300 years later (B. C. 869.)

How long the monarchical form of government continued at Carthage, we have no means of ascertaining, nor are we acquainted with any of the circumstances which befell the infant state. There is a chasm in the history of the Carthaginians of no less than three hundred years. Their progress in this interval could not have been slow; for from the first notice we have of their existence as a people in the ancient historians, (Herod. in Clit. Thucyd. lib. i. p. 11.) we find them in alliance with the Tuscans, bringing forward a fleet of 120 sail, and combating with the Phœnicians, who had settled in the island of Corsica, in their progress from Asia to the southern shores of France. (B.C. 539.) The Phœnicians were victorious; but Herodotus intimates, that the victory was in the end greatly detrimental to their interests. At about this period also, the Carthaginians, as Justin informs us, (lib. xxi. c. 7.) engaged in war with the neighbouring African princes, in which they were victorious by the skill and bravery of their general, Maleus, or as Vossius would correct it, Malchus. Under the command of the same general, they made, for the first time, a descent on Sicily, and Sicily, subjugated a great part of the island. This event supplies a convincing proof, that they had now begun to be animated by that spirit of enterprise which afterwards rendered them so remarkable. Elated by their success in this instance, they proceeded to carry their victorious arms into Sardinia; though it appears that at the same time they were agitated by domestic discussions, and wasted by a most destruc-

ve sort, which is not to be attributed to the republic or her allies.

Having thus noticed what is most important and peculiar relative to Carthage, its domestic policy, and external relations, we resume our summary view of its history:—premising, that of those circumstances which are not important either in themselves or their consequences, our sketch will be slight and rapid, in order that we may be enabled more fully to describe events of superior importance.
Diodorus, and for his disobedience in refusing to join him in the first instance, ordered him to be crucified. The citizens, dismayed by this act of resolute severity, surrendered immediately, and gave themselves up to the conqueror's mercy. He contented himself with ordering for execution ten of the senators, by whose advice the late violent resolutions had been undertaken. Thus peace was restored; but Malchus, soon after being suspected of aiming at the sovereign authority, was put to death.

The Carthaginian power was now rapidly increasing; for Herodotus informs us, (lib. iii.) that Cambyses, in the sixth year of his reign, was desirous of making an expedition against Carthage, but he was compelled to abandon his design, because the Phoenicians refused their co-operation, alleging in excuse, their intimate connection with the Carthaginian people. (Polyb. lib. iii.) In the first year after the expulsion of the kings, (B.C. 509,) the Carthaginians sent ambassadors to Rome, and concluded a treaty with that people. The objects of this treaty, as we have stated above, were purely commercial; and its regulations are in the highest degree curious and important. It is preserved to us by Polybius, who professes to have copied it from an ancient document existing in his time. The treaty appears to have for its object the entire exclusion of the Romans from any connection with the richer and more fertile parts of the Carthaginian territories, whilst it leaves open the colonies and the capital. The successor of Malchus in his influence and office was Mago, the founder of that most powerful family from which sprang the illustrious Hannibal. Justin (lib. xxx. c. 1.) has transmitted to us the most favourable character of him: under his auspices the affairs of Carthage flourished both at home and abroad, and its army was for the first time reduced to a state of discipline and subordination. His two sons, Hasdrubal and Hamilcar, succeeded to his power in the state. Under these leaders, a war was begun with the Sardinians, probably with a view of confirming the Carthaginian power in that island, which appears to have been but imperfectly established; however, they seem not to have made good their object; for Hasdrubal was slain, and we have no account of the success of his forces. It must have been about this time (B.C. 495.) that Darius Hystaspes sent that embassy to Carthage, of which we have before made mention. Its object was to reduce the Carthaginians to abstinence from human sacrifices; from the custom of eating dog's flesh; and from the practice of entombing their dead. He added a request, that they would co-operate in the war he then meditated against Greece. It is in Justin only that we find an account of these various circumstances; and he neglects to inform us on what pretext the Persian king thus ventured to interfere in the domestic policy of an independent state. He adds, that the Carthaginians were eager to comply with the former stipulations, as from the situation of their own affairs, they were compelled to decline taking any part in the war.

Some years afterwards, the Grecian colonies in Sicily, finding themselves harassed by the Carthaginians, applied for assistance to the Spartans; (Justin. lib. xix.) The application was fruitless; nevertheless Gelo, who had (B.C. 491.) obtained the sovereignty in Syracuse, not only made resistance to their aggression, but even extended his own dominions.

The embassy of Darius, mentioned above, seems to have produced some effect; for, in the third year with his successor Xerxes, (B.C. 489.) we find (Herod. lib. vii.; Diodorus, lib. xi.) an alliance offensive and defensive entered into between the two states, in which it is stipulated, that the Carthaginians should invade Sicily with all their forces, at the same time that Xerxes proceeded, with all the strength of the Persian empire, to attack Greece itself.

In pursuance of these engagements, the Carthaginians made vast preparations for the war. Xerxes supplied them with immense sums of money; yet the armament was so enormous, that three years elapsed before it was completely equipped. All things being at last in readiness, they set sail with an arm of 300,000 men, principally mercenaries, a fleet of more than two thousand ships of war, and three thousand transports. The commander of this mighty force was (according to Justin,) the same Hamilcar, brother to Hasdrubal, and son of Mago, of whom we have before spoken; but Herodotus calls his father Hanno. The fleet was partially scattered by a storm, and the commander's baggage was entirely lost; which the Carthaginians, with their characteristic superstition, considered as ominous of the misfortunes which ensued. They landed at Panormus, and after three days rest advanced to Himera. Hamilcar prosecuted the siege with great vigour: he was attacked in his trenches by the combined forces of the Sicilians, under Gelo and Theron; the former of whom had lately usurped the supreme authority at Syracuse, the latter at Agrigentum. The battle was severely contested, but it ended in the complete annihilation of the Carthaginian army. According to the statement of the historians, not less than one hundred and fifty thousand were killed, and the remainder compelled to surrender at discretion. Hamilcar perished with his troops. Herodotus gives a very extraordinary account of the manner of his death. He describes him, as employing himself during the action in heaping up human victims; and when he found the battle was irrecoverably lost, he himself rushed into the midst of the flames. The loss of the Carthaginians was not confined to their land forces, the conquerors quickly made themselves masters of the fleet; twenty ships which had been left afloat, set sail for Carthage, but were lost in the passage, so that only a single boat escaped to tell the news. It should be observed, that Herodotus (lib. vii.) gives another account of the cause of this war, which he said he received from the Sicilian writers of his time. This would represent the war as undertaken for the purpose of restoring one Teleilus, who had been ejected from Himera by Theron the tyrant of Agrigentum. This might perhaps have been one of the collateral motives, but it is surely in itself inadequate to account for the magnitude of the Carthaginian preparations.

Gelo conducted himself with great moderation; Treaty he granted peace to the Carthaginians, on the very with ease conditions that they should pay 2000 talents of silver towards the expenses of the war; and second-

ly, that they should build two temples, * in which the tablets containing the conditions of the treaty might be consecrated; and thirdly, that they should cease to offer human sacrifices.

When the Carthaginians began to look abroad after this terrible overthrow, their attention was again attracted towards Sicily. A dispute between the cities of Egista and Selinus supplied them with a pretext. Hannibal, the grandson of Hamilcar, (Diodor. lib. xiii,) who was at this time one of the Succedes, had ascendency in their commonwealth, and under his command they again hazarded all their force, upon the chances of a Sicilian campaign. He landed (B. C. 409,) near the promontory of Lilybaem, and advanced to Selinus, which, after a vigorous resistance, he took by assault. He appears to have treated this city with an excess of barbarity, which even Carthaginian ferocity does not prepare us to expect. Sixteen thousand of the inhabitants were put to the sword, five thousand were carried away captives, and the miserable remainder escaped to Agrigentum. The city itself was utterly destroyed. Himera was his next object, not only from its importance, and from its unvarying animosity to the Carthaginians, but as it was the scene of his grandfather's overthrow, he was eager to subdue it. The citizens made a most desperate but ineffectual resistance. Diodorus has given minute details of this siege, which are highly curious, as they afford information of the state of military science at this period. The city experienced the same fate as Selinus; and Hannibal, leaving a small body of troops to assist the confederates, before the conclusion of the year returned to Carthage, where he was received with the most distinguished honour.

The Carthaginians were so elated with their recent success, that they seriously meditated the conquest of the whole island of Sicily. They made the greatest preparation for this renewed attack; and having joined Hamilcar, the son of Hanno, in commission with Hannibal, who, from his age and infirmities, was unequal to the various duties of the chief command, the expedition set forth.

Their first object was Agrigentum, a city second only to Syracuse. (Diod. Sic. lib. xiii.) The Sicilians had not been negligent in their preparations to oppose this formidable invasion; in consequence, the Carthaginian generals had scarcely time to form the siege, before they were attacked by a force which the Syracusans sent to the assistance of their allies, under the command of Daphneus. Hamilcar detached a force to oppose them, but they were completely worsted; and, had the garrison availed themselves of the opportunity, the whole army might have been completely destroyed. They had reason to repent of this negligence; for Hamilcar, having corrupted a part of the garrison, and received information that the remainder were distracted by jealousies and dissensions, carried the place by storm; and, as usual, put the inhabitants to the sword, and pillaged the whole city.

The Syracusans now began to contemplate with alarm the progress which the Carthaginians had made. The domestic disensions which ensued in consequence of this alarm, gave Dionysius an opportunity of assuming the sovereign power. Hamilcar next proceeded to ravage the territories of Camarina and Gela. He laid siege to the last city, and Dionysius in vain endeavoured to relieve it. The inhabitants were by a successful artifice, escaped, and left the city to the mercy of the conqueror. Camarina shared the same fate; but Hamilcar finding his army weakened, partly by the cruelties of war, and partly by a destructive pestilence, offered terms of peace to the conqueror. The offer was gladly accepted by Dionysius, and a Treaty with Dionysius.

Likewise Camarin and Gela.

Treachery

of Diony-

sius.

Dionysius, in pursuance of the plan he had laid His pro-
down, without waiting for an answer from Carthage, at once attacked Motya, a celebrated Carthaginian colony, near Mount Eryx. He succeeded in carry-
ing the place by surprise. The resistance of the in-
habants and garrison was, as usual, most obstinate. Sieges were at this time seldom undertaken with any other view than that of plunder. In consequence, the garrison was always roused to that excess of va.

Takes Mor-

our which is the natural result of despair. Caritu.

ation was invariably followed by indiscriminate pil-
lage, and the most dreadful slaughter. There is, be-

sides, something in the circumstances of a siege which, beyond all other motives, gives birth to the most obstinate valour. Every age and every country
A peace of nine years continuance followed; which was again broken by the restless ambition of Dionysius; another sanguinary war succeeded, and after it as usual, a hollow and suspicious peace. At length death relieved the Carthaginians from this implacable foe. Dionysius was carried off by the effects of a debauch. He was succeeded by his son in the government of Syracuse. (Diod. Sic. lib. xv.)

Habitual indolence induced the younger Dionysius to maintain the peace inviolable, so long as his influence continued; but the Syracusans being torn by intestine commotions, the Carthaginians persuaded themselves that they had a good opportunity of accomplishing their favourite object, the reduction of the whole island. (Plut. in Vit. Timol. Diod. Sic.)

The Syracusans applied to Corinth for assistance, from which state they were supplied with a body of troops under the command of the celebrated Timoleon. (B. C. 341.) It would be some relief to the mind, wearied with contemplating this unvarying series of cruelty and perfidy, if it could dwell for a short time on the character of this illustrious person; but the limits of this work forbid it.

Timoleon, though opposed by a superior force, made good his landing in Sicily, at Taurominium, Andromachus, the father of Timaeus the celebrated historian of Sicily, then possessed that doubtful sort of authority at Taurominium, which the ancient historians describe under the general name of a tyranny; by which they, for the most part, intend to signify an ascendancy in the public affairs, obtained and preserved only by the weight of talents and personal character, which controlled the laws, while it affected to act in suberviency to them. In the commonwealth of Greece, instances of this sort of authority are continually occurring. It supplies an unanswerable argument against the theories of the speculative republican, when we find the democracies of Greece, each in its turn, yielding to this kind of authority; and Rome, in every period of hazard and public calamity, compelled to have recourse to the necessary but pernicious authority of a dictator. The nature of this tyranny seems to have depended on the personal character of him who possessed it. Nothing could have been more hateful than the authority which Dionysius exercised, whilst the sway of Andromachus, in his city Taurominium, seems to have been most gentle, and most salutary. He governed, says Plutarch, (Συνεχίσεως) with justice, and according to law. The Carthaginians threatened Andromachus with their vengeance, unless he dismissed Timoleon from his territories. (Plut. in Vit. Timol.) Plutarch has preserved the form of the menace, which is so striking, and so characteristic of those oriental manners, with which the Carthaginians were still imbued, that it should not be passed over. The messenger stretched out his hand with the palm upward, and thus turned it over, implying that Taurominium should be treated in the same manner. Andromachus appears to have estimated the menace as it deserved; he steadily adhered to the party which he had espoused; and thus gave occasion to that rapid and glorious career which places Timoleon amongst the most celebrated commanders of antiquity. Dismayed by the rapidity of Timoleon's first movements, the Cartha-
Carthage.

Their selected one Hamilcar, (surnamed Rhodanus,) a man eminent for his eloquence and skill in negotiation, who, representing himself as an exile from his native country, procured, through the intervention of Parmenio, an introduction to Alexander, and obtained permission to accompany him in all his expeditions. He was thus enabled to do his country signal service, by communicating all Alexander's plans, and appears to have managed this most difficult duty with the utmost address; nevertheless his barbarous and ungrateful country required him by a cruel death, upon a charge that he had failed to do all that was in his power.

After a few years, we find the Carthaginians again embroiled in the affairs of Sicily.

Agathocles, (Justin, lib. xxii. c. 1. Diod. Sic. lib. xix. sub init.) by an almost singular union of courage, artifice, and good fortune, had raised himself from the lowest condition to the sovereignty of Syracuse. But this unhoped-for advancement failed to satisfy his ambition. By degrees he contrived to make himself master of the Grecian dependencies in Sicily, and now threatened to become to the Carthaginians a more formidable opponent than they had hitherto been called on to encounter. In the first instance, his cause had been espoused by the Carthaginian commander in Sicily; but the senate quickly saw the impolicy of this conduct, and found that they were fanning a flame by which themselves would in the end be consumed.

They determined to strengthen their forces in Sicily; a considerable reinforcement was therefore dispatched, but the fleet was overtaken by a storm, and many ships of war and transports were lost. Notwithstanding this severe reverse, the Carthaginian general found himself at the head of 40,000 foot, and 5000 horse. With these he succeeded in defeating Agathocles near Himera, (B.C. 309.) Their success in this engagement was principally owing, as Diodorus (lib. xxxix. xxii.) informs us, to the skill of the slingers from the Balearic Isles. This victory involved many important consequences. All the principal places yielded to the conqueror, and Agathocles, in despair, shut himself up in Syracuse. The Carthaginians invested the place with their whole force; when Agathocles, finding himself deprived of all resources, and on the point of falling into the enemies' hands, adopted the spirited and almost incredible determination of carrying the war at once into Africa. The mouth of the harbour was closely blockaded by the Carthaginian fleet, yet Agathocles watched his opportunity so artfully, and availed himself of circumstances so adroitly, that he managed to elude their vigilance, and sailed straight for Africa. The Carthaginian admiral was not slow in the pursuit, but did not come up with the Syracusan fleet till they were in sight of the African coast. A partial engagement ensued, but Agathocles was not to be diverted from his main object; he made good his landing, and then, under pretence of fulfilling a vow he had made to Ceres and Proserpine, he set fire to his ships. (Justin. xxii. and Diod. xx.)

The consternation at Carthage, when the news of this descent of Agathocles arrived, was excessive. The flower of their army was in Sicily; their city

In the following year, the Carthaginians exerted their utmost strength to crush the increasing power of Timoleon, and recover their former influence in Sicily. Seventy thousand land forces, two hundred ships of war, and a thousand transports, with a vast equipment of military stores, were entrusted to the care of Asdrubal and Hamilcar. Timoleon had not passed the interval in idleness, the art of war was progressively becoming more an object of attention amongst the Grecians, and Timoleon was one of those who had most successfully cultivated it. His forces scarcely amounted to 7000, and even these were greatly weakened by desertion as the season advanced. The armies met near the river Crinmisus, and the Carthaginians had now to experience, for the first time, the inefficacy of their numbers, when opposed to a general of disciplined valour and consummate skill. (B.C. 340.) Their immense army met with a complete overthrow. Ten thousand were left in the field of battle, and the conquerors were enriched by the plunder of their wealthy camp. Disconcerted as they were by these repeated overthrows, the Carthaginians still made a shew of renewing their efforts; but their preparations seem to have been continued only for the purpose of giving effect to a negotiation which they had already entered upon with Timoleon.

A peace was the consequence, of which the most important condition was, that the river Lycaus should in future be the boundary of the Carthaginian territory in Sicily; and the Carthaginians pledged themselves to abstain from all interference with the independent states of Sicily. It is to this period we must refer the attempt of Hanno to subvert the constitution of Carthage, and institute arbitrary power.

Justin (lib. xxi. c. 4.) gives us the account at some length; but, as is common to him, the narrative is obscure and inconsistent. Hanno's plan was to assemble the whole senate, on pretext of assisting to celebrate his daughter's marriage, and by mixing poison with their wine to destroy them all. The plot was discovered; but as he was too powerful for the senate to dare at once to punish him, they contented themselves with counteracting his scheme, by passing a law to regulate the expense and magnificence of wedding feasts. Hanno, finding that suspicion was awakened, retired with 20,000 of his slaves to his country seat; he afterwards yielded to the superior forces sent out against him, and expiated his infatuated ambition by a cruel death.

The attention of the whole world was now excited by the surprising successes of Alexander. (Justin, lib. xxxix. c. 6.) Carthage could not regard them with indifference; the destruction of Tyre, and the transfer of its commercial greatness to Alexandria, which it was boasted would speedily become the emporium of the world, excited their fears lest the forces which had overrun the whole East should be turned to their shores, and that Africa should be called upon to cope with those veteran troops which Asia had in vain endeavoured to resist. They adopted a scheme not unworthy of their national character.
carthage.

was wholly unprepared for defence, and the country, which had now for a long period been exempt from the calamities of war, was filled with dismay and confusion. Agathocles advanced to Tunis, and ravaged the whole neighbourhood of Carthage. In this conjunction, Hanno and Bomilcar were appointed to command the forces, which had been hastily brought together; and eager to check the tyrant's destructive ravages, they instantly took the field. They advanced with no small confidence, for their army consisted of forty thousand, while that of Agathocles did not amount to fourteen thousand men. This confidence was their destruction; they were routed. Hanno was slain, and Bomilcar, with difficulty, drew off the shivered remains of his army. Diodorus attributes this discomfiture in a great degree to the treachery of Bomilcar, who covertly aimed at the sovereign authority, and who wished to convert this invasion of Agathocles into an instrument for effecting his design.

The citizens of Carthage were extremely disheartened by the result of this engagement, as they persuaded themselves that the tutelary deities of their country must have taken part against them. To appease these offended deities, they resolved to renew their offerings to the Tyrian Hercules; and as they had failed in the exact performances of the sacrifices to Saturn, they made horrible atonement, by selecting two hundred infants of the noblest families for immolation; and more than three hundred persons of both sexes voluntarily offered themselves victims to their bloody idol.

They then dispatched messengers to Hamilcar, who commanded in Sicily, requiring him to come to the relief of his country; he does not, however, seem to have been aware of the extreme urgency of the case, as he contented himself with dispatching 5000 men. By pressing the siege of Syracuse, he thought to draw Agathocles from his purpose; but in an attempt to surprise it by night, he was slain, and his troops completely discomfited.

In the mean time Agathocles had made himself master of all the open country, and Carthage itself must have fallen, had it not been for a mutiny which broke out in the invader's camp. (Diod. xx.) He succeeded indeed in quelling the mutiny, but by it his efforts were crippled, and he was constrained, instead of assaulting the capital itself, to be content with endeavouring to detach the tributary states from its interests. He contrived also to delude Ophellas, one of Alexander's captains, who had established himself in Cyrenaica, to co-operate with a large army; promising to assist him in becoming sovereign of Africa. Ophellas (Diod. n. b. supra.) little suspected the snare that was laid for him; he joined Agathocles with a considerable force; but Agathocles caused him to be assassinated, and persuaded the troops of Cyrenaica to enrol themselves under his standard. A transaction at this time was taking place at Carthage, which, if Agathocles had received timely information, would have enabled him to put an end to the war. Bomilcar, to whose treachery the loss of the last battle had been attributed, now began openly to avow those designs of which he was then only suspected. He endeavoured, with the assistance of some mercenaries, whom he had contrived to assemble, to get forcible possession of the chief authority in Carthage. His scheme was, however, frustrated, and he himself crucified in the midst of the forum. He endured his sufferings with great constancy; and from the cross he harangued the multitude, and upbraided them with their ingratitude to so many illustrious commanders. The singular good fortune of Agathocles now began to forsake him. The Carthaginian party in Sicily made such rapid progress, that he determined to leave for a season the management of affairs in Africa, and to return to Sicily. His return to Sicily was as fortunate as he could have hoped; but he was quickly recalled, by the news that his son Archagathus had been twice defeated by the Carthaginians, and that he laboured under the most severe want of provisions. With his usual activity, he returned on the instant to Africa; his troops were sunk almost into a state of despair from want of food; he found himself therefore reduced to the necessity of engaging immediately, and the consequence was an entire overthrow. The tide of fortune had now ebbed so low with him, that his only anxiety was to save himself from falling into the hands of the Carthaginians. He succeeded, after great exertion, in effecting his escape, but he left his children and his remaining troops to the mercy of the conqueror. Enraged to find themselves thus deserted, they put to death the tyrant's sons. The Carthaginians, however, were well pleased to grant them very easy terms, and purchased the cession of those strong places which were still in their hands, at the price of 300 talents; engaging to give those who were unwilling to enter into their service safe conduct to Sicily. This treaty was in the following year ratified by Agathocles, with an additional article, which, availing themselves of his necessities, they extorted, viz. that all those cities which they had formerly possessed in Sicily should be restored to them. Thus did these most extraordinary wars, which had threatened the destruction of the Carthaginian name, terminate in the disappointment and discomfiture of their enemy. Their effects, however, did not cease here; the success of Agathocles gave to the Romans the first notion of the practicability of invading Africa; and Livy (lib. xxvii. c. 43.) makes Scipio expressly quote this example, to justify the opinion he had given, that the war might with advantage be transferred to the enemy's country. Diodorus is so strongly impressed with the importance of these occurrences, that he goes out of his way to point out the peculiar circumstances, which shew the intervention of an over-ruling Providence.

Agathocles, however, did not entirely forego his Death of A.-animosity to the Carthaginians; and he was making gathocles preparations for another war when death put an end to his plans, (B. C. 298,) and gave to Sicily a period of tranquillity to which it had so long been a stranger.

Circumstances now began to connect the Carthagi- Treaty gians and Romans with each other, and gradually with Rome gave birth to those jealousies which, in the end, produced such important consequences. The arrival of Pyrrhus in Italy, equally alarmed both nations, and induced them to renew their existing treaties with-
an additional article, by which they agreed mutually to support each other against the designs of that prince; and not to enter into any separate treaty with him, inconsistent with this defensive alliance: and it was further stipulated, that the Carthaginians should furnish the whole of the shipping, both transports and armed galleys; but that the expense of every armament should be defrayed by that party in whose defence it was employed. In compliance with the terms of this treaty, they dispatched a fleet of 120 sail, under the command of Mago, to the assistance of the Romans, as soon as they had learnt that Pyrrhus was actually landed: (Justin, xviii. c. 2.) This assistance the Romans declined. Mago then had an interview with Pyrrhus, in order to fathom his intentions with regard to Sicily, of which state the Carthaginians were now very jealous. Nor was this jealousy unfounded: within a very short period Pyrrhus received an invitation from the Syracusans to come to their assistance against one Maenon, who was supported by the Carthaginians in his endeavours to usurp the supreme authority. Pyrrhus very gladly availed himself of the opportunity; he was happy to have a pretext for quitting Italy; and his vanity was flattered by finding himself called upon to be the defender of the Grecian colonies. Having sent Cyrus before him to arrange the terms of his reception, he set sail from Tarentum with a powerful fleet, and in a few days landed at Tauromenium, where he found himself at the head of 30,000 foot, and 2500 horse, exclusive of his Sicilian auxiliaries. The Carthaginians were then occupied in the siege of Syracuse, which they immediately abandoned. Agrigentum expelled the Carthaginian garrison, and opened the gates to the conqueror; Eryx was taken by storm, and no town of any importance remained to the Carthaginians except Lilybeum. This city had always been esteemed one of the keys of Sicily, and the exertions made in defence of it, were proportionate to its importance. The Carthaginians were, however, so cast down by the king's previous successes, that they offered to abandon all their claims on Sicily, if he would allow them to retain Lilybeum. Flushed with good fortune, Pyrrhus rejected the offer; a conduct he had reason to repent, for he was compelled to raise the siege after he had pressed the town to the utmost. Disheartened by this failure, he determined, with his usual levity, to abandon Sicily entirely, and to set sail for Rhegium; but he was met at sea by a strong squadron, which had been fitted out on purpose to intercept him: thus he was constrained to adventure an engagement, in which he was so completely defeated, that he reached Locri with only ten ships, and from thence, with difficulty, marched to Tarentum. The Carthaginians immediately set about reducing the Sicilian towns, which had been before in their possession, and settled their affairs in Sicily upon a firmer footing than ever.

We have now reached that period when Rome and Carthage, which had for some time menaced each other from a distance, came actually in contact; when the great question, whether the seat of universal empire should be fixed in Africa or in Europe was decided. Before we enter into the detail of circumstances which gave rise to the first Punic war, it will be expedient to take a short survey of the actual state of Carthage, the extent of her dominion, and the nature of her influence.

The limits of the Carthaginian dominions in Africa had been progressively advanced, till they extended from the western borders of Cyrenaica to the Pillars of Hercules; but at this distance of time, and with our scanty means of information, it is impossible to trace the various stages of this progress. The period in which the Carthaginians first settled in Spain is involved in great obscurity; but as Diodorus intimates that the mines of Spain were the great nerve of the Carthaginian power, by which they were enabled to fit out such wonderful fleets, and bring such formidable armies into the field, we may conclude that they had established themselves in that country at a very early period, previously to the reigns not only of Darius and Xerxes, but also of Cyrus himself.

Justin states, that they were, in the first instance, led to intermeddle in the affairs of Spain, with a view of assisting that sister colony which the Phcenicians had established at Gades, (lib. xlv. c. 5.) The assistance afforded by them was effectual in defending it against the attacks of the neighbouring people; but not content with this, they managed to obtain possession of the colony itself, and of the whole province in which it was situated. This event probably took place about the middle of the second century, after the foundation of Carthage; for Diodorus distinctly states, (lib. v. c. 1.) that at this time a colony was established in Ebusus, (now Iviaca), and in all likelihood the whole of the Balearic islands were colonised at the same time: Now, it seems reasonable to suppose, that the advance of the Carthaginian colonization was progressive, and therefore that the settlement at Cadiz would be subsequent to that at Ebusus; hence, we may perhaps be allowed to infer, that the Carthaginians made their first descent into Spain about 160 years after the building of their city. Nevertheless, it appears, from the accounts of Livy and Polybius, that the greatest part of Spain remained unsubdued till the wars of Hamilcar, Aemelius, and Hamilhabl. In Sardinia, their settlements were almost coeval with their existence as a people; the whole island appears to have been in subjection to them at the period of their first treaty with the Romans.

Coriica, too, was occupied by them from very ancient times; they probably succeeded immediately to that colony which the Phoenicians were compelled to abandon. Herodotus (lib. vii.) mentions the Corsicans among those nations which were united to form that vast armament with which the Carthaginians invaded Sicily in the days of Gelon. The small islands of Melita and Gaulos (now Malta and Goza) were likewise in subjection to the Carthaginians. According to Diodorus, these islands were first peopled, either from Carthage or Phoenicia. (Diod. Sic. lib. v. c. 2.)

This rapid survey may suffice to give us some idea of the actual extent of the Carthaginian influence. The Romans, on the other side, had now begun to feel their strength, and were considerable elated by
their recent success against Pyrrhus. That experienced commander foresaw the collision which was about to take place between these powerful rivals, and is said, upon leaving Sicily, to have pointed out that island as the subject and the first scene of the contest. (Plutarch. in vit. Pyrrhi.)

Notwithstanding the Carthaginians had been thus successful in dislodging the Epirots from Sicily, they had still two powerful enemies to contend with, the Syracusans and the Mamertines. The former had recently appointed Hiero for their leader, who is uniformly represented by the ancient historians as a consummate hero, and most amiable prince: under his command the Syracusan forces obtained several considerable advantages over the Carthaginians. (See Justin, lib. xxiii. c. 4.; Theocrit. in Idyllio. 16.; Pind. in Olymp. i.)

The Mamertines were originally a body of Campanian mercenaries, which Agathocles had retained in his service. They were afterwards involved in a dispute with the citizens of Syracuse, as to their right of giving votes in the election of magistrates; the consequence of which was, an agreement that the Campanians should evacuate Sicily within a limited time. Under pretence of embarking for their native country, they retired to Messina, of which town they took possession by treachery, expelling or assassinating all the inhabitants, and assuming to themselves the name of Mamertini, a word which, in the ancient language of southern Italy, is used to signify a warlike people.

In this horrid action they soon found imitators: Some Roman troops, to the number of about 4000, had been posted at Rhegium, during the late wars in Italy, under the command of one Decius, a Campanian: these, assisted by the Mamertines, murdered the citizens, and seized their property; but they were speedily punished by the Romans with exemplary vigour. The Mamertines, on their side, were closely pressed by Hiero, who was eager to retaliate upon them the injuries they had committed. They were at length reduced to such distress, that they resolved to surrender themselves to the first power that could afford them protection; but being divided in their choice, one party made an offer of submission to the Carthaginians, another to the Romans. The latter scrupled to avow themselves the protectors of a crime which they had so lately punished; but while they hesitated, the Carthaginians, availing themselves of the delay, and of the neighbourhood of their own military stations, got the start of their rivals, and were received into Messina.* This unexpected advantage, gained by a power of which they had so much reason to be jealous, roused the Romans: they instantly sent orders to the consul Appius Claudius, who had charge of the forces in the neighbourhood of Rhegium, to assemble all the shipping which could be found on the coast, from Tarcentum to Naples, and to pass with his army into Sicily. As soon as his fleet appeared, the party in the city which had favoured the admission of the Romans took arms, and forced the Carthaginians to evacuate the place. (Polyb. lib. i.)

Thus commenced the first Punic war. The first First Punic object of either party was no more than to command war. the passage of the straits, by securing the possession of Messina; but their views were gradually extended, and the contest quickly assumed its real form, a struggle for the sovereignty of the whole island and the dominion of the seas. Unfitted as the Romans were, both by their habits and by the nature of their resources, for a naval war, yet the commanding aspect of their first descent on Sicily, induced Hiero to unite with them. The small force which Appius had so hastily transported, was replaced by two consular armies; these were sufficiently powerful to make Hiero tremble in his capital; he had also grounds for suspecting the intentions of the Carthaginians towards him, and he was influenced perhaps by that hereditary animosity which the people of Syracuse must have felt against the Carthaginian name. All or any of these reasons may be sufficient to account for the line of conduct pursued by him. The accession of Hiero to the Roman cause, altered the whole character of the war. It enabled the Romans to plan and to execute designs within, under other circumstances, must have been impossible. The Carthaginians were not dispirited by this sudden change; they made new levies in Gaul and Liguria; reinforced their armies; and fixing on Agrigentum as their principal military station, they appointed Hanno commander of their forces. The Roman army was engaged in the siege of Agrigentum when Hanno assumed the command; he immediately led his troops to the relief of the place. A severely contested battle ensued, in which the Romans were victorious. The possession of Agrigentum was the first fruit of their victory; it served also to establish the wavering fidelity of Hiero, and confirm his adherence to the cause he had espoused. (Polyb. lib. i. p. 29. Edit. Casaub.)

The Romans perceiveing that, notwithstanding their success by land, their coasts of Italy still continued open to the depredations of the Carthaginian fleets; resolved at once to equip a fleet which might enable them to cope with their foes, even on his own peculiar element. This attempt, so bold in its conception, a fleet, and so important in its ultimate consequences, induced Polybius, (as he himself states,) to write the history of this war, " in order that the circumstances which attended the first formation of the Roman marine might never be forgotten." A Carthaginian vessel, which had been accidentally stranded at Messina, served them for a model, and within the short period of sixty days, they had fitted out, and manned for sea, 100 galleys of five benches of oars and twenty triremes. These vessels were extremely rude, both in their materials and construction, yet the labour of building them must have been immense, as a quinary was capable of carrying 300 rowers and 200 fighting men.

While the galleys were building, the Romans exercised their rowers on benches erected on the beach.

* No expression can be stronger than that used by Polybius, γαρ ἐν ταῖς Καρθαγινείς ἰσιοί γαφρονταῖς τε τις Ἱππαῖος οὐκ ἔτι ἀνεκβαίνει.
And in order to counterbalance the advantage which the Carthaginians were likely to derive from their superior seamanship, the Romans, (or rather in the opinion of some writers, improved), the machine called the corvus, by which they were enabled to grapple and bind the vessels together, so as to give to their soldiers full scope for the exertion of their bodily strength and activity.

In the first rencontre of the hostile fleets, the Carthaginians were, as it might be expected, successful; but in a subsequent engagement, they met with a severe check, and their admiral, Hannibal, having lost the greater part of his ships, with difficulty made his escape. The command of the Roman fleet had now devolved upon the consul Dullius, to whom is attributed the invention of the Corvus. He engaged the Carthaginian fleet without delay, and by the help of his new engine succeeded in giving them a complete overthrow. (B. C. 260.) The loss of the Carthaginians is variously related; Hannibal, having been obliged to abandon his own vessel to the enemy, returned to Carthage, where he obtained reinforcements for his shattered fleet. Putting to sea again, he steered for the coast of Sardinia, where he was surprised by the Romans while at anchor, who carried off some of his ships, and took great numbers of his men prisoners; this so incensed the rest, that they seized their admiral and crucified him. The affairs of the Carthaginians in Sicily had, in this interval, assumed a more favourable aspect. Hamilcar, their commander, availing himself of a dispute which had occurred between the Roman legions and their auxiliaries, surprised their camp, put four thousand to the sword, and dispersed the rest. Notwithstanding this disaster, the terror of the Roman arms was still sustained by the vigilance and bravery of the consul Florus, while his colleague Cornelius Scipio, made a descent on Corsica, and menaced the coasts of Sardinia. Several engagements, both by land and sea, ensued with various results, but for the most part to the advantage of the Romans, who were thus, by degrees, encouraged to prepare for an invasion of Africa itself, as the means by which they could oblige the enemy to evacuate Sicily. (Polyb. lib. 1. p. 22.)

In the ninth year of the war, the consuls Manlius, Dulso, and Attilius Regulus, with the fleet under their command, consisting of 350 galleys of different sizes, held their rendezvous at Messina. Having taken their land forces on board, they proceeded along the coast. The Carthaginian fleet, which, as to the number of vessels, was about equal, was lying at Lilybæum, under the command of Hanno and Hamilcar. The hostile squadrons met near Heraclea Minoa. The Roman commanders drew up their fleet in the form of a wedge, the Carthaginians were in line. The consuls observing that this line was weak towards the centre, caused it to be vigorously attacked in that part. A most obstinate conflict ensued, which terminated in favour of the Romans, who lost in the action only 24 galleys, whilst the Carthaginians had 30 sunk and 63 taken. After the battle, Hamilcar sent Hanno to make proposals of peace to the consuls, which being rejected, the war continued to rage with as much fierceness as ever; and the consuls soon after setting sail for Africa, landed without opposition near Clupea; or, as Polybius calls it, Aspis. Nothing could exceed the terror and astonishment which the news of the Roman invasion caused at Carthage. These were, however, in some degree diminished by the intelligence that, contented with ravaging the whole country almost to the very gates of the capital, one of the consuls had returned to Rome with the best part of the troops, leaving the management of the war to his colleague Regulus, with only 40 ships, 15,000 foot, and 500 horse. Hamilcar was recalled from Sicily, and was joined with Asdrubal and Boitar, in the command of the army. Regulus having spent the winter at Clypea, hearing that the Carthaginian army was in motion, advanced with his forces, and encamped upon the Bagrada in the neighbourhood of Carthage. Here he is said to have met with that monstrous serpent, of which several ancient writers make mention: the descriptions are probably hyperbolical, yet it is impossible to refuse all credit to a story for which there are so many authorities. (Val. Maxim. lib. i. c. 8. Liv. epit. lib. xxx.)

The Carthaginian generals advanced to give him battle, but most unwisely took up a position in ground that was unfit for the operations of elephants or horse, in which the great part of their strength consisted. Regulus profited by this mistake, attacked them in the night, and entirely defeated them. This victory was productive of the most important consequences; Utica opened its gates, Tunis was forced to submit, and nothing now remained but to lay siege to Carthage itself.

To complete the misfortunes of the Carthaginians, their territory was, at this time, invaded by the Numidians, who committed the most dreadful ravages. The Roman consuls, elated by his good fortune, and desirous to terminate the war before the arrival of a successor, offered to treat with the vanquished, but on terms so extravagant that they were at once rejected by the senate.

At this conjuncture, a Carthaginian officer who had been sent to Greece to levy soldiers, returned with a body of mercenaries, amongst whom was one Xantippus, a Spartan, who had some reputation for military science. To him the command of the remaining forces was entrusted; and he succeeded in infusing into them some knowledge of the Grecian tactics, and an unbounded confidence in his own skill and experience. Regulus was little prepared for this change; when he saw the Carthaginian army again advancing, flushed with the hope of new successes, he at once led his men to the attack, and ventured even to cross the river which separated the two armies. This rashness led to the entire destruction of his army. Xantippus profited to the utmost of his antagonist's misconduct, and only two thousand of the Romans escaped from the field. Regulus himself was taken prisoner. The Carthaginians treated all their captives with great humanity except the general. The story of his sufferings and constancy is well known. Xantippus, to whose conduct the whole of this success must be attributed, withdrew from Carthage immediately afterwards. "Wisely and prudently, (says Polybius,) as the splendour of his action must have excited a degree of jealousy and envy sufficient..."
to overwhelm even a citizen; how much more a stranger and a foreigner.” (Polyb. p. 37. Appian. 
in Libycis, sub init.)

The Romans sent out a strong squadron to bring off the remains of the defeated army; but in the passage to Sicily on their return, they met with a dreadful tempest, in which they lost almost their whole fleet. This, and several subsequent calamities, so greatly dispirited them, that they determined for a season to lay aside all naval operations. The Carthaginians were thus left masters of the sea. The theatre of war was now again removed to Sicily, where it raged with unabated violence. The affairs of the Carthaginians were in a state of progressive deterioration, till the appointment of Hamilcar, surnamed Barcas, to the chief command. His valour and enterprise restored for a short time the drooping fortunes of his country, but in the end he was obliged to yield. The Romans had soon become sensible of the absolute necessity they were under of restoring their ships; and they did so with a resolution and vigour which enabled them once more to prevail over the superior skill and address of their enemy. Another defeat at sea compelled Hamilcar to seek for peace. (B. C. 242.) It was granted, but upon conditions so harsh, and dictated by the Romans with so much insolence, that Hamilcar from that moment conceived an invincible aversion to the Roman name. He concluded peace, only that he might give his country time to breathe, and that they might afterwards be able to chastise the insolence to which they were at present compelled to submit. The terms of peace were these: That the Carthaginians should evacuate Sicily; that they should not, for the future, make war on Hiero king of Syracuse, or any of his allies; that they should release all Roman captives without ransom; and within twenty years, pay to the Romans a sum of three thousand Euboic talents.* The people of Rome refused to ratify this treaty, till they had sent ten commissioners into Sicily to examine into the actual state of affairs. By these, some additional articles were added of inferior importance, but still harsher tendency. The ratifications were then interchanged, and Asdrubal retired to Lilybaeum, where he resigned to Gisco the care of transporting the troops to Africa. (Polybius ubi supra.)

Thus, after twenty-three years continuance, ended the first Punic war; leaving the contending parties weakened, indeed, but not dispirited—with their resources exhausted, but their mutual animosity increased and exasperated beyond measure. The excellent Polybius, in a recapitulation of the most remarkable circumstances of the contest, gives the preference to the Roman soldiers above the Carthaginian; but at the same time he allows, that Hamilcar Barcas proved himself, both in bravery and conduct, the greatest captain of the age.

War of the mercenaries.

Carthage had no sooner relieved itself from the pressure of this bloody and expensive war, than it found itself involved in another, which had very nearly proved fatal. The mercenary troops, when they returned to Africa, found that the public treasury was too much exhausted to discharge their arrears of pay. They quickly became clamorous, and committed the greatest disorders in the city. The senate endeavoured to pacify them, by giving a sum of money for their present subsistence, and persuading them to retire to Sicca, promising that when the remainder of the troops arrived from Sicily, all their demands should be satisfied. At Sicca, they quickly became more licentious than ever; and Hannu, one of the Suffetes, was sent to ally their discontent. Upon his arrival at Sicca, he conducted himself in the most preposterous and imprudent manner. He expatiated upon the poverty and distresses of the state; and, instead of answering the high expectations of the discontented, he desired them to be satisfied with receiving part of their pay, and remit the remainder to meet the pressing exigencies of the commonwealth.

The mercenaries were highly exasperated by these disappointments; and still more, when they saw their cause entrusted to Hannu, to whom their merits and services were utterly unknown, while neither Hamilcar, nor any of the officers under whom they had served in Sicily, came forward on the occasion. Immediately they had recourse to arms; and advancing to Tunis, they encamped before it, with a force little short of twenty thousand men. The Carthaginians, greatly alarmed by the approach of such a body of irritated enemies, endeavoured to soothe them with promises and concessions. After much discussion, the mutineers consented to refer their claims to Gisco for decision. He had obtained the affection and confidence of the troops, when left by Hamilcar in command at Lilybaeum. Relying on their tried attachment, he set out at once to the camp near Tunis. Having conferred with the several officers apart, and expostulated with them in a firm yet insinuating manner on their misconduct, he succeeded in persuading them to consent to take their arrears of pay, and return to their allegiance; when on a sudden all his labours were frustrated by the machinations of two miscreants, who had distinguished themselves as leaders in the mutiny. Spondius was a mercenary slave from Rome, and dreaded to fall again into his master’s power; and Mathos, who, though an African and free-born, had been very active in exciting the rebellion, and was apprehensive of the punishment which awaited him from the Carthaginians. Inflamed by the artifices and misrepresentations of these men, the troops at once rejected all means of conciliation, seized Gisco and his attendants, and loaded them with irons. (Polyb. p. 68, 69, 70.)

Carthage was now reduced to a state of the utmost distress; the tributary states of Africa joined themselves to the mutineers; and thus she saw herself surrounded on all sides by active and irritated enemies, and deprived, at the same time, of all her resources and accustomed means of defence. Notwithstanding these adverse circumstances, she did not despond. All citizens capable of bearing arms were mustered, new levies were made wherever soldiers could be procured, and the fleet was refitted with all expedition. The command of the forces was given to Hannu, who at first gained some slight advantages; but was soon af-

Carthage.

And are in turn defeated by Hamilcar.

B. C. 238.

The Carthaginians turn their attention to Spain.

Death of Hamilcar.

ter surprised in his camp, and even suffered the mercenary to possess themselves, without opposition, of the isthmus which connected the city with the mainland of Africa. To remedy these disasters, Hamilcar Barca was once more called to the head of affairs. He marched against the enemy with about 10,000 men, horse and foot, which were all the troops the Carthaginians could at that time assemble for their defence. Having passed the Bagrada by a stratagem, he gave battle to the mercenaries, and completely defeated them, killing six thousand, and making two thousand prisoners. Notwithstanding this defeat, the malcontents had still such advantage of numbers, that their army, under Spondius, and Antonius a Gaul, were able to surround that of Hamilcar. So completely was this effected, that the whole army must have been destroyed, had it not happened that a young Numidian of rank, by name Naravasus, being struck with admiration for Hamilcar's character and talents, came over to him with two thousand horse. Thus strengthened, he was enabled to give battle on more equal terms. After a most obstinate conflict, in which ten thousand of the mutineers were killed, he remained master of the field. The genius of Hamilcar enabled him to surmount all the difficulties which opposed him. The war continued for three years and four months, and was carried on with extreme cruelty on both sides; such (says Polybius) as had never before been witnessed. Its conclusion was much more fortunate than the Carthaginians could have been warranted to expect; they still retained all Africa in subjection, and retrieved themselves on the first instigators of the rebellion, by the infliction of the most cruel tortures. (B. C. 238: Polybius, lib. 4. and fin.)

During the Libyan war, the mercenaries stationed in Sardinia had declared against the Carthaginians, and possessed themselves of all the strong places in the island. The Romans not only gave countenance to this revolt, but actually sent the consul Sempronius with a fleet to support the malcontents. The Carthaginians being exhausted by their domestic disasters, were obliged to surrender the island without resistance, and to purchase a continuance of the peace by a present of twelve hundred talents.

Hamilcar, by the happy conclusion of the Libyan war, had restored tranquillity to his country; but he found that she would be still unable to cope with her haughty rival. He determined, therefore, to undertake the entire conquest of Spain, in the hope that it would supply to the Carthaginians both a school of military discipline and a magazine of warlike stores whenever they should renew the contest with Rome. Hamilcar did not attempt to disguise his hatred to the Roman name; he publicly avowed the motives of his expedition, and took with him Hannibal his son, and Hasdrubal his son-in-law, having inspired them both with an implacable aversion against those, whom he considered as the destroyers of his country's grandeur. (Polyb. lib. iii. p. 167.) Nine years he fought in Spain, subjecting either by force or by persuasion, the greatest part of the country to the Carthaginian power, and at last fell gloriously in the field of battle at the head of his troops. (Polyb. lib. ii. p. 90. Liv. lib. xxi. c. 2.) The army elected Hasdrubal to succeed him, which appointment was confirmed by the senate of Carthage. He conducted himself with great prudence; and, to secure the acquisitions of his predecessor, built a city, which was afterwards called New Carthage. (B. C. 227.) The Romans viewed the progress of the Carthaginian arms in Spain with considerable jealousy. For the present, however, they contented themselves with concluding a treaty, the articles of which were, 1st, That the Carthaginians should not pass the Iberus. 2d, That the Saguntum, with the neighbouring Greek colonies which had implored the protection of Rome, should enjoy their ancient rights and privileges. Hasdrubal still pushed on his conquests, though he was cautious not to pass these limits. Having managed the Carthaginian affairs in Spain for eight years, he was at last assassinated by a Gaul, whose master he had put to death. Hasdrubal three years before had written to Carthage to desire that Hannibal, then twenty-two years of age, might be sent out to him. This was opposed by Hanno, who represented that it would give undue weight to the Barcine party. The objection was over-ruled, and the young soldier was suffered to depart. He quickly drew upon himself the attention of the whole army, who were eager to hail the opening virtues of the son of Hamilcar. Even Livy himself seems, in speaking of Hannibal, to lay aside his animosities as a Roman, and to dwell with delight on the various qualities of this extraordinary man. "Never," says he, "was there a disposition better qualified even for the most opposite things, whether for obedience or for command. Boldly adventurous in undertaking dangers, he displayed eminent skill and presence of mind when engaged in them. No labours could exhaust his body or depress his spirits. He was capable alike of enduring heat and cold, and in his food consulted only the demands of nature, not the suggestions of appetite: No stated hours were allotted by him for sleep or study, either by night or day. It was only the time unoccupied by business that he gave up to repose, courting it neither by silence nor the softness of his bed. On the contrary, he was often seen lying on the ground, amidst the sentinel and guards. He was distinguished from his equals by no superiority of dress, but his arms and his horses were always conspicuous. In the performance of military duties, whether of cavalry or infantry, he was ever foremost: the first in entering the combat, he was the last to quit the field. Eminent as were these virtues, they were equalled by the enormity of his vices. His cruelty was disgraceful to human nature; his treachery without example, even at Carthage; he utterly condescended all truth and sanctity, all fear of the gods, all reverence for oaths, all the obligations of religion." To the latter part of this character the subsequent conduct of Hannibal is in direct contradiction. Much must be allowed to the prejudices of Livy; yet he cannot be acquitted of a malicious intention to blacken, by vague and general censures, the character of the man who unquestionably proved himself the greatest general that has existed in any age.

Such was the man, who now, by the unanimous voice of the army, was called to conduct the affairs of the Carthaginians in Spain. He was in his twen-
ty-sixth year, full of confidence and hope. From the first moment of his appointment, he conducted himself as though Italy had been the province allotted to him. After several successful enterprises against the natives of Spain, which served both to secure his previous conquests and to augment his resources; then, having, with singular address, furnished himself with all things necessary for the important enterprise, without affording to the Romans a pretext for declaring war, he on a sudden laid siege to Saguntum; and thus, by the infraction of Hasdrubal's treaty, struck the first blow in this eventful war. (B. C. 219.)

The train for this tremendous explosion had been laid long before. Polybius mentions three causes, which more immediately led to the second Punic war: the fraudulent and tyrannical conduct of the Romans with respect to Sardinia; the jealousy which was entertained, of witnessing the progress of the Carthaginian arms in Spain; and, lastly, that bitter hatred to the Roman name and nation, which Hamilcar had bequeathed to his son Hannibal, and which was in both the predominant feeling influencing the whole conduct of their lives.

Hannibal opened the siege of Saguntum with an army consisting of 120,000 foot, and 20,000 horse. The defence is one of the most memorable in history. The limits of this work do not allow us to enter into the minute details which Livy and Polybius supply. We must be content with stating, that, after a contest of eight months continuance, almost unparalleled for its fierceness and obstinacy, the city was razed, and its inhabitants, without distinction of age or sex, put to the sword, or sold for slaves. The Saguntines had early in the siege dispatched ambassadors to Rome, and deputies were in consequence sent to expostulate against this infraction of the treaty; but Hannibal refused to give them audience. They proceeded, therefore, immediately to Carthage; but found the senate and people little disposed to censure the conduct of their favourite general. After the capture of Saguntum, a formal embassy was sent from Rome, to require a disavowal of the conduct of Hannibal, and satisfaction for the injuries he had inflicted on the Saguntines. Hanno and his friends exerted themselves vigorously to counteract the views of the Barcine party; but in vain. The Roman embassy were not able to effect their purpose of frightening the senate into submission. Upon which, Quintus Fabius, the senior of the ambassadors, held up a fold in the bosom of his robe, and said, "We bring both peace and war; choose ye." He was answered, "We choose that which you like best." "Then be it war," said he, throwing open his robe; and from that, both parties prepared themselves for the contest. (Livy, lib. xxi. c. 18. Polyb. lib. iii. p. 187.)

Hannibal had probably long devised the invasion of Italy, and had convinced himself of the practicability of the attempt. War being now declared, he made his dispositions for the safety of Spain and of Africa, and collected his troops for that great undertaking, the conduct of which had procured for him a reputation superior to all other military commanders. He had well weighed the difficulties of the enterprise, the various dangers of the march, and the uncertainty of procuring supplies; To these were opposed, the advantages which would accrue from carrying the war into the heart of the enemy's country; the assistance he might expect, if he could once reach Italy in force, from those states which were actually in rebellion against the Roman authority, or bore to it only a feigned and uncertain allegiance. Let us not, therefore, magnify the courage of this celebrated warrior at the expense of his judgment, nor suffer the unwarrantable rashness of inexperience to shelter itself behind the great name of Hannibal.

In his march to the Iberus, he experienced no interruption. Thence to the Pyrenees he was obliged to force his way; and apprehending some inconveniency from the leaving an hostile people in his rear, he stationed his brother Hanno, with ten thousand foot and one thousand horse, to observe their motions, and secure the passes of the mountains. During the passage of the Pyrenees, a considerable body of the Spanish allies deserted. Lest this example should prove contagious, he gave out that they had fallen back by his express order, and that he meant to spare a few more troops of the same nation. By these separations, his numbers were reduced from 90,000 to 50,000 foot; he had likewise 9000 horse and 37 elephants. (Livy, book xxi. 23. Polyb. lib. iii. p. 189, 190.)

After entering Gaul, his march was for some time hindered by the jealousy of the natives; but upon his convincing them he had no object in view besides a mere passage through their territories, he was suffered to proceed without molestation. The river Rhone presented the first serious obstacle. As the Gauls, who inhabited the country contiguous to it, seemed resolved to oppose his passage, he contrived to disperse their forces by a stratagem; but a new difficulty occurred, he had no means of waiting the elephants over this broad and rapid current. The difficulty was at last obviated, by the construction of a sort of flying bridge, by means of which they were all transported in perfect safety. (Livy, Polyb. ut supra.)

Hannibal crossed the Rhone at Lauriol in Dauphiny. Hence he marched up the left bank of the river, towards the midland parts of Gaul; not because this was the direct road to the Alps, but because he thought the further he advanced from the sea the less likely he was to meet the Romans. Nor was he mistaken; for at the very time he reached the banks of the Rhone, Scipio (the father of Africanus) landed at the mouth of it, and a rencontre actually took place between some detachments of cavalry from the two armies. Marcus, a prince of the Allobroges, having offered to become his guide, advanced towards the Alps, following the course of the Rhone. Turning to the right, he passed through the country of the Tricastini; and from the grand angle of the Rhone at Lyons, to the deep indent
which it forms at St Genis. Here he entered Savoy, ranging along the limits of the Vocontian dominions, from this indent to the Sier. Hence he passed through the country of the Tricorii to Geneva, without impediment, crossing the Arve (Drentia) in his march. From Geneva he proceeded to Martigny. Here the hills have an opening to the south 80 paces in width, which, in the days of Hannibal, formed the only channel of communication between Gaul and Italy. The Seduni had occupied this pass; but Hannibal, in the night, seized the heights which commanded it, and obtained possession of their chief city, now St Branciere. Here the Salassi met him in a friendly manner, and offered to conduct him to Italy by a better road than that he was pursuing. Under their guidance, he turned to the right into the Val de Bagnes, where, in passing a defile, the Salassi fell upon him unawares. The steadiness of his troops saved him from this imminent danger. His infantry got possession of a white rock, (that on which the village of Lutier now stands,) from whence they resisted all the assaults of the enemy. Bewildered by this treachery, he wandered through the Alps for some days, and at last reached the regular road only seven miles from the point at which he had quitted it. It is uncertain by what pass he at last actually reached Italy. Livy does not give any positive opinion. Many circumstances conspire to prove, that it must have been by the Mons Peninus, (Great St Bernard.) Hence he descended to St Remy, having excited the ardour of his troops, by pointing out to them the rich vales of Italy, and the site of Rome itself. At this point the road, which was before steep, had, by a recent subsidence of the earth, been rendered precipitous. The chasm extended across the road to the distance of a thousand feet.† It was an even wall of stone, such that even a man on foot could not descend it without difficulty. Hannibal endeavoured to find a path by which he might avoid this ravine, but his horses, elephants, and baggage sunk in the snow, and he found it impossible to proceed. They rested on the bare ground for the night. The next morning, the Carthaginians employed themselves in felling a number of large trees, and raised a vast pile of fuel on the crags. The trees being of a resinous nature soon flamed, and the rocks appeared glowing beneath them; they then applied vinegar to soften them, and finally opened a path through the burning rocks with their pick axes. This account has been derided by many historians as an incredible fiction, yet, if stripped of the marvelous circumstances which have been added to it by some writers, it contains nothing improbable, nothing which could not have been effected by the ingenuity and indefatigable labour of such a leader, and such an army.‡

The events of this war are so involved with the affairs of Rome, or rather they form so completely an integral part of the Roman history, that we must refer the reader for its details to that article. The domestic history of Carthage during this eventful period, though it offers but few circumstances worthy of observation, conveys a most important lesson.

In all governments which are in any degree popular, there must be two parties in the state. Those who conduct public affairs, must expect to have their measures scrutinized and thwarted by all who are desirous either of diminishing their influence, or succeeding to the possession of their power. In Carthage, a party such as this (which in modern times we have taught ourselves to call "the opposition") was regularly organized, and its exertions were systematic and incessant. The avowed leader of this party was that Hannibal, whose incapacity and misconduct we have more than once had occasion to notice. His constant object was to undermine and destroy the influence which Hannibal, by his talents, success, and family connections, possessed in the state. So violent was his animosity against the Barcine party, that he appears to have disregarded all the real interests of his country, so long as he could cripple their exertions, and mar the execution of their designs. The peculiar fault of the Carthaginian constitution (as we have noticed in the outset) was, that in all cases which produced a difference of opinion, and, on this account, would deserve graver and more mature deliberation, it lost its representative character, and an appeal was directly made to the blindness and party zeal, the narrow conceptions, and infirmitative prejudices of the populace. Hannibal did not lose sight of the power which this singular anomaly in the constitution afforded him. He availed himself of it on every occasion, and it enabled him to work the destruction of his political opponents; but his country fell with him. The power of Carthage was annihilated on the plains of Zama; and the short remainder of its history contains nothing but a detail of insolent aggressions on the part of its victorious rival. These were met by the Carthaginians on their side by the most unworthy concessions: They gave up their general, they submitted to endure the most unwarrantable interposition of their affairs; in short, they drank the cup of humiliation to its very dregs, in the hope of procrastinating their existence. But the hope was vain; the haughty spirit of the Roman people could not endure, that a city, which had for a long time resisted the progress of their arms, and even made them tremble in the Capitol, should continue to

---

* So called, from a statue or temple of Jupiter Pennius erected on it. In the Celtic, pen signifies a peak, or headland.
† Whitaker suggests, that "longitundinem" should be read for "altitudinem," in Livy, 21, 36; and the corresponding passage in Polybius tends to support the conjecture.
‡ That fire was commonly applied to divide rocks, may be proved from Diod. Sic. The effect of the vinegar might have been only to act upon the rock by a sudden change of temperature. "The granites of these parts of the Alps are composed," says Sauvages, "of laminated rocks, abounding in quartz and mica. I admired, at St Remy, the very hard rocks which separate of themselves into tables, perfectly even and perfectly dressed: Their matter is white quartz mixed with yellow mica; and there are thin beds of this mica, the parts of which having little cohesion, make them to split according to their direction. I measured one which was six feet long and three in breadth, and not more than two inches in thickness." (Sauvages, iv. 221.)

The supply of vinegar cannot be a subject of surprise, since it was the common drink of the soldiery. It was generally called acetum, sometimes porca. (Vit. Lips. in Not. Mil. Glor. Plaut. i. 2, 25.)

Summary view of the later events of Carthaginian history.
Carthage. 577

Carthage. 577

and the military skill of Scipio Æmilianus was called upon to effect that destruction, which the savage ambition of the elder Cato had resolved upon. The conduct of the Roman people towards the Carthaginians, (as will be shown when we come to treat of their history,) was stained with cruelty, perjury, and injustice. It was necessary, for the aggravation of their city, that Carthage should be destroyed, and they cared little what means were used to accomplish its destruction. This event took place in the year of Rome 608, about 146 years before the commencement of the Christian æra.

Such was the fate of Carthage. Its decay and final destruction ought to be attributed to the intrigues and misconduct of its factious citizens, rather than to the actual power of its rival, however formidable it might appear. The treasure carried off by Æmilianus, even after the city had been delivered up to the soldiers to be plundered, was immense. The destruction was complete; and the senate issued a decree, enjoining, that it should never again be inhabited, and denouncing the most dreadful imprecations against those who should attempt to rebuild any part of it. However, all persons who desired, were admitted to see Carthage; nothing affording to Æmilianus greater pleasure, than to make it as a triumphal show of the ruins of his country's rival. Thus, says Paterculus, "does hatred survive the very fear which gave it birth; a rival ceases not to be an object of detestation till it has ceased to exist."

Notwithstanding the denunciations of the senate against all who should attempt to rebuild Carthage, they were induced in a very short period themselves to sanction the undertaking. Twenty-four years after the victory of Æmilianus, (B. C. 142,) the sedition of Tiberius Gracchus began to be formidable to the patricians, since he was supported by the great body of the people, in his endeavours to pass an Agrarian law. Gracchus finding himself unable to accomplish his purpose, was probably not unwilling to accept the offer made him by the senate, of becoming the leader of 6000 citizens to the site of Carthage, for the purpose of its restoration. (Appian in fin. lib. Punic,) Gracchus was terrified by prodigies from proceeding in his purpose. It seems probable, however, that a few buildings began to spring up among the ruins; and we have reason to conclude, that, from this time for many centuries, they increased in number, beauty, and convenience. Compared with its former glory, the city was long considered as in ruins. When Marius took refuge there, outcast and deserted, he is said to have dwelt in a hovel amidst the ruins of Carthage; and Sulpicius addressing Cicero, speaks of it as razed to the foundation. (Vell. Pater. lib. ii. c. 19. Ser. Sul. ad Cic. lib. iv. p. 5.) Julius Caesar, too, when in Egypt, in consequence of a dream, in which he beheld a numerous army weeping, determined to rebuild Corinth and Carthage. His death prevented the execution of his purpose. Augustus, finding a record of his intention among his papers, piously fulfilled it, and sent 3000 Romans thither, who were joined by the inhabitants of the neighbouring country. These established a colony adjacent to the ancient city, but not upon the very spot, lest they should be obnoxious to the curse invoked by the sacrifice. (App. ubi sup.) Such at least is the account of Appian; yet Strabo speaks of Carthage as the second city in the Roman empire for wealth and power, and he wrote in the reign of Tiberius. This time is scarcely sufficient for so great an advance to be made towards its former magnificence. Perhaps we shall form a just notion of the fact, if we conceive, that Appian has lessened, and Strabo has exaggerated, its importance. Pliny mentions it as a very considerable colony; and it was soon after the commencement of the Christian æra regarded as the metropolis of Africa.

The precise period of the introduction of Christianity we are unable to ascertain, but it is evident that it should be fixed very early. For in the middle of the second century, arose Tertullian, the first Latin father of the church with whose writings we are acquainted, and he speaks, as of a notorious fact, of the wide extent of Christianity in Africa. His words are, "Were we disposed to act the part of enemies, should we want forces or numbers? Are there not multitudes of us in every part of the world? It is true we are but of yesterday, and yet we have filled all your towns, cities, islands, castles, camps, courts, palaces, senate, forum;—we leave you only your temples." Gibbon, with his usual unfairness wherever Christianity is the subject, attempts to understand an expression of Tertullian (ad scapulam) to mean, that a tenth of Carthage alone was converted. That father says, if you would punish the Christians, you must decimate Carthage, that is, you must imitate the Romans when the whole army is equally guilty; you must put to death every tenth man. In the year 311 arose the schism of the Donatists. Caecilius of the Donatists had been chosen bishop of Carthage, without the participation of the Numidian bishops in his election; and upon his refusing to submit to their cognizance, they appointed Majorinus in his place. Mutual resentment, and all the bad passions which necessarily mingle in controversy, inflamed the partizans of each faction to the highest pitch of rancour. In 316, Constantine himself heard the cause, and decided in favour of Caecilius. The Donatists were supported by a band of ruffians, who called themselves Circumcelliones, and who had recourse to fire and sword as the means of success. Hence all Africa was filled with murder and rapine. Constantine having tried every other method of accommodation, at last had recourse to that which usually has alloyed the fury and fanaticism of sectaries, a full permission to the people to follow the tenets of which they approved; but here without effect. And it was only after their defeat at Bagnia by Macarius, the lieutenant of Constantine the son of Constantine, that the Donatists were repressed. (Mosheim, cent. IV. pt. ii. chap. 5.)

The emperor Julian revived the failing sect, which found a strong and active enemy in St Augustine. The bitter hatred of these schismatics, and the revolt of Count Boniface, governor of Carthage, (A. D. 431,) paved the way for the invasion of Genseric, king of the Vandals. He had landed from Spain at the desire of Boniface, who too late found his error in employing a foreign and barbarous force to do right to an injured subject. He opposed him on his entrance into Africa, and though worsted in several
Site of Carthage.

Several modern travellers have visited the ruins of Carthage. We shall give extracts from two of them:—from Shaw, because he is unquestionably the most learned; and from De Chateaubriand, because his visit was most recent.—Shaw's account is as follows.

"Carthage has not much better supported itself against the encroachments of the north-east wind and the Mejer dah, which together have stopped up its ancient harbour, and made it almost as far distant from the sea as Utica. The place is still called El Mersa, the port, lying to the north and north-west of the city, and forms with the lake of Tunis the peninsula upon which Carthage was built. Upon the other side of the peninsula, Carthage hath been a lesser by the sea, for in that direction near three furlongs in length; and half a furlong or more in breadth, lieth under water. A little to the northward of these ruins, but to the south-east of El Mersa, are the traces of a Cthon, scarcely a hundred yards square. This was probably the new port which the Carthaginians built after Scipio had blocked up the old; and might be the same that was called Mundracium in the time of Procopius. The greatest part of Carthage hath been erected on three hills, inferior in elevation to those on which Rome was built. Upon that which overlooketh the south-east, there is the area of a spacious room, with several smaller ones by it. Some of them had tesselated pavements, but neither the design nor the materials are worthy of notice. The Byrsa, I presume, had formerly this situation. In rowing along the shore, the common sewers discover themselves; which, being well built at first, time hath not in the least injured or impaired. The cisterns are other structures which have submitted the least to the general ruin of the city. Besides those appertaining to particular houses, there were two sets belonging to the public; the greater whereof, which was the grand reservoir of the aqueduct, lay near the western wall of the city, and consisted of more than twenty contiguous cisterns, each of them about 100 feet long and 30 broad. The lesser is in a higher situation, near the Cthon; having been made to collect the rain-water which fell on the top of it, and upon some adjacent pavements made for that purpose. This might be repaired with little expense; the small earthen pipes through which the rain water was conducted wanting only to be cleaned. Besides these, there are no other tokens left us of the grandeur and magnificence of this ancient city, the rival of Rome: we even meet with no triumphal arch, or sculptured piece of architecture; no granite pillars, or curious entablatures; but the broken walls and structures that remain to this day, are either built in the Gothic manner, or according to that of the later inhabitants. —Shaw's Travels, p. 150—154."

The account given by Chateaubriand differs from this in many respects. Differences which it would be impossible to reconcile or decide upon, without an actual inspection. We subjoin it in his own words:—"The ship in which I left Alexandria having arrived in the port of Tunis, we cast anchor opposite to the ruins of Carthage. I looked at them, but was unable to make out what they could be. I perceived a few Moorish huts, a Mahometan hermitage at the point of a projecting cape, sheep browsing among the ruins; ruins so far from striking, that I could scarcely distinguish them from the ground on which they lay. This was Carthage?"—"In order to discover these ruins, it is necessary to go methodically to work. I suppose then, that the reader sets out with me from the fort of Golletu, standing upon the canal by which the lake of Tunis discharges itself into the sea. Riding along the shore in an east-northeast direction, you come in about half an hour to some salt-pits, which extend towards the west. Passing between these salt-pits and the sea, you begin to discover jetties running out to a considerable distance under water. The sea and the jetties are on your right; on your left you perceive a great quantity of ruins upon eminences of unequal height, and below these ruins is a basin of a circular form and of considerable depth, which formerly communicated with the sea by means of a canal, traces of which are still to be seen. This basin must be, in my opinion, the Cthon or inner port of Carthage. The remains of the immense works discernible in the sea would, in this case, indicate the site of the outer mole. If I am not mistaken, some piles of the dam constructed by Scipio for the purpose of blocking up the port, may still be distinguished. I also observe a second inner canal, which may have been the cut made by the Carthaginians when they opened a new passage for the fleet."—

Having now settled the situation of the ports, the rest will not detain us long. I suppose that we have pursued our way along the coast to the angle from which the promontory of Carthage projects. This cape was never included in the city. Leaping the sea, and striking off to the left, we first find the remains of a very extensive edifice, which seems to have formed part of a palace or of a theatre. Above this edifice, ascending to the west, you come to the beautiful cisterns, which are generally accounted the city relics of ancient Carthage; they were probably supplied with water from an aqueduct, some fragments of which may be seen in the plain. This aqueduct was fifty miles in length, commencing at the springs of Zawan and Zangar. There were temples above these springs. The largest arches of the aqueduct are seventy feet high, and the columns which support these arches are sixteen feet square. The cisterns are prodigious; they form a series of vaults communicating with each other, and are bordered throughout their whole length with a corridor. This is a truly magnificent work. A rugged road leads from the public cisterns to the hill of Byrsa, from the summit of which the eye embraces the ruins of Carthage.
which are more numerous than is generally imagined. 

They resemble those of Sparta, having nothing left in tolerable preservation, but covering an extensive space. I saw them in the month of February; the fig and olive trees already were clothed with their young leaves, large angelicas and anathouses formed verdant thickets among marble fragments of every colour." See Chatelubiand's *Travels*, vol. ii. p. 285, &c. (J. M. T.)

**CARTHAGENA.**

Carthage, a sea-port town of Spain, situated in the province of Murcia. It was founded by Asdrubal in the year of Rome 524. It was first called New Carthage, being intended by the Carthaginian colonists to rival their African capital: and afterwards it received from the Romans the name of Carthago Spartaria, on account of the great quantity of spart or broom which grows in its vicinity. Anciently it was the principal place of a Roman province, hence called Provincia Carthaginensis; and the scene of great contention, first between the Romans and Carthaginians, and then between the Romans and Barbarians. In the year 421, it was taken and utterly destroyed by the Vandals; but was entirely rebuilt by Philip II. for the sake of its excellent harbour. The town stands on the declivity of a hill, and is separated from the harbour by a small plain. On the south and the west are high mountains and barren rocks. Towards the north and east it is open, and communicates with an extensive valley, which is of a finely varied surface, has a fertile soil consisting of a sort of red earth and frequently returning sixty fold, produces different kinds of grain, and abounds in elms, poplars, olives, figs, pomegranates, &c. The streets are spacious, but very few of them are good. The houses are in general flat roofed, and sufficiently commodious. On the top of the hill commanding the city, there is a castle, which is rather in a state of decay; and on the adjoining heights there are walls of considerable strength erected for the defence of the harbour, arsenal, and dock-yard. The public buildings are not remarkable. They are chiefly the new parade, which is raised on a regular plan—the royal hospital, which is a large establishment, intended for the reception of the sick, both in the navy and army—the cathedral, which is a miserable pile, and, since the bishop's see was removed to Murcia, has been degraded to the rank of a parish church—the convents, none of which deserve particular notice—the arsenal, which is a spacious square situated to the south-west of the town, under the mountains, defenceless on the land side, but protected by cannon in its approach from the sea—and the dock-yards, consisting of wet docks, where the men of war are moored each of them opposite to the door of its own magazine of stores, and of dry docks, so much infested with water oozing from the marshy soil, that they would never be clear of it, were it not for several fire engines, which are continually going, and a great pump, which is wrought without intermission by multitudes of Spanish criminals and Babylonians. The harbour is the best in Spain, so good, that Andrew Doria, the famous Genoese admiral, was wont to say, he knew but three good ports, and these were June, July, and Carthage. There is none, indeed, which surpasses it in regularity and safety. It is very spacious, and to deep, that vessels may be moored close to the land; and in one position in it, a large fleet may lie in the utmost security, completely out of the view of all ships that may be at sea, or even in the narrow part of the entrance to the harbour. Its great outline, which is in the figure of a heart, is entirely formed by the hand of nature. On the east and west, high naked mountains rise very steep from the water's edge; and on the north, a low and narrow ridge of hills, on which the city stands, shuts out the view of the inland country. The entrance, which is defended by two redoubts, has the island Escombrera, lying off it in such a way as to shelter it from the violence of the winds and waves. And, indeed, so perfectly is it protected by the high hills which surround it, that from the mole—which is nothing more than a pitiful platform, though protected by twelve pieces of cannon—the entrance of the harbour and basin alone are visible, and even in the time of a storm the water remains calm and unruffled. In the centre of the haven, however, in a line between the mouth and the mole-gate, there is a ledge of rocks, which being only five feet under water, and not indicated by any breakers, is attended with danger to strange ships and careless pilots.

In the immediate vicinity of Carthage that spart or broom is cultivated. Anciently, as Pliny tells us, it furnished the common people with materials for bedding, clothes, shoes, and fire. It is still used for making shoes, ships' cables, and mats for houses, and even a line thread has been spun from it for the purpose of being weaved into cloth. Although not so much attended to as formerly, it is yet considered of sufficient importance to be an article of exportation, and to be subjected to the operation of duties and monopolies. The fishery here is considerable, and is carried on both within the port and in the open sea. The fishing within the port belongs to a company established by royal charter, while in the open seas all mariners who are enrolled, have a right to pursue that occupation. The fish are of various kinds, the tunny, melvas, &c. A good deal is consumed at home; but the greatest proportion is salted and sent to the foreign market. This branch of industry, as usual, is much discouraged by various injudicious regulations and unfair exactions on the part of government and its inferior officers.—The most important and valuable article of commerce at
CARThAGENA.

Carthagena is *barilla*, or potash; the quality of which is excellent, and of which great quantities are annually exported. The plants which yield this substance are all indigenous, and are particularly to be found in a swamp called Almojar to the eastward of the city. Government, with its accustomed folly, has subjected the barilla to an oppressive tax, which operates very much against the manufacture and exportation of it.—Wool and silk also are articles of commerce. —The chief imports at Carthagena are bale goods and merchandise of various kinds.—There are some excellent schools at Carthagena, for teaching navigation, mathematics, experimental philosophy, drawing, fortification, hydrostatics, &c. but they are instituted for the benefit of pupils for the royal navy, and the public at large have no access to them. There is likewise a botanical garden on a small scale, where lectures are given on botany by a professor of that science.—The most prevalent diseases are intermittent and putrid fevers, occasioned, it is believed, by the proximity of the swamp of Almojar. In the year 1785 and 1786, the city lost by these diseases no fewer than 4500 of its inhabitants.—Carthagena is under a military governor, with his alcaldes mayor, thirty regidores, and two syndics. The governor is supreme judge for the army, and for strangers settled in the country. His alcaldes preside in the tribunal for the citizens. The office of the regidores goes by inheritance, if not previously sold, and these, with the Escrivanos del' numero, who likewise succeed by inheritance, are constantly intent on plunder, and extremely tyrannical in the exercise of their power. The syndics are chosen by the people; but the election is under the influence of the regidores, and, as it is annual, they dare not attempt any thing in the way of redressing grievances.—Murders and assassinations are frequent in Carthagena, owing to the want of energy in its municipal government. Seldom are the perpetrators of these crimes punished, unless they be miserably poor; for the escrivanos are always ready to protect those who will gratify their rapacity. —The marriage vow is here violated in the most shameless manner. A gentleman one morning said gravely to his friend, “Before I go to rest this night, the whole city will be thrown into confusion.” This confusion he actually produced, by going home an hour before his usual time, and surprising his wife’s paramour, who in like manner returning suddenly, occasioned the same bustle and retreat at his own house; and this succession of regiment and surprises pervading the whole town, he literally fulfilled his morning’s prediction.—Swinburne says, that though there are several regiments here in garrison, besides engineers and naval officers, we can scarcely imagine any thing so dull as the town of Carthagena; and that, with the exception of the wretched comedy and the coffee house, there is not the least life or amusement going on. Laborde gives a very different account. He tells us that Carthagena is quite unlike the rest of Murcia, as it is distinguished by affability, society, amusements, and pleasures: strangers are well received, and the inhabitants are very hospitable. He adds, however, that there are few Murcians among them, the greatest part of them being foreigners, English, French, and Italian, who are either merchants, sailors, or soldiers.—In this town there are three tolerable inns, which are kept in the French style, and afford good entertainment. —The population is about 60,000, which is distributed among 15,000 houses. East long. 1° 6’, North lat. 37° 34’. See Polybius, lib. x.; Swinburne’s Travels through Spain, vol. i. p. 188; Townsend’s Journey through Spain, vol. iii. p. 121; and De Laborde’s View of Spain, vol. ii. art. Murcia. (r)

CARThAGENA, a province of South America, in the vice-royalty of New Granada. Its boundaries are the Carribean sea on the north, the river St Martha on the east, Terra Firma on the south, and the sea and gulf of Darien on the west. It is 100 leagues in length, from north-east to south-west, and 80 in width, from east to west. It was discovered in 1520, by Roderigo de Bastidas. The people being of a warlike character, resisted various attempts that were made to conquer them; at length they were subdued in 1533, by the governor, Pedro de Heredia. A great part of this country is composed of mountains and forests; but there are also some very fruitful valleys, which the natives call savannas, and in these are many settlements of Europeans, Indians, and Spanish Creoles. Towards the north, a part of the territory is swampy, sandy, and from the lowness of the ground full of sea-water pools. The climate is remarkably hot and moist; and from May to December, the weather is almost continually rainy or tempestuous. Accordingly the earth is covered with perpetual verdure, and rice and Indian corn are raised in sufficient quantities for the consumption of the inhabitants. The same circumstances which render the production of these so easy and certain, are unfavourable to the growth of wheat and other grains that are cultivated in Europe. There is a great variety of plants, trees, and fruits. Of trees, the principal for size are, the *caoba* or *acajou*, the wood of which is beautiful, fragrant, and close in the texture, and is employed in making canoes and other small vessels; the *cedar*, which is of two kinds, white and red, the last being the most esteemed; the *mario*, from which the maria oil is obtained; and the *balsam*, which distills the balsam of Tolu, so called from a village where it is found in the greatest abundance, and of the best quality. The fruit trees consist of the tamarind, the medlar, the sapote, the papayo, the guayabo, &c. Of most of these, not only is the fruit palatable and wholesome, but the timber also is finely variegated, and very durable. Pine-apples, limes, melons, grapes, oranges, medlars, dates, papayas, cocos, plantanes, bananas, &c. are in vast abundance. The mancinillo deserves particular notice. It grows to a large size; near the top its branches form a kind of crown; its wood is very hard, of a yellowish cast, and exquisitely veined like marble. Its fruit resembles an apple exactly in shape, flavour, and colour, but contains a very strong and deadly poison. Its white juice has the same quality in such a degree, as to render it unsafe to work the wood until it be thoroughly dried. Even those who happen to take shelter under it in a shower, feel the same effect from the dropping of the leaves as if the juice had fallen upon them. And the very beasts are said to have such an instinctive aversion to it, that
they will neither eat of the fruit nor approach the tree. Palm-trees, too, of different sorts, grow on the mountains in great numbers, producing various kinds of fruits, and exuding a juice from which, when fermented, a species of wine is made, of a whitish colour, a racy taste, and an intoxicating quality. The guacumin, and the guava, are also very common. The hardness of their wood is almost equal to that of iron. There are numerous plantations of sugar-canes; a great many cotton trees, some of which grow spontaneously, while others are planted and cultivated; and cacao-trees, which are chiefly found on the river de la Magdaleno, and the fruit of which, both in size and goodness, excels the same kind of fruit in all the other parts of the country, except Socunusca and Caracecas, whose cacao sells highest at Cadiz. Of the vegetables, which grow here in such profusion and variety, the sensitive plant is one of those most frequently met with. There is also a great quantity of bejucos, one species of which is particularly known on account of its fruit, called the bean of Carthagena. This bean is reckoned the most effectual antidote against the bite of the venomous animals, which are found here in great numbers. The cow and the hog are the only tame eatable quadrupeds to be seen in this district; but these are in great plenty. The flesh of the former is not remarkably good; that of the latter is extremely delicate, and the ordinary food of the inhabitants. The hides and tallow furnished by the cattle, form a considerable article of commerce. Poultry, pigeons, partridges, and geese, are both good and plentiful. Nothing can surpass the variety and beautiful plumage of the birds. Bats appear in great multitudes; and are said to be the most dextrous fliers both of men and cattle. Deer, wild boars, foxes, armadillos, squirrels, rabbits, and monikies, are extremely numerous. There are also leopards and tigers, which make great havoc among the cattle, and sometimes prove destructive to the inhabitants. Poisonous reptiles abound. The principal ones are snakes, coral-snakes, rattle-snakes, and the culibras de bejucos,—the centipedes,—which swarm here, and are monstrous large;—and scorpions, which are equally numeros, and of various kinds.—The principal rivers are the de la Magdalena already mentioned, and the San Juan, or Atracto, both of which are navigable, and contain alligators, tortoises, and a multitude of fishes.

This province contains two cities, seven towns, and ninety-six settlements or villages. When first discovered, it was well peopled, but since that time, the population is considerably diminished. According to the numerical of the of the royal audience of Santa Fé, Don Francisco Moreno y Escandon, there were in the year 1770, of whites, 59,293; of Indians, 15,993; and of negro and mulatto slaves, 7770. See Juan and Ullao's Voyage to South America, vol. i.; Aleoso's Geographical Dictionary of America and the West Indies, with Thompson's Additions, vol. i.; and Peuchet's Dict. Univers. de la Geograph. Commerce. tom. iii. (v)

CARThAGENA, the capital of the province just now described, is situated in a large and convenient bay of the same name. It stands upon a sandy peninsula, and communicates with the continent by narrow necks of land and wooden bridges. The city and the suburbs are well laid out. The streets run in straight lines; are wide, uniform, and tolerably well paved. The houses, which are mostly built of stone, have only one story above the ground floor; their apartments are well contrived, and their balconies and lattices are of wood, which, from the nature of the climate, are there preferable to iron for such purposes. The outside of the buildings, on account of the smoky colour of the walls, has a dirty and disagreeable aspect. The fortifications are constructed after the modern manner, lined with freestone, and of considerable strength. Besides a precinct and bastions, there is a half moon, which defends the entrance, or gate; and several castles situated on small eminences, and on the side of the bay. In this place there is a great number of religious communities, who have churches and convents for their accommodation. These are characterised by poverty in their ornaments, though their architecture is appropriate, and their capacity sufficient. The cathedral church is magnificent. There is a college of Jesuits. A tribunal of the Inquisition is also established here, in which respect Carthagena is on a footing with the metropolitan cities of Lima and Mexico. The power of this tribunal reaches to Isla Española where it was first settled, Terra Firma, and Santa Fé. Carthagena is the head of a bishopric erected in 1554 by Pope Clement VII. The jurisdiction of the bishop extends as far as that of the civil and military government. The government of the city is managed by a person who resides in it with the title of governor, having under him a requisite number of civil and military officers. In civil matters, an appeal lies to the audience of Santa Fé, and in military affairs to the viceroy of New Grenada. The police of the city is conducted by a secular magistracy, consisting of regidores, from whom are annually chosen two alcaldes. There is also a revenue office, where all taxes are received, and the necessary payments issued. Processes are determined by a man of the law, with the title of auditor de la gente de guera.—Carthagena, on account of its advantageous situation, and the excellence and safety of its harbour, very soon became the most important settlement and emporium of the Spaniards in South America. So early as the year 1544, it was a town of some commercial celebrity. Being selected as the port in which the galleons should first trade on their arrival from Europe, and to which they were ordered to repair previous to their voyage homeward, the resort to it was so great, and the means of prosperity so copious, that in a short time it rose to be one of the most populous and most opulent cities in America. And though, from the arrangements which have since taken place respecting the galleons, and the general circumstances of the commercial world, it has declined very much, it still carries on a considerable inland and foreign trade, and preserves no small portion of its comparative importance. It is reckoned by Humboldt to stand before all the other ports, with the exception of Vera Cruz, the Havana, and Lima. Including the small adjoining ports of Rio Hacha, Santa Maria, and Portobello, with which it is connected by the most intimate com-
mercial relations, it exports annually of the produce of native agriculture to the value of £252,000 sterling. The quantities of that produce are as follows: of cotton 3,307,500l. avoid.—of sugar, 220,500 ditto—of indigo, 22,050 ditto—of Brazil wood, 882,000 ditto—of quinquina of New Grenada, 220,500 ditto—of balsam of Tolto, 2035 ditto—and of ipecacuanha, 13,230 ditto. Besides these articles, there is a considerable exportation of the precious metals, which are carried to Old Spain. The value of the importation amounts to £840,000 sterling annually. The articles imported are brandy, wine, oil, almonds, raisins, tobacco, confectionaries, &c.—The bay of Carthagena, on which depends so much of its commercial consequence, extends two leagues and a half from north to south. It has a sufficient depth of water, and good anchorage; and is so well sheltered, that the ships are no more agitated than if they were in a river. There are so many shallows, however, at the entrance, and on some of these there is so very little water, that a skilful pilot is always requisite to steer the vessels into it with safety. The difficulty of navigating vessels in it is also increased, by the irregularity of the tides, which increase the danger of striking, and by the slimy and tenacious consistence of the bottom, which, when a vessel does run aground, renders it often necessary to lighten her, before she can be got off. In this bay there is great plenty and variety of fish, both wholesome and agreeable to the taste. The turtles are large, and of excellent flavour. Sharks are here very common, large, voracious and destructive. There are vast multitudes of croak-fish, from which the country on this coast got from the Indians the name of Calamari, signifying the land of croak-fish. All along the coast, salt is produced in great abundance.

The importance and wealth of this place have made it the object of frequent attacks. In 1544, it was taken and pillaged by some French adventurers, under the direction of a Corsican pilot. About forty years afterwards, half of it was laid in ashes by Sir Francis Drake, and the rest was saved from destruction by the neighbouring colonies, who paid for it a ransom of 120,000 silver ducats. It was a third time invaded, in 1597, by the French under the command of M. de Pointis, to whom it capitulated, but whose avarice consigned it to plunder. It was again besieged in 1740, by the English under Admiral Vernon, but it held out successfully, and the besiegers were obliged to retire after a great loss of men and labour. The inhabitants of Carthagena consist of various castes or tribes: whites, negroes, and Indians, and the different classes produced by the intermarriages of these. They drink brandy in the forenoon, make use of a great deal of chocolate, and are fond of smoking tobacco, which last practice is indulged in equally by both sexes. The fandango is the common amusement. This ball, or dance, which is the ordinary mark of rejoicing on festivals and remarkable days, is conducted with great propriety in houses of distinction; but among the lower orders it is accompanied with hard drinking, indecency, and quarrels. Their funeral ceremonies they observe with great pomp and ostentation, lamenting for the deceased in the most clamorous and frantic manner, and continuing their mourning in the house for nine days after the interment. Their diseases are chiefly the black vomit, with which the distemper that attacks Europeans on their first landing frequently terminates; the leprosy, to which the people both in town and country are very subject, and for the purpose of stopping which, a hospital, called San Lazaro is erected on the top of a hill in the neighbourhood, where persons of both sexes infected with it are strictly confined; the cobrilla, or little snake, so called, from the general belief that it is one of these animals which has introduced itself beneath the skin of the patient; and the espas, or convolution, which is very prevalent, seldom comes alone, and always proves mortal. The intense heat and moisture of the climate, naturally lead to the conclusion, that the inhabitants must be unhealthy; yet it is a fact that in general they enjoy good health, and it is not uncommon for them to survive their eightieth year. The profuse perspirations, however, occasioned by the high temperature, render their complexions wan and livid, and all the movements sluggish. The population is said to be between 20,000 and 30,000, of which above 9000 are in communion. West: Long. 75° 26' 45", North Lat. 10° 26' 35". CASAL, a town of France, in the department of Marengo, and formerly the capital of Lower Montferrat, is situated on the right bank of the Po. It received the name of Casale Sancti Evasii, after the death of St Evasius, who was martyred by a Duke called Astabolo. It is highly probable that it was built not far from an ancient town called Sculto, and not, as some authors have imagined, on the ruins of Badimocongo or Industria; (see Pliny Nat. Hist. lib. ii.) The few huts which were built by the devotees over the place where the body of the martyr was preserved, gradually assumed the form of a town, while Liutprand, king of the Lombards, built the church which still exists, and which was afterwards erected into a cathedral. In the year 1173, Casal was erected into a free city; and, about
the end of the 11th century, it became the residence of its sovereigns. Pope Sixtus IV. erected Casal into an episcopal city; and, in spite of the revolt of its inhabitants, the Dukes of Mantua preferred it to Mantua as a place of residence. About this time, when the arts made such a rapid progress in Italy, this city acquired fresh lustre. New palaces and new churches were erected; and many families removed to it from Mantua. While it was in the possession of the French, Catino, who was the governor, constructed the citadel, which was reckoned one of the strongest in Italy. It was, however, carried away by the Piedmontese and Spanish troops in 1695, and all the fortifications were demolished. There now remains only an old castle, where a small garrison might hold out for some hours.

The principal public buildings in Casal are, the theatre, the seminary, the lyceum, the palaces of M. M. Gozzani St George; Gozzani Odalengo, Vincent Ricci, and Rond Devalle; and the churches of St Dominique and St Philippe. There is a charming promenade from the Marengo gate to that of the Po. The principal hotels are, the Hotel Mogul, the Trois Rois, and the Nouveaux Puits.

Casal is inhabited by several ancient and illustrious families, some of whom pretend to have their descent even from Numa Pompilius. Population 14,000.

East Long. 8° 51', North Lat. 42° 5'. (x)

CASAL MAGGORE, a name of a town which is the chief place of a district of the same name in the department of the higher Po and the kingdom of Italy. It is situated near the Po, and was made a town in 1754. Population 4150.

CASAN. See KAZAN.

CASABON, Isaac, a very learned critic and editor, was born at Geneva in February 1559. His natural abilities were good, and so great was the progress which he made under the tuition of his father, who had been minister of Crest in Dauphiné, that he was scarcely nine years of age, when he could both write Latin with correctness, and speak it with ease. But his father being under the necessity of going from home on business for three years together, Isaac's education was neglected, and he almost entirely lost what he had acquired. When he reached his twelfth year, he again applied to his studies, and partly by his own exertions, partly by the occasional assistance of his father, he began to recover his classical knowledge. This method, however, being uncertain and tardy, he was sent in 1578 to Geneva, to study under the professors there; and so great was his diligence, and so attentive were his teachers, that he soon redeemed all the time which he had formerly lost. Such was his proficiency in Greek, that Francis Portus, the Cretan, by whose instructions he had been made acquainted with it, thought him worthy to be his successor in the academical chair at the age of twenty-three; and to that honourable situation, accordingly, he was appointed in 1582. In 1586, his father died, and shortly after he married a daughter of the celebrated printer Henry Stephens, by whom he had twenty children. After holding the professorship of Greek at Geneva for fourteen years, during which time he studied philosophy and civil law, and paid some attention to Hebrew and the Oriental languages, he removed to Montpellier, as professor of the Greek tongue and polite literature, with a more considerable salary than he enjoyed at Geneva. This change of situation was occasioned, not merely by the difference in his emoluments, but also by the morose temper of his father-in-law, and by his own restless disposition. At Montpellier, he was at first much esteemed, and greatly pleased; and resisted the invitations which were given him, first by the city of Nîmes, and afterwards by that of Franeker, to accept of a chair in their universities. But he soon began to be disgusted with the treatment which he received. The promises that had been held out to him were not fulfilled; his salary was neither regularly nor fully paid; and he experienced so much vexation from these and other causes, that he was just on the eve of returning to Geneva, when better prospects were opened up to him in another quarter. By M. de Vicq, a man now at Lyons, whom he visited in 1588, he was taken to Paris, and introduced to King Henry IV., President de Harley, President de Thou, (Thuanus) and other persons of eminence, who gave him a very civil reception. The king offered him a professor's place, and, after his return to Montpellier, renewed the offer by letter.

He at last resolved to go to Paris, though he was warned by M. de Vicq and Scaliger, that his expectations would probably be disappointed. Henry received him most graciously; but the jealousy of the other professors, and his own Protestant principles, were the occasion of much opposition and trouble, and even prevented him ultimately from obtaining the situation which his majesty had promised. He was, however, appointed one of the judges on the Protestant's side at the conference between these and the Catholics, held at Fontainbleau in 1600. And afterwards he was nominated keeper of the king's library, which gave him access to a valuable collection of books, and enabled him to prosecute his literary views with great success. He had also a pension from the king, which was considerably augmented, in order to prevent him from yielding to the many pressing solicitations and pecuniary inducements which he had to go to other places. Many artful and unworthy attempts were made to bring him over to the Romish faith, but these he uniformly resisted, and lived and died a Protestant. The murder of the king, which happened in 1610, distressed him deeply, as it deprived him of his chief patron; and in the same year, the conversion of his eldest son to the Roman Catholic religion, gave another blow to his feelings, and he felt it the more, because it was generally reported, and by many believed, that he himself had contributed to this change. These affecting circumstances, together with the continual vexations in which he lived at Paris, determined him to set out for England, into which country he had been frequently invited by James I. He arrived there in 1610, and experienced from persons of rank and learning the kindest reception, though he himself has complained, that from the inferior classes of people, he met with more insults than he had even done at Paris in the midst of Papists. The king shewed him particular attention, took much pleasure.
in conversing with him, admitted him several times to his own table, presented him with a sum of money to enable him to visit Oxford and Cambridge, grant- ed him a pension of three hundred pounds, and nom- inated him to two prebends, one at Westminster, and the other at Canterbury. Casaubon was not un- grateful; and he seems to have expressed his grati- tude in a way most agreeable to the feelings of James, namely, by flattering his literary vanity, and humour- ing his silly prejudices. In the letters which he wrote, by the direction of James, to De Thou res- pecting his history, and which, it is not improbable, were inspected by the royal eye, he eulogises the king in the most fulsome manner for his learning and his virtue, and actually talks of him as a kind of miracle or prodigy. He also remonstrates with De Thou on that part of his history which affected the character and conduct of the king’s mother, and in James’s name demands satisfaction for the injuries which he had done to her reputation. This remon- strance produced some effect; and by these and similar compliances with the temper of James, Casaubon contrived at once to make his acknowledgments for past favours, and to lay a foundation for future claims. His object was not lost. So much was his majesty pleased with him, that he wrote to the queen re- gent of France, through whose indulgence Casaubon had been permitted to come to England, begging her to allow him to prolong his stay in this country, and the royal favour seemed to promise him dis- tinctions and preferment; but a painful distemper soon closed these flattering prospects, and put an end to his life. He died July 1, 1614, in the 55th year of his age, and was buried in Westminster Abbey. His character, religious as well as literary, has been variously represented; but there appears to be good reason for believing, that in both these views he was highly respectable. That he was a Protestant, there can be no reasonable doubt, though the contrary has been insinuated, and though he entertained, along with Grotius and other eminent men, the foolish project of forming an union between the Catholic and reformed churches. The probity and correctness of his moral deportment have never been disputed. Of his extensive learning, he has left a multitude of satisfactory proofs in the various editions of Greek and Latin authors, and other works which he pub- lished in the course of his life. A large volume of his Letters was published, from which a tolerably correct idea, both of his temper and classical attain- ments, may be derived. A complete list of his writ- ings is given in the Biographia Britannica, art. Casaubon. Besides that article, and the Letters above mentioned, (Almeleven’s Edition, containing a life of Casaubon,) see Niceron, Memoire pour servir à l’Hist. des Hom. Illust. tom. xviii; and La Vie de M. de Thou in Durand’s Hist. du xvi. Siecle tom. vii. (r.

CASBIN, CASVIN, or CASWIN, supposed to be the ancient Aracicia, a city of Persia, in the province of Irak-ajami, situated in an extensive plain of the same name, surrounded with mountains at some miles distance. Casbin, which is now a complete mass of ruins, was formerly about six miles in circumference, and contained 12,000 houses, and 100,000 inhabi- tants; but, in consequence of the civil wars with which the country has been agitated, it has been greatly reduced both in magnitude and opulence. Its walls and palaces are completely destroyed, and it is at present defended neither by forts nor garrisons. An earthquake, according to Morier, within no dis- tant period, threw down the buildings which were in the Tottie, and made cracks in almost every wall. A large mosque, erected by the Abbasses, has been in many places rent in its thick walls, and totally ruined. The Royal Piazza, or Hippodrome, was no less than 700 paces long, and 250 broad. The Khan is a very large building. The Bason is remark- able for its agreeable construction; and the principal mosque is well built.

The following interesting account of Casbin is given by Hanway, which we are obliged to present to our readers in his own words, as we have no means of ascertaining whether or not the buildings which he describes are now in existence.

“The houses are, for the most part, below the surface of the earth, as are many of the gardens joining to them, to obtain the convenience of the water, which is brought to them from a considerable dis- tance in channels; for, as we usually bring water up to our houses, they level their houses to the water, which, however, are not the less agreeable in hot weather. They are generally built with sun-dried bricks, and their cement is a strong lime. The roofs are flat; so that it is easy and familiar to sleep on the house tops. These buildings are enclosed with a mud wall: they consist of two divisions; the outer stands in a large area, and consists of a spacious room, one side of which is open, and supported with pillars. In these they dispatch their business, and also eat, when they do not retire to the women’s apart- ment. There are niches in the wall, which an- swer the purpose of tables: the floors are covered with large worsted carpets; and on the sides of the room are felts, about a yard broad, and are generally two or three yards long. These are called namets, as already mentioned; and are made either with wool or camel’s hair; and, being very thick and soft, are used for sitting upon. In the wings of this apart- ment there are smaller rooms for lodging. In the same yard there are apartments for the servants, and also their stables. On the back part of this build- ing is another, likewise enclosed by a wall, which, for the sake of privacy, is generally entered by two turnings. Here is the women’s apartment, into which no man is suffered to enter, except the master of it.

I then went to see the new palace which Nadir Shah had built in this city, adjoining the old one. The entrance of it is formed by an avenue of lofty trees, near three hundred yards long, and fifteen or twenty broad. The wall round it is about an Eng- lish mile and a half in circumference; it is thick and lofty, having only one entrance, which is an arched- gate. The top of this gate projects, and is formed into many small squares. Within are four large squares, with lofty trees, fountains, and running wa- ter, which makes the place awful and majestic. The apartments are raised about six feet from the ground. The Aivan, or open hall, is in the centre, and shu-
The rooms are ornamented in an Indian taste, and the ceilings formed into small squares, embellished with writings of moral sentences in very legible characters. Most of the windows are of thick-coloured glass, made transparent, and painted with such art, and in such proper shades, that the glass seems cut into the several figures it is designed to represent. Many of the floors are of hard earth; others of a composition of beaten stone. The seeming defect in this instance is made up by the constant use of carpets.

The Haram is magnificent, consisting of a square within its own wall of brick, about thirty feet high, and two and a half thick. There are four distinct apartments, in some of which are fountains, which serve to moderate the heat of the summer, by giving the air a refreshing coolness. The rooms are lined with stucco, painted in the Indian taste, with birds and flowers of different magnitudes; the colours beautiful, and set off with gilt edgings. These apartments have small chimney-pieces, in a mean taste; and some are ornamented with looking-glasses in small squares, of many different dimensions, set into the walls. There are some few rooms below ground, admirably contrived for coolness. Near the Haram is the eunuchs' apartment, remarkable only for its having but one door, and that a very strong one. The brick of which the whole of the modern building is made, appears to be ill prepared for duration. Here are also some old apartments built by Shah Abas, yet standing, in which are some bad pieces of European figures by European painters. The Persians themselves are as ignorant of shades as the Chinese. The apartment where the Shah kept his Casbin treasury, I was not permitted to see,—not even the place where it stood. They said he had above twenty millions of crowns there, of which part was in large ingots of gold, run into cavities of the earth, the better to secure it from being plundered."

Both at Casbin and at Herot, the blades of sabres are fabricated from the steel of the country. A kind of tapestry, of a most expensive kind, is manufactured here from pieces of cloth of various colours. Stuff of silk and cotton are likewise manufactured in this place. All kinds of arms, but particularly fire-arms, fine cloths, watches, and engraved stones, are among the principal objects of commerce in this city. Rubies, granites, and turquoise stones, find a ready market in Casbin. The latter, which are called **Firus**, are found in great quantities near Nisabur and Firus-calh, of the size of a pea; and those which are as large as a small bean are sold for 20 or 30 sols.

"Casbin is admirably situated for connecting the commerce of Hyrcania, Iberia, and Media, with the southern provinces of Persia. It is the great mart for the silks of Guilan and Chyrvan; and there is brought to it a part of the rice of Guilan and **Ma-**

zanderan.

The fields and gardens in the neighbourhood of Casbin produce great quantities of vines, which yield the finest grapes in Persia; and almonds, pistachios, and melons, are raised with great success. " This place," says M. Morier, "labours under great inconvenience from the want of water; indeed, through the whole extent of the immense plain that we traversed during the day, there was not one natural stream, but many kanauts were making; and wherever there is irrigation there is fertility, and the cultivation is rich. Upon the whole, therefore, our route from Teheran displayed a country of much more promising appearance than we might have expected in Persia."

Within the space of twenty leagues round Teheran, the King alone goes in a litter; and even his children have not this privilege. General Gardanne was obliged to quit his; and his brother, who was wounded by a blow from a horse, could with difficulty obtain an exception from this rule.

The river Kulma passes at some distance from this city. In the time of Hanway, Casbin contained only 1100 houses. Olivier makes the population from 20,000 to 25,000; but, according to the author of the *Journal d'un Voyage*, en 1807 and 1808, it is now inhabited by about 60,000 souls. East Long: 49° 39', North Lat. 26° 19'. London, 1812. (π)

**CASE.** See GRAMMAR.

**CASEARIA**, a genus of plants of the class Decandria, and order Monogyenia. See BOTANY, p. 214.

**CASERTA**, a city of Naples, in the country of Lavora, situated at the bottom of a lofty range of hills, and celebrated chiefly for the magnificent palace erected by Charles III. of Spain, from the designs of Vanvitelli.

The palace of Caserta, which is situated in a plain near the site of the ancient Capua, is an oblong square 787 feet in length, and 616 in width. The two principal fronts contain five stories, with 37 windows each, while the other sides contain five stories, with 27 windows in each. It is divided by intermediate ranges into four courts. - In the centre is an open vestibule, with a stair-case 60 feet by 90, which leads by double flights into an octagonal saloon, 90 feet in diameter, which is divided by eight marble columns into a circle, and surrounding gallery. On one side is a long row of antichambers, leading into halls of audience, presence chambers, and state bed-rooms, with numbers of cabinets, wardrobes, and waiting rooms. On another side is a range of private apartments adapted to domestic convenience, and on a third side is the splendid chapel, inclosed with pannels of yellow marble, and not inferior in size or decoration to that of Versailles. Antique columns of alabaster support the roof of the theatre, and divide the house into 42 boxes. The gardens, which correspond in magnificence to the palace, are very extensive, and are formed with wide alleys, and with crowded rows of statues.

The aqueduct, which is 27 Italian miles and 218
palms long, conveys the rivulets of the Appenines into the reservoirs of Caserta. The aqueduct properly so called, is two miles long, and consists of three stories of arcades, of which the upper one is divided into 43 arches, while the lower one contains a smaller number. It is paved with calcareous stone from the neighbouring mountains, and the rest of it is built with volcanic tufa. In the construction of the aqueduct, an ancient tomb was found at the depth of 90 feet. The expense of building the palace and aqueduct amounted to seven millions of crowns. "Caserta," says a modern traveller, who visited it in 1802, "is not yet finished, and probably never will be, though it has been in hand for half a century, as the situation is so flat as to be incapable of modern decoration, and his present majesty takes more pleasure in the present mansion-house of Saint Lucio, where he amuses himself with superintending a manufactory of silks and gauzes." See Spalanzani’s Travels; Swinburne’s Travels; Reichard’s Guide des Voyageurs, &c. tom. i. p. 478; Travels from Paris through Switzerland and Italy, by a native of Pennsylvania in 1801 and 1802, letter 28; and Encyclopedia Methodique, art. Aqueduc. (e)

CASHAN, KASHAN, or CACHAN, a town of Persia, in the province of Irak-ajemi, situated in the plain of Cashan, which is bounded with the distant range of mountains, of which Damawend formed the most conspicuous and the highest point. This mountain is distinctly seen at the distance of 150 miles, and the Persians maintain that it can be seen from Isphahan from the minaret of Mejid Shah, which is 240 miles distant. It is of a conical shape, and rises abruptly from a long and unbroken range. This town, which was founded by the wife of the Caliph Haroun-el-Raschid, is fully a league long from east to west, and more than half a league from north to south. The houses are built of earth and brick. The principal public buildings in Cashan are the bazaars and baths, the royal inn, the royal palace, and another palace for ambassadors, and about forty mosques and three grand sepulchral monuments in honour of three descendants of Ali. M. Olivier, who lately visited this city, remarks, that it is the largest, the finest, the richest, and the most populous that he saw in Persia. It had almost entirely escaped the disasters of the civil wars; and though nearly a fifth part of the houses were destroyed, yet the mosques, the caravanserai, the bazaars, and the royal palaces, (which were singularly beautiful,) were all in a good condition. Cashan was once famous for its pottery, and has various manufactories of silk and cotton stuffs, brocades, and all sorts of copper utensils. The inhabitants work a great deal in gold, silver, and steel. Savas and poignards are also made to a considerable extent. The surrounding country produces abundance of rice, cotton, tobacco, wheat, barley, and fruits of all kinds. They cultivate also the ricinus, from which they extract their oil for burning. The vine is common, and raisins and dried apricots form a considerable article of commerce. The population of Cashan under the Sophis, was 35,000, but at present it does not exceed 30,000. Chardin makes the number of houses 6500. East Long. 51° 21’, and North Lat. 33° 59’. See Char-

CASHMERE, Cashmere, or Kashmir, a province of Hindostan, and formerly subject to the king of Candahar. It is situated between 33° 18’ and 34° 15’ North Latitude, and between 73° 30’ and 75° 12’ East Longitude. It is only a valley of an elliptical form, surrounded by hills, which in its largest extent from south-east to north-west is hardly 80 miles; its greatest breadth may be from 40 to 50. Towards the north and north-east, this district of country is bounded by what, in these parts, are termed the mountains of Thibet; a branch probably of that immense range which, rising near the Black Sea, penetrates through Armenia, and skirting the south shore of the Caspian, extends by way of the north-eastern provinces of Persia to Thibet and China. On the east it is bounded by the river Chunaub; on the south-east and south by the territory of Jummao and Kishetwaw; on the south-west and west by the territory of the Ghickers, Prouence, Muzzuffeberabad, and some other independent districts. In a north-eastern direction from this province lies Great Thibet. Little Thibet is to the north-west of it. Southward are the provinces of Lahore and Cabul: to the west Great, and to the north Little Bucharia. In the Ayeen Acberry, Cashmere is divided into two parts, viz. Merraje and Kamraje; the former being the eastern part, and containing the districts situated to the east, the south-east, and the north-east of Sirinagur, which is the principal town of the province; and the latter the western part, containing the north-
Cashmere. west and south-west districts. On the south-east of Siringur, at some distance, beyond the great circle of mountains that surrounds the valley of Cashmere, is the district of Bannaul, which, though a fertile vale of ten or twelve miles in length, and dependent on the Cashmerian territory, is yet suffered by the governors of that province to remain uncultivated, that it may not afford shelter or provision to the bordering Hindoo states, which, in former periods, have through this tract approached the interior passes of Cashmere. In as far as a place may be secured against foreign attack by means of its natural boundaries, there are few tracts of country to which such defence has been more liberally afforded than it has been to Cashmere. It is, in fact, so completely inclosed within the lofty mountains that separate India from Great Tartary, that it is only by climbing over rocks of an immense height that it can be entered on any side. Surrounded thus by mountains, whose summits are, during a great part of the year, covered with snow, it is moreover elevated considerably above the level of the adjacent low grounds to the south. Hence it is that the air of this district is colder than its latitude would lead us to expect; and even within the space of little more than two degrees there is found an almost complete change in the vegetable productions, few of these of any kind being in this country the same with those of more southern India, and of the fruits of the latter region hardly any being to be traced here except the mulberry.

The valley or country of Cashmere, thus situated, is yet celebrated through Upper Asia, and indeed generally has been in high reputation wherever it has been known, for its romantic beauties, the fertility of its soil, the temperature of its atmosphere, and a picturesque variety of landscape. The author of the Ayen Aecberry dwells with rapture on the beauties of this province, and the ideas which have been entertained of it may, in some degree, be understood from the epithets by which it has been so commonly characterised: the happy valley,—the garden in perpetual spring,—the paradise of India. The periodical rains which almost deluge the rest of India are shut out of Cashmere by the height of the mountains, so that only light showers fall there, but these are in sufficient abundance to feed thousands of cascades, which are precipitated into the valley from every part of the stupendous and romantic bulwark by which this favoured spot is incircled. At the foot of that exterior chain there is an inner circle of hills abundantly clothed with grass, trees, and various sorts of vegetation, and frequented by numerous animals, both in a wild and in a tame state. The soil of the plains is every where the richest that can be conceived. Indeed, it is considered to have been composed of the mud deposited by the principal river of the district, which flowing in this direction, and finding no outlet, at first formed its waters into a lake that covered the whole valley, but eventually having opened for itself a passage through the mountains, left this spot so fertilized, an ample field for human industry and for the accommodation of a happy race. The circumstances which indicate that to have been the mode of its formation, appear to have been such as to have satisfied a very competent judge. Although this account, says Ma-

or Kenna, has no living testimony to support it, yet history and tradition, and what is yet stronger, appearances have impressed a conviction of its truth on the minds of all who have visited the scene, and contemplated the different parts of it. It is indeed, by remarks, a mere natural effect, and such, he conceives, must be the economy of nature in all cases, when water is inclosed in any part of its course by elevated lands. If the lake be formed near the sources of the river, and the ground is solid, no doubt such a lake may remain for an indefinite length of time, or for ever, in the same state, for want of sufficient force in the river to work out a passage for itself; but when the lake has been formed in the lower parts of a river, even the most apparently insuperable obstacles will, in consequence of the great accession of water, and consequently of strength, in such circumstances be forced at last to give way. This is exemplified, not singly in the instance of the river of Cashmere. In the same manner the Euphrates has been found to open a passage for itself through Mount Taurus, the Ganges through the Imaus. The length of time which the lake in Cashmere seems to have occupied in effecting its emancipation, is evinced by the great depth of soil deposited by it previously to its departure.

The river of this place alluded to, which continues to pass through the province, is still, even within its limits, large, and navigable at least for small craft. Its current, throughout the whole valley, is remarkably smooth—a proof of the uncommon flatness of the country, as the body of water contained in it is very great. Its breadth is irregular: in some places it is not less than two miles. In one part of its course it is formed, by the hollow surface of the country, into a sheet of water, of seven or eight miles in circumference, known by the name of the Oller or Wuiler. The outlet through which it departs from the valley, and where it runs with much greater rapidity and force than elsewhere, is at Barchmoolah, between two steep mountains, whence proceeding, it, after a long course, joins with the Chinab. In this river, now known by the name of the Behut or the Chelum, we recognise the famous Hydaspe of antiquity, which Alexander the Great passed over, about 100 miles below the limits of the valley.

As the surface of this district is generally flat, and it is copiously watered, it yields abundant crops of rice, which is the common food of the inhabitants. At the base of the surrounding hills, where the land is higher, there are cultivated wheat, barley, and various other descriptions of grain. Hemp and saffron are also common productions, and iron of an excellent quality is found in the adjacent mountains. A great number of nuts for dyeing are raised here. A wine is made in the country resembling Madeira; also a spirituous liquor is distilled from the grape. The vegetable productions of Cashmere, moreover, are not such only as are subservient to mere unadorned use. The plane-tree, the species of it termed the platanus orientalis, which, though common in most parts of Asia, is said to arrive at greater perfection here than in other countries, has, when in full foliage, a grand and beautiful appearance, and in hot weather it affords a refreshing shade. Still more deserving of
Cashmere, in this view, is the rose of Cashmere, the season of the first appearance of which is hailed with so much delight by the natives, and of which the essential oil or otta is held in universal estimation. In all directions in this province, there occur the European plants, flowers, and fruit and other trees; and in the gardens there is abundance of melons, skirrets, beets, radishes, with all the variety of our pot-herbs. The pasture-grounds of Cashmere are plentifully stocked with the useful domestic animals, as cows, sheep, and goats. There is a kind of sheep here called Hundoo, which is used to carry burthen. There are also gazelles and musk. Game abounds in the country, and there is a plentiful and productive stock of bees. Indeed the whole of this favoured district may be said to resemble a garden, interspersed with towns and villages, which rise amongst green meadows, beautiful trees, and all the variety of other vegetable productions; watered by numerous streams and rivulets, which, flowing in all directions from the surrounding rising grounds, hasten to convey their tribute to the Behut or Chelum, the parent of the soil; intersected by canals, which wind through it in every variety of form; still farther diversified by lakes, in some of which are observed floating islands; and cheered, enriched, and enlivened by all the varied aspects of active and animated nature. Still one dreadful evil of a physical kind is here experienced. This is the frequent recurrence of earthquakes, to secure themselves against the fatal effects of which, the inhabitants commonly build all their houses of wood, of which an abundant supply is to be obtained from the neighbouring mountains.

The Cashmerians are considered to be the most ingenious of all the nations of India. With as much taste for poetry and capacity for science as the Persians, they are more industrious and more laborious. They fabricate the best writing paper of the East, which was formerly an article of extensive traffic, as were also its lacker-ware, cutlery, and sugars. Their elegant works in wood, are in request in all the surrounding districts of country, and they are deservedly admired for their address and expertise in the arts of varnishing, veneering, and gilding. But the most noted and the most important of all the artificial productions of Cashmere, consists in its shawls, which, with good reason apparently, have attained a celebrity hitherto univalved. It has been alleged that the wool of which one description of these shawls is made, is not found in the country, but is brought from Thibet. It has also been pretty commonly understood that those of another kind are made of goats' hair. But both of these notions seem to be founded in mistake. The breed of sheep, whence the wool in question is obtained, though not peculiar to this country, is at least common to it with Thibet and Boutan, and the shawls which have been considered to be formed from goats' hair, are the produce of the wool of the camel.

The same circumstances which constitute Cashmere one of the finest regions of the earth, contribute also not a little to the beauty of its flocks and the superiority of its wool; its pure air and constantly serene sky, brilliant nights, continual dews, innumerable springs which water the hills and the plains, and the union within itself from its particular situation, in respect to vegetable produce, of the advantages of all climates. Particularly, the mountains which surround this rich and fertile district yield abundance of aromatic plants that afford excellent pasture for sheep; they are covered almost the whole year with wild thyme and sweet marjoram. By a due care on their own part, added to these advantages, for which they are indebted to nature, the Cashmerians obtain in favour of their manufactures that to which chiefly they owe their excellence, the finest wool in the world. The sheep from which this wool is procured, is one of the most beautiful of its species; its mean length is from 36 to 40 inches, its height from 20 to 22, and its weight from 55 to 60 pounds. The most distinguishing characters of this race, are a small head and lively eyes; their front is not rough, and they have a long and wrinkled dewlap. The lambs are brought forth with crispy wool on the flanks, but they have only a few flocks on the back and along the spine. Each sheep produces at an average about three saris, of thirty ounces, of clean wool. It is a valuable and essential quality of these sheep, essential at least in such a district of country as that to which they are confined, that they can bear the extremes either of heat or cold. Yet to secure them against the injurious effects that might possibly ensue from their exposure to the greater heats of the summer season, they are, during the continuance of these, made to traverse a lake or a river several times a day. In Cashmere, moreover, as in Greece and in Spain, the sheep are moved from place to place within the limits of the province, (a range, narrow indeed as to extent, but very considerable in respect to variety of climate), that throughout the whole course of the year they may be kept nearly in an equal temperature. At the same time, they are never, with a view to this object, crowded into cots or confined places, which, it is justly apprehended, would be in every respect only injurious to them. By such management, at once the health of the flock is preserved, and the wool is whitened and becomes of a texture soft and silky. Without any further care, besides that of preferring always a lamb of the second birth for a breeding ram, avoiding to cross the breed, providing a little nourishment for the sustenance of the animals at those seasons, when they are not suffered to range abroad, or when little is to be found for them in the fields, and meeting, with a few simple remedies, any incipient or apprehended disease, the Cashmerians obtain that extraordinarily fine white silky wool, which generally, from the nape of the neck to the flanks, is from 20 to 22 inches in length, and even on the flanks and lower parts of the body, is not less than five or six, and equally of that length, which, in short, both for fineness and for whiteness, surpasses every other wool, even the most celebrated for those qualities throughout the known world.

The general practice in Cashmere is to shear the sheep only once in the year, the operation taking place 15 or 20 days after the return of the great heats, when, from the perspiration of the animals, the wool may have become more soft and pliant. During the period of the shearing, the sheep are washed.
Cashmere commonly twice a day, or oftener, but as well for the safety of the animals, as to guard against crippling or hardness in the wool, only at those times in the morning or in the afternoon when some degree of diminution has taken place in the strength of the sun's rays. It is indeed an estimable and peculiar quality of the Cashmerian wool, that it has no hard coarse part; a quality the more deserving of notice, as it is not possessed in common with it even by the wool of the Spanish sheep.

The Cashmerian wool, exclusive of the fleeces of lambs under two years of age, which are set apart for certain inferior purposes, is divided into the arouel, or the wool of the young sheep, and the duaume, which is the name given to that of the old. The first of these kinds is a little shorter than the other; it is obtained from sheep between the age of three years, when the shearing of what, in the language of the country, is called the tooss, begins, and that of seven or eight. The duaume is longer than the arouel, a little less greasy, weaker, and less silky. These two kinds of wool are each subdivided into two sorts, that of the back and that of the belly. The wool of the belly is used only for the manufacture of a particular stuff, that is consumed in the country and the neighbouring provinces. The finer parts of the wool having been first exposed to the vapour of a slight lea, formed from the ashes of the leaves of the banana tree, or of a clayey barren and white earth, which by the Indians is called ole, then washed with the farina of a small cylindric bean, called moungue; known in botany by the name of mango, and lastly rinsed repeatedly in pure water, are employed, as they are of the one or the other of the descriptions above named, either in the manufacture of shawls, or of those pieces of cloth which have retained the name of the country, and which it has been so often attempted, but commonly with such indifferent success, to imitate in Europe. The common fine shawls manufactured in Europe are the white; in the preparation of others the yarn of the wool is previously stained with such colours as may be judged the best suited for sale. These shawls have flowered corners, and a border of greater or less breadth, according to the price. The border, which usually displays a variety of figures and colours, is attached to the shawls after fabrication, but in so nice a manner that the junction is not discernible. The texture of these shawls resembles that of the shalloon of Europe, to which it has probably communicated the name. They are usually made 3-4 ells in length, and half an ell in breadth. The price at the loom of an ordinary shawl is eight rupees; thence in proportion to quality they produce from 15 to 20; even 40 are sometimes paid for very fine pieces; and by the introduction of a great deal of flower-work, the value, or rather the price, may be increased even to 100 rupees. The superfine shawls are those that are made of the wool of the camel. This wool, which is more beautiful than that of Vicuna, is extremely scarce, being found only on the forehead and around the ears of that animal. It is dear in proportion to its scarceness, so that the shawls formed from this material, besides costing, even at the manufactury, the sum of ten guineas, are at that price with difficulty to be procured. Shawls, the weft of which is camel's wool, are distinguished by the name of cacocheli; the white, with the weft of sheep's wool, are called assamiti; and the rest are known by the appellation of pesarti. The superior softness and beauty of the shawls of Cashmere, comparatively even with those formed from similar materials in the neighbouring provinces, is attributed by Bernier to something in the water of the country. They have a very extensive sale over all the Western and Southern Asia; and, agreeably to the remark of Volney, which seems as if intended to indicate the variety of the circumstances in which they are to be met with, they make a part of the dress of the Egyptian Mamelukes, and they are worn by English ladies. The Cashmerian pieces of cloth are more than sixty French ells in length, and rather beyond one-half ell in breadth. The price at the manufactories amounts only to the moderate sum of 15d. These cloths are far superior to the imitations of them either in England or in France, and they last much longer; a superiority to be attributed no doubt to the better quality of the wool.

The articles of manufacture which have been just mentioned, form the great object of the trade and industry of the Cashmerians. All, even to their children, are employed in them. In former periods, when the country enjoyed, in a greater degree than it afterwards did, the advantage of a good government, the province is said to have contained 40,000 shawl-looms. At present, they are not considered to be more than 16,000.

There are still seen here merchants and commercial agents of most of the principal cities of northern India; also of Tartary, Persia, and Turkey; but owing to the heavy oppression of the government, and the rapacity of the bordering states, which prey upon the foreign traders, and often plunder whole cargoes, the commerce of Cashmere has fallen, for some time, rather into a declining and languishing state.

Intersected as it is with numerous streams, navigable for small vessels, great advantage and convenience might arise to this country, especially in respect to its interior commerce, from the water conveyance; but in this, as in other instances, the miserable policy of the Afghan government, has been at once at variance with its own interests, and the prosperity and happiness of the people.

Cashmere seems, at one period, to have been subject to the Turkish dominion. This is indicated by the name by which it has been formerly known, that of Turchind, or the India of the Turks. Previously to the Mahometan conquest of India, this province was celebrated for the learning of its Bramins, and the magnificent construction of its temple. The area of its subjection to the Mahometans appears not to be very precisely ascertained; but it is probable that a country containing a valuable commerce, and a profusion of natural beauties, would at an early date attract notice, and invite their conquest. It was governed in long succession by a race of Tartar princes of the Chuug or Chugatay tribe, until the year 1586, when it was subdued by Acaar, more it is said through the aid of internal treachery, than by the force of his own arms. It remained annexed to the
Cashmer.

House of Timur for the space of 160 years, after which it was betrayed by the Mogul governor to Ahmed Shah Duranny, who formed it into a province of the Afghan empire. In this situation it is commonly placed under the authority of an individual deputy, commissioned by the sovereign, on the personal character of which individual, of course, a great deal will depend, as to the extent, at any time, both of its freedom and its happiness. The measure of either of these, at a late period, when the country was visited by European travellers, appears to have been far from being considerable.

The annual public revenue of Cashmere has differed at different periods, influenced no doubt by causes, which during the same times influenced, in one way or another, the general prosperity of the district, and the welfare of its inhabitants. In the time of Aurengzebe, only about L. 35,000 a-year were derived from it. During Shah Ivan's reign, the revenue of this province was no more than L. 25,000; and it was only L.20,000 in the time of Mahomed Shah. More recently, a revenue of between 20 and 30 lacks of rupees has been collected from it, of which a tribute of seven lacks is remitted to the treasury of the reigning prince. Unfortunately, in the case of a country circumstance as this is in respect to government, the amount of the revenue actually obtained from it at any time, is no adequate criterion of the measure, at the same time, of its prosperity. It appears that the great increase of revenue, which in later periods has been drawn from Cashmere, has been forced from it only by means of the most rigorous and oppressive extortion.

The military force of this district consists of about 3000 horse and foot, chiefly Afghans: the natives of the country are systematically excluded from it. From some examples that have been noticed, it would appear that these troops are very poorly, as well as irregularly, found in pay, insomuch as, upon occasions, to have been obliged to pick up, as they best could, a scanty subsistence from the spontaneous productions of the country.

The language of Cashmere is, by some writers, considered to be peculiar, and of very ancient date: others hold that it is derived from the Sanscrit. It resembles in sound that of the Maharrattas, but with more harshness; on which account, probably, it is that the inhabitants of this country have been accustomed to compose their songs in the Persic language, or have adopted those of the Persian poets. Notwithstanding the rugged character of their own speech, it is said that a taste for music is universal amongst all classes of the people of this province.

The Cashmerians are supposed to have a religion of their own, different from that of the Hindoos. Abul Fazil says, that the most respectable people of that country are the Keyshees, who, though they do not suffer themselves to be fettered by traditions, are doubtless true worshippers of God. It appeared to some who had travelled in those parts, that the inhabitants generally were extremely lax, in regard to matters of a religious kind, being ready to adopt any system, or none, as might best suit their particular interests, or as might be recommended to them by prevalent fashion. Yet, every where here, there occur the evidences of the force of superstition; the places of worship dedicated to Mahadeo, to Bishen, and to Droma, abounding throughout this sequestered spot, and great respect being paid to miraculous fountains, or other things or places esteemed holy.

Numbers of hermits have been observed in this quarter, who occupy places nearly inaccessible, and are highly venerated, some of them being supposed to have the power of exciting the fury of the elements, or to possess other supernatural or miraculous endowments.

The population of Cashmere is stated to be, in inhabit proportion to its extent, very considerable. The plains abound with inhabitants, as also, where they will admit of it, the declivities of the hills. The Cashmerians are stout, well formed, and as the natives of a country that lies so much within the range of the greater heats of the sun, may be considered a fair people. They have been praised, but apparently without adequate ground, for the fineness of their features, and for countenances rather European than of Tartarian aspect. Certainly these advantages are more subject to question, at least, than that which has been attributed to them in respect to the colour of their complexion. On the contrary, it would appear that the features, even of their females, are ordinarily broad, and that there prevails among them a coarseness of figure.

The dress of the people of Cashmere consists of a dress, large turban, a great woolen vest with wide sleeves, (under which people of the higher class wear a piran-hun, or shirt, and drawers,) and a sash, wrapped in many folds round the middle. The women of the higher class are never seen abroad, so that little can be said relative to their dress; but the external, and often only garment worn by those of the inferior orders, is of cotton, and shaped like a long loose shirt. Their principal, or only ornaments—an article in which indeed they do not much indulge—are introduced in the manner of dressing their hair. This people are generally gay and lively, and much addicted to pleasure, which inclination, though somewhat blunted, has not been wholly eradicated in them, even under the rigours of the Afghan government.

The prevailing character of the Cashmerians has been drawn by one who, at no very distant period, visited that country, in lineaments little honourable to them. He never knew, he says, a national body of men more impregnated with the principles of vice than the natives of Cashmere. He represents them as eager in the pursuit of wealth, ambitious in seeking aggrandisement, indifferent as to the means by which those objects of their desire may be attained; arrogant, on the one hand, and rapacious, and on the other ingenious in devising and multiplying modes of luxurious expense; deceitful and treacherous; with the cruelty of cowards; fickle in friendship, and implacable in enmity. In short, it would appear that the numerous train of despicable vices, usually called forth and kept alive in a state of slavery, are here exhibited in frightful deformity; and a land that nature formed for a terrestrial paradise, is, through the depravity of the inhabitants, converted into a scene which, instead of any of the more grateful sentiments of the human mind, is calculated only to excite a heart-felt pity, or a most mortifying and
CASHMERE, CACHMER, or CASHMIR, the capital of the above province, called also Sirinagur, and sometimes Nagaz, is situated in N. Lat. 34° 12', and E. Long, 73° 45'. Rennel places it in N. Lat. 33° 49', E. Long, 73° 11'. This city has been supposed, but there is reason to believe incorrectly, to be the same that is mentioned by Herodotus, under the name of Caspira, or Caspurs. That opinion has been sanctioned by D'Anville. Dr John Reinhold Forster, on the contrary, conceives the old Caspurs not to have been Cashmere, but a city lying nearer to Persia, perhaps Ghazna, or Ghazmin. (See Bartolome's Voyage to the East Indies.) It extends on both sides of the river Chelum for about the space of three miles, and the different parts of it thus disjoined are in some degree connected by four or five wooden bridges, which are here thrown over the river. The houses in this city are slightly built of brick and mortar, with which there is intermixed a large proportion of timber work. Many of them are two or three, some even four or more stories high. The usual manner in which the different parts of these houses are appropriated is this: the lower floor is occupied by the cattle, the second is inhabited by the family, and the third, and those above, are used as warehouses. On a standing roof of wood, there is laid a covering of fine earth, by means of which a defence is formed for them that is equally useful in every season. During the winter, it shelters the buildings from the great quantity of snow that falls at that period, and communicates an agreeable warmth. In the summer, it yields a refreshing coolness; and the tops of the houses being at the same time planted with a variety of flowers, exhibit at a distance the spacious view of a beautifully chequered parterre. This city enjoys many natural advantages. Besides that of a river, which flows through its centre, it is blessed with a mild salubrious air. There is a lake also which extends from the north-east quarter of the city, in an oval circumference of five or six miles, and which joins the Chelum by a narrow channel near the suburbs. This lake has been long noted for its beauties, and the pleasure which it affords to the inhabitants of the country. The citizens frequently go upon it in boats, having, many of them, for this purpose, a communication by little canals even between it and their own houses. They here enjoy the sport of pursuing the cranes or other birds which frequent the lake. Taken in connection with the adjacent and neighbouring grounds, the scene which is at the same time presented by it to their eyes, is at once rich in pleasing natural prospects, and exhibits the remains of many striking works of art. Towards the east, the Tucht Suliman, and the Hirncy Purvet, form the two sides of what may be called a grand portal to the lake. These are two hills, of which the one is sacred to the great King Solomon, who is revered in Cashmere as he who cleared this favoured valley of its excess of water; on the other, Muckdoom Salheb is honoured, to whom, on every important occasion, persons of all descriptions, and of both sexes, present their ear- nest, and often, it is said, successful vows. The northern view of the lake is terminated, at the distance of twelve miles, by a detached range of mountains which slope from the centre to each angle, and from the base of which a spacious plain, preserved in constant verdure by numerous streams, extends with an easy declivity to the margin of the water. In the centre of the plain, as it approaches the lake, there is a spacious garden, which appears to have been constructed by Shah Jehan, one of the Delhi emperors, during the period that this district was in the possession of the Moguls. This garden is abundantly stored with fruit trees and other flowering shrubs. Some of the rivulets which intersect the plain are led into a canal at the back of the garden, and flowing through its centre, or occasionally thrown into a variety of water works, form one of the chief beauties of the place. It is farther decorated by various elegant and commodious pieces of architecture, in the erection and distribution of which, the Mo- gul princes of India have displayed equally taste and magnificence. These buildings are said to have derived some of their ornaments from the spoils of a Hindoo temple. The other sides of the lake are occupied by gardens of an inferior description, two of which, however, that are the property of the go- vernment, the Baugh Nusseem, lying on the north- west, and Baugh Nishat, on the south-east quarter of the Shalimar, are deserving of notice for their lar- ger size and their agreeable appearance. The scene is farther ornamented by the numerous small islands which emerge from the waters of the lake. To the east of this pleasing spot, is the wreck of a fortified palace, erected by Amir Khan, a Persian, when go- vernor of Cashmere. He used to pass much of his time in this residence, which, was curiously adapted to the enjoyment of the various species of Asiatic luxury; but the materials of which it was built had been so un substantial, that within the space of not more than eight years from the period when it was erected, it could no longer with safety be inhabited. The environs of the town, in general, to the east and the west, are laid out in private gardens, which skirt the banks of the Chelum, or supplied with canals from the lake, afford to the inhabitants various pleasant retreats, and the several little hills that border upon the water, are decorated with villas, mosques, and pagodas, which, intermingled with trees and other forms of beautiful vegetation, pre- sent a prospect at once grateful to the eye, and high- ly pleasing to the imagination. Many of the houses in the city of Cashmere are large and commodious. No buildings, however, oc- cur particularly worthy of remark. The Cashme- rians, indeed, boast much of a wooden mosque, cal- led the Junah Mussid; * but its claim to distinction appears to be very moderate. The subahdar, or go-

* This is the appellation by which the principal place of prayer in Mahometan cities is usually distinguished.
C A S P I A N  S E A ,

A detached sea, or large lake of salt water in Asia. It is bounded towards the north, by the Russian province of Astracan and the Caucasus; and on the south, east, and west, by different provinces of Persia. It extends in length from north to south about 680 miles. It is nowhere more than 260 miles in breadth, varying between that of the CN and that of the Kaspius Sea. It is situated in latitude between 37° and 47° north, in longitude between 50° and 56° east. Its superficial contents have been estimated at somewhat above 36,000 square English miles. This sea has at different periods, and among different nations, been known by different names. By the ancient Greeks, it was distinguished by the appellation of the Hyrcanian, i.e. the Persian Sea. By the Tartars it is denominated Akdinghis, or the White Sea. By the Georgians, it is termed the Kurtshenskian Sea; and the Persians call it by the name of Gursen, from the old Persian capital Gurgan, which is said to have stood in the province of Astrabad, only seven versts from the sea.

We find the Caspian Sea noticed at a very early period by ancient writers. Herodotus, who lived in the 5th century A. C., mentions it in his works, and gives such a description of it as corresponds pretty nearly to what we know of its present state, particularly adverting to the circumstance of its having no apparent outlet, nor any visible connection with any of the great seas. “The Caspian,” says he, “is a sea by itself, unconnected with any other: its length is as much as a vessel can sail with oars in fifteen days, and its greatest breadth as much as it can sail in eight days. It is bounded, he adds, on the west by the Caucasus, and on the east by an immense plain, which extends beyond the reach of the eye.” Aristotle describes it in a manner similar to this, and with his usual precision contends, that it ought to be called a great lake, not a sea. With these writers also concurs Diodorus Siculus. But others of the ancient writers, and these commonly too of rather later date than those who have been named, have expressed themselves with respect to this sea in such a manner as would indicate, on their part, a more imperfect knowledge of it than had at periods so much earlier been attained. Strabo speaks of the Caspian as a bay that communicates with the great northern ocean, from which it issues at first by a narrow strait, and then expands into a sea, extending in breadth 500 stadia. With him Pomponius Mela agrees, and describes the strait by which the Caspian is connected with the ocean, as considerable in length, and in breadth so narrow, that it had the appearance of a river. Pliny gives a similar description of it. In the age of Justinian, this opinion concerning the communication of the Caspian Sea with the ocean, was still prevalent. Some of the writers, among whom is Quintus Curtius, seem to have considered the Caspian Sea to be connected with the Euxine. Arrian also, who, from his residence for some time in the province of Cappadocia as governor, might certainly have obtained more accurate information, declares in one place, that the origin of the Caspian Sea was still unknown, and expresses a doubt whether it was connected with the Euxine or with the great eastern ocean which surrounds India. Ptolemy maintains its communication with the Euxine, but this by a subterraneous passage, conceiving it to be impossible, without some supposition of this sort, to account for the flowing of so many rivers into it, while on the one hand, there is no appearance of any channel out from it, nor on the other any perceptible swelling of its water, except in the spring, when it is obviously occasioned only by the melting of the snow at that season. Indeed it has in all ages been found a problem of great difficulty to furnish any tolerable solution of the phenomena connected with the sea in question, both in respect to the circumstance just alluded to, and also as it appears in the character of a large sheet of water, possessing the distinguishing properties of sea-water, but disused and insulated completely, so far, at least, as is perceptible to any human eye, from all connection with the other portions of that widely extended fluid. The waters of the Volga, the Yaiek, the Yenbra, the Kur or Cyrus, the Araxes, the Bystria, the Akisa, the Koisa, the Terek, with many others generally of considerable, some of them rivers of very great magnitude, run into the Caspian Sea. What is, it is reasonable to inquire, becomes of all this water, which certainly cannot be evaporated by the sun alone so fast as it contributes to the enlargement of the body of this sea, and for which, however, there is no other apparent means of escape? And how, moreover, is it that we meet here, in an inland country, and even in the midst of deserts, with a sea detached from all others, yet possessing the same properties, and yielding similar productions? Perhaps the notion of a subterraneous passage is one, which, amidst these difficulties, would occur as naturally, and which really
might seem to offer as plausible a solution of them as any other. It has accordingly been strenuously asserted, both in ancient and in modern times, and various arguments have been adduced in support of it. Two of these are as follows: The Caspian, it has been observed, rises very high with a westerly wind, whereas the Euxine, on the contrary, rages most when the wind is at east. It has hence been inferred, that the east wind favours the exit of the waters of the Caspian, and the west wind impedes it. It has, in the second place, been alleged, that there is a whirlpool in a particular part of this sea, by which all its surging and restless water is, with a tremendous noise, discharged into the Euxine; and it has been asserted, that near to the mouth of the vortex, there is found a species of sea-weed, which grows only on the shores of the Caspian; that a sort of fish peculiar to the Euxine has been observed in the Caspian sea, near to the place of the supposed vortex; and lastly, that in former days, a fish was taken in that sea with a golden ring about its tail, on which was this inscription, "Mithridates habi dabit in urbe Sinope libertatem et hoc donum." But as to the first of these arguments, it is to be observed, that the connection attempted to be traced between the character and effects of particular winds and a subterranean communication between the Euxine and the Caspian seas, does not seem to rest upon any satisfactory grounds. In fact, it is known that all winds that bring with them humid vapours, are more stormy than those which proceed from arid regions; and this circumstance is plainly sufficient, without any reference to causes, the existence of which is unknown, to account for the greater agitation produced in the Caspian by winds coming towards it in the direction of the Euxine and the Palus Maeotis, than is caused by the eastern winds, which, in their approach to it, pass over a great extent only of dry, and even parched land. Of the whirlpool alluded to, it is enough to say, that we find no notice of it in the latest accounts we have relative to those parts. Sea-weed grows every where along the shores of this sea; but we know nothing of any particular description of this kind of plants which grows only there.* We would require also more particular information as to the fishes that are said to be found only in the Caspian and the Euxine seas. The story which Kircher, in his *Mundus Subterraneus*, introduces respecting the fish with the ring, is unworthy of notice.

It has likewise been conceived, that the concealed communication is between the Caspian sea and the Gulf of Persia; and in proof of this it has been alleged, that there were every year seen floating on the water in the vicinity of Ormus, a great quantity of willow leaves, of which kind of tree, those who make the remark say, that a great abundance grows in the environs of the Caspian, but none in the interior of Persia. The Tigris, however, it is known, receives a great number of rivers from the quarter of Kurdistan and the frontiers of Media, in which places this tree is sufficiently frequent. It occurs also about Bagdad, and perhaps also in the more southern part of Persia. And, were they supposed to be conveyed by the Dilia, or the little Zarb, these leaves would have a shorter course towards the place of their destination than that which is assigned to them.

The phenomena of the Caspian Sea have likewise been ascribed to the quality of the bottom, which consists not of a thick slime but of a shell sand, the particles of which, touching only in few points, render it very porous. The whole shore nearly is formed of a similar substance, which layer upon layer, lies here to the depth of three fathoms. Through this sand, it has been alleged that the water is filtered, and falls into the abyss beneath in the same quantity which flows into the sea. In the bay of Emba, it is added, above the river Yaik, the water is not let through, the consequence of which is, that it stagnates in that particular part of the lake, even the fishes putrefying, and the exhalations being extremely noxious.

It has been observed, that the districts extending in different directions from the Caspian are sandy and saline, and present the same shells that are found in the channel of that sea, but which, at the same time, are of a very different character from those met with in the beds of the rivers, that did formerly, or do now, run in those parts. Sea salt also occurs in the same tracts, in beds of great depth, and in such quantity as to prevent all vegetation, besides that of marine plants. Salt marshes are another distinguishing feature in this quarter; and, generally, from the appearance of the ground here, the small degree of its elevation, and the nature of the substances which either form the constituent parts of the prevalent soil, or present themselves in a more occasional manner in or upon it, there seems reason to infer, that that sea at one period reached beyond the limits within which it is at present contained. The conclusion to which we are naturally led by these appearances, coincides, at the same time, with the results of certain historical notices which have been transmitted to us, as well as with what we know of the determination of ancient geographers respecting the position and the boundaries of this sea. Thus Ptolemy, it is known, gave to it an extent of 23\(\frac{1}{2}\) degrees, from west to cast, and made it advance 3° more to the north than it does at present; and, in the Byzantine historians, we find mention made of an extensive marsh, that even in the fifth century occupied a large portion of the tract of ground which lies to the north of Caucasus, and between the Caspian sea on the one hand, on the other the Euxine. Hence it appears probable, that in remote times, long prior to the era of our most ancient historical details, the Caspian Sea extended, in a north-west direction, beyond the Martysh and the Sarpa; towards the north, over all the plains that are watered by the Volga, the Yaik, and the Emba; that it was united to the lake of Aral; and that it covered a part of the plains of Great Tartary. These suppositions being admitted, it may, in connection with them, be allowed, that in the time of Ptolemy the Caspian Sea had an extent somewhat greater than it has at present, though certainly not so

* Amongst the sea-weed of this quarter there occurs in some parts a great profusion of the plants proper for the manufacture of soda, an object which might be attended to here with much advantage. Pallas's *Travels*, vol. I. p. 293.
notwithstanding the early attention which this sea seems to have received, it does not yet appear, that any of the ancient authors, that have been named, or others who have left any statements relative to it, succeeded in determining even nearly its true form and extent. It was not apparently even ascertained whether its greatest length was from north to south, or from east to west. So much, indeed, was this point misunderstood, that, in the ancient maps which illustrate the geography of Ptolemy, it is delineated as in modern times, the first considerable information obtained in Europe concerning the true form of the Caspian, was furnished by Anthony Jenkinson, an English merchant, who, with a caravan from Russia, travelled along a considerable part of its coast in the year 1558. The accuracy of his description was confirmed by an actual survey of that sea, made by order of Peter the Great, A.D. 1718, when it was found to be in length about 1100 versts from the mouth of the Ural to the coast of Mazanderan: its greatest width, from the mouth of the Terek to the extremity of the bay of Mervol Kulyuk, being 8°, rather more than 700 versts; and the measurement in other situations more to the southward varying with the position; in one place it was found to be 6°, or somewhat more than 525 versts; in another it was 2° 35', or 225 versts. The circumference of the sea, comprehending the great gulfs, but excluding the little sinuosities, is stated at 4180 versts. Whatever may be, in other respects, concluded concerning the ancient limits of the Caspian, it will at least hardly admit of doubt, that the chain of mountains which branches from the west of the Ural to the north of Orenburg, and reaches to the Volga, must in all ages have restricted it towards the north.

In an eastern direction, the elevated level which now presents itself between this sea and the Aral, may have taken its rise from the quantity of sand rolled down by the Gihon, the Sirr, and other rivers that still flow into the latter sea.

Of the coasts of the Caspian as they now stand, Coasts, the following is a very brief and general delineation. Towards the north, from the river Terek, in a westerly direction, as far as the eastern extremity of the bay of Mervol Kulyuk; the shores are low, flat, swampy, and overgrown with reeds; the water, too, is shallow, and the air, being generally hazy, it may be difficult often for those who have occasion to navigate this part of the sea, to distinguish clearly the places, by which, as a sort of landmarks, it would be useful for them to direct their progress. On the other shores, from the Terek to the desert of Korgan, near Astrabad, and from the northern part of the bay of Balkan to that of Mervol Kulyuk, the country generally is mountainous, the shores bold, and the water very deep; so much so, indeed, that even in the vicinity of the shore a distance of 500 fathoms will not reach to the bottom.

The ports of the Caspian Sea may be divided into Potsa, the Russian, the Persian, and the Tartar ports.

The Russian are, I. Astracan, (a full account of which has already been given under that word.) The principal of the commodities that are forwarded from Astracan to the ports of the Caspian Sea, are Dutch, French, Silesian, and English cloths, vi- triol, soap, alum, sugar, Russian leather and linens, needles, velvet, glass-ware, paper, a few furs, hides, a little tea, corn, butter, wine, brandy, wooden vessels for household uses, sea-horse teeth, iron, copper, tin, lead, iron-ware, clocks, indigo, cochineal, looking-glasses, and cotton stuffs. The most considerable articles of its importation, are silk, chiefly in a raw state, from Shirvan and Ghilan, lamb skins from Bucharia, rice, dried fruits, coffee, wine, spices, saffron, drugs, a little salt, sulphur, and naphtha. The Indians, and the merchants of Khiva, bring to it occasionally, also gold and silver in ingots and bars, gold-dust, precious stones, and pearls.\(^1\)--The second of the Russian ports is Gurief, which is situated at the exit of the Ural, and near to a bay which occurs in that part of the Caspian. There is here a strong fortress, by which the frontiers of the empire are guarded in the direction of the territory of the Kirghes Tartara. There are in the town scarcely 100 houses. Besides the garrison, almost the only inhabitants are a few Armenian merchants from Astracan.

---

\(^1\) In 1773, the value of the cloth sent from this port to those of the Caspian amounted to L. 32,600, the cochineal to L. 15,600, and the indigo to L. 7000. The amount of the imports, in raw and manufactured silks, chiefly the former, is stated at L. 43,840.

---

* Professor Pallas considers the actual junction between the Caspian and the Euxine Sea to have been formed by a strait, which communicated on each side with the anciently extended limits of those seas. "It is very probable," says he, "nay almost beyond a doubt, that the low counties of Ulugam-Ternik, Albuga, and Byloe, are the old bed of the strait, which, agreeably to the hypothesis advanced in the third part of my former journey, united the Caspian Sea with that of Azof. Even at this day the Caspian Sea, when swelled by tempests, easily overflows the extensive low countries before mentioned. The sand hills which at present separate these low countries from the Manysh, manifestly originate from the sand banks thrown up by the Caspian Sea, and which are carried by the wind into the steppes; or, perhaps, they were in some degree formed by the sand that remained in the strait itself, as they occupy only a small tract between the two valleys. These sands have also choked up the passage at the mouth of the large river Kunia, which formerly had a free current into the Caspian Sea, by the gulf of the same name." Pallas's Travels through the Southern Provinces of the Russian Empire, in the years 1793 and 1794, vol. 1, p. 296; see also p. 302.
The Persian havens are, 1. Derbent, in the province of Shirivan. Owing to the rocks and shoals that prevail in this quarter, vessels can rarely approach the shore, but are obliged to lie at anchor 2 or 3 miles off. On this account, not more than 3 or 4 Russian ships come annually to this place, which are usually laden with oats and rye, bringing with them likewise iron, steel, and lead, for the Lesgehes, and other Tartarean nations dwelling on the eastern chain of the Caucasus. There is here a fortress surrounded by high brick walls. The inhabitants are chiefly Persians, Tartars, and a few Armenians. A little corn is produced in the neighbourhood, but not in sufficient quantity to answer to the consumption. It is asserted, that a peculiar sort of grass grows between this place and Terek, on which all the quadrupeds feed with avidity, and that to the horse alone the eating of it is fatal. The town of Derbent lays claim to a high antiquity, a part of it, as is alleged, having been built by Alexander the Great.—2. Niesovaia Pristan, or Nizebad, in the same province, is a port that was formerly much frequented by the Russians. The merchants, particularly from Shamachie, come hither in great numbers with European commodities, to supply the surrounding country. Near to the harbour there are several wretched villages.—3. Baku is reckoned the safest, if not indeed the only proper harbour of the Caspian. Ships may lie here at anchor in seven fathoms water. In some places, however, the entrance is dangerous, on account of shallows, islands, and sand banks. The fortress is of a similar construction with that of Derbent. The inhabitants of this place are Persians, Tartars, and a few Armenian merchants. The trade here is not considerable, and chiefly centres in the neighbouring districts. The principal articles of export by which its traffic is supported, are the naphtha and the fine rock salt, both of which are obtained from mines on the east of the bay. Saffron and cotton are cultivated by the inhabitants, but not with any considerable advantage. It is supplied with raw silk and silk stuffs from Shamachie, an inland town, and the capital of this province of Shirvan, which is situated from Baku, one also of its towns, at the distance of only 66 miles. It was to the silk trade that Shamachie owed its former commercial importance, and by the same means it is still preserved from ruin, though its traffic has been greatly reduced, in consequence of the exorbitant exactions of the khans of Kuba, and, in the same proportion, the numbers of its inhabitants diminished, and the manufactures of the place even within a short time have greatly degenerated. Baku is usually the residence of a Russian consul.—4. Ei- nizelle, though the most frequented by the Persian trading vessels of all the ports of this sea, is yet but a most wretched place. An entrance into its bay, was formerly found through a particular channel which communicated with the sea, but that passage having been obstructed by an accumulation of sand, the vessels which now come hither must remain at anchor in the road. Einizelle, situated on the south-west coast of the Caspian, consists of an old and new town, the former inhabited by Persians, and the Armenians subject to the jurisdiction of the sophi; the other by Russian merchants, and such Armenians as acknowledge the authority of the Russian government. A Russian consul resides here, who has under him a garison of 30 soldiers; and the Russians trade to this port to great advantage. It is happy in its position, as it lies in the province of Ghilan, the district the most noted for those articles, which have always been chiefly in request with the traders who have engaged in the commerce of these parts, silk, viz, and silk stuffs. Commodities go from hence to Reshd, through which a supply of European goods is thus furnished to the bordering provinces of Persia, and the neighbouring independent states as far as Georgia. The remaining part of the supply for those more northern states, is derived immediately from Astracan, through Kitzljar and Mosdok. A portion is also sent from Shamachie, for the use of the Lesgehe Tartars, and other independent tribes in that vicinity. In the town of Einizelle, there are churches belonging to the Russians and the Armenians, and about 300 houses formed mostly of reed. It is the refuse only of the Persian and European commodities that is sold here. The great mart in this quarter is Reshd, where there is a concourse of merchants from Tauris, and the principal cities of Persia, Armenia, and Turkey, for the purchase of these, and of the raw silk and the manufactures of Ghilan. Here, accordingly, the Russians dispose very advantageously of their European commodities, obtaining in return for them the rich productions of this province, which are esteemed the best of their kinds in Persia, and which for the last 60 years have been in such reputation, that Reshd is become one of the first commercial towns in this part of Asia. The finest sort of the silk of this province is usually white, and is chiefly sent to the inland cities of Persia, or is sold to the Turks. The inferior kind is yellow, and is principally disposed of among the Russians. From the great and constant demand for these silks, their price has for some time past been rising every year.—5. Farbat, and 6. Medahetizar, on the southern coast, in the province of Mazanderan, are mere villages. In the latter, however, a considerable trade was for some time carried on, owing to its vicinity to Balfrash, the chief town of the province, whither the Russians and
the Armenians were accustomed to bring their wares. This traffic has suffered a diminution, in consequence of the impositions of the khans of the province. Yet the port continues to be in some degree frequented, as well by the Russian merchants as by others from Kiskan, Isphahan, Scheeraz, Khorasan, &c., who bring with them the Persian and Indian products. From this province itself there is exported silk, much however inferior in quality to that of Ghilan; also large quantities of rice and cotton.—7. The bay of Astrabat, whence the Russians are accustomed to proceed in the prosecution of their mercantile business to the capital town of the same name. The products of the province of Astrabat, with its exports and imports, are nearly the same with those of Mazanderan. Astrabat trades mostly with Canda- har. As to the roads, generally of the southern coast of the Caspian, it may be observed, that, though they afford good clean anchoring ground, and in a sufficient depth of water, yet they are in this respect disagreeable, that they are so much exposed to heavy swellings of the sea, occasioned chiefly by the prevalence of the westerly winds. Few, if any of the ports of this sea, are altogether exempted from the like inconveniences. The Tartarian ports are 1. The Balkanskiy bay, and, 2. Mangushak, both of which are situated on the eastern part of the Caspian, and which both, particularly the latter, have pretty secure roadsteads. The Russians visit the islands in the Balkanskiy bay, which are mostly inhabited by pirates of the race of Turkoman Tarts. They yield rice and cotton. One of them, also named from that circumstance, Naphthonia, furnishes a great quantity of naphtha. The commerce of Mangushak is more considerable. To it the neighbouring Tartars bring the products of their own country and also those of Bugaria, such as cotton, yarn, stuffs, furs, hides, rhubarb &c.

In consequence of the manner in which the Caspian Sea is inclosed on all sides by land, and its banks being so much in the vicinity of very high mountains, its navigation is, in some measure, necessarily of a peculiar kind. Certain winds dominate over it with such absolute sway, that vessels are often deprived of every resource; and of all the ports that have been enumerated, or if there are any other that occur throughout the whole extent of this sea, there is among them all hardly one that can be called perfectly safe. There are no tides in the Caspian, but strong currents prevail in it, which, uniting their influence with that of the violent storms of wind so frequent here, and indeed common in some measure to this, with all other inland seas, occasion not a little difficulty and danger to the description of vessels which principally frequent its, and perplex and incommode extremely the rude and untutored sailors of the countries to which it is principally useful as a channel for their trade. These difficulties and inconveniences are farther increased, in consequence of the incredible numbers of shoals and small islands.

The vessels which frequent this sea, are commonly of rude construction, without decks, of such magnitude only as to draw from 9 to 10 feet of water, and carried forward by means of a single square sail, or by that with the addition sometimes of top sails. The long flat-bottomed craft which, among the Russians, have now taken place of the circular kind of vessels, that, at an earlier period, navigated this sea, are, in all their necessary appendages, more noted for a clumsy strength, than for any ingenuity in the mode of their formation. The vessels belonging to the Persians are commonly made of elm, which abound in their provinces southward of the Caspian; the sails are of cotton, the cables of flax, and some of the bark of trees. They have others of a somewhat different structure, and of larger dimensions, of the burden perhaps of 30 to 40 tons; known by the name of sandalls, but which, notwithstanding the great attention directed in the manner of building them to the points of long duration and usefulness, are seldom in condition to keep the sea for more than 4 or 5 years. The most really serviceable, and indeed the most esteemed part of the Persian marine in this sea, seems to consist in the small boats called kirijens, with which their necessary business in the different parts of the same, or in immediately contiguous districts, but, as may be easily supposed, nothing requiring a progress to any considerable distance, is conducted with sufficient economy and dispatch. The ship-builders of Persia are chiefly deserters from Russia; and from the number of shipwrecks which take place, as well as from the timidity and awkwardness with which every thing relating to the management of the vessels of this country while at sea is conducted, it would be well, that, unskilful as the Russians themselves are in this department, the navigation of these vessels were also placed in the same hands.

Of the provinces which surround and immediately border upon the Caspian Sea, those most towards the north are the kingdom of Astracan, and the territory of the Calkmucks; whence proceeding by the west of it, round towards the same point, there occur the possessions of the Lesgee Tartars, Shirvan, the Mogan-plains, Talish, Ghilan, Mazanderan, Astrabat, the Korgan desert, and other similar tracts, occupied or frequented chiefly by the Turkomans, or other tribes of independent Tartars, closing with the territory of the Kharakhupack, and of the Y'ik Cossacks. The information obtained by travellers respecting these districts of country, is scanty and uninteresting, and will be given in another part of our work. On the banks of the Volga towards the north, chiefly in the province of Casan, there are large tracts of forest ground, which supply a sufficiency of oak and other timber for the construction of vessels, as well to be employed on that river itself, as to be engaged in the commerce of the Caspian Sea. Good timber for the same purpose is also found in Ghilan and the adjacent provinces subject to Persia; and iron ore might be obtained from Mazanderan. The country all round this sea, where not in the state of a desert, is very fertile in grain, fruits, and other productions, which are to the people dwelling in those parts the subjects of a lucrative commerce.

The water in the vicinity of the Caspian is frequently brackish; but here and there along its coasts, or in the islands which rise out from it, the vessels, by which it is frequented, may be supplied with water better fitted for use. In Hanway's Account of the British Trade over the Caspian, there will be found a jour-
Rivers.

The Caspian Sea, as has been already remarked, is the receptacle of many large rivers. The Emba, the Urula or Yalta, and the Volga, run into it from the north; the Kuma, Terek, Kuri, and Kizil Ozen from the west; those which it receives from the south are inconsiderable; but from the east it is supposed still to receive the Tedjen. Other rivers were understood formerly to disembogue themselves into it, some of which do not now exist; such are the Jaxartes and the Oxus, which are said to have flowed into it in ancient times, the latter particularly by one or two branches, till it afterwards bent northwards, and joined the sea of Aral.* It is probably owing to the great influx of river water into this sea, as well as to the nature of its bottom, that its water, particularly near to the shore, is so generally very turbid and impure. To the same circumstance it must be attributed, that though the taste of this water is salt, yet the proportion of salt found to be actually contained in any given quantity of it is comparatively inconsiderable. The degree of its saltness is said likewise to vary, not only with the depth, and according to the nearness to the shore, but also with the variation of the winds. Besides the salt and bitter taste common to it with all sea water, it has been observed, that the water of the Caspian has a certain peculiar taste quite distinct, and which affects the tongue with an impression similar to that made by the bile of animals. The degree in which this taste is perceptible at different periods is said, as in the other case just alluded to, to vary with the direction of the winds; and it has been attributed to the springs of naphtha, or other mineral or combustible substances, lying in the tract between Derbent and Baku, towards the west, or in the islands in the bay of Balkhan. Whether there is any plausibility in this notion or not, there is at least no doubt that the substances mentioned are found in and form a valuable production of these parts. Glauber salt, which is so intimately connected with naphtha in its nature and origin, is also observed to be a constituent in the water of the Caspian, as well as to enter into the composition of the saline earth, that is found in such quantity in efflorescence along its coasts. In particular situations, it is dug out of mines, which occur also in the same vicinity.

Much has been written respecting supposed periodical risings and fallings of the water of the Caspian; and it has been represented as a striking peculiarity, that for the space of thirty or thirty-five years its waters are constantly increasing, and then for the same term continually decrease. It has also been remarked, that, in proportion to the extent of this sea, the variety of its productions is by no means considerable. This has been attributed, and apparently with justice, to its want of communication with the ocean, which is thus precluded from imparting to it of its inexhaustible stores. But of the animals which this sea nourishes, the greater part are of very valuable kinds; and they multiply to such a degree, as to be a never failing source of profit and wealth to those of the contiguous nations, that are in a condition to turn them to account. Salt, Produc-

* The Jaxartes is the Syr-Daria that falls into the Aral. The Oxus is the Ula, or the Amu-Daria, connected also with the same sea. See D'Anville; Muller; Dictionnaire Geographique de Flandiniier, art. Aral; and the general charts of the Academy of Petersburg.
four species of cockle, the common muscle, some species of snails, and one or two others. This sea is much frequented by birds of various kinds. Those most commonly seen in its vicinity are storks, herons, bitterns, spoonbills, red geese, red ducks, and the like. The most beautiful of these is what is called the red goose, which, however, contrary to what is suggested by the name, is for the greater part white, having only the tips of the wings, the orbits of the eyes, the beak, and the feet of a scarlet colour. It is about the size of a stork, with long neck and legs, and, though it lives on fish, is very savoury to the taste. The same in this respect is the character of a species of wild ducks, which is also frequent in these parts, and which is noted for the sort of noisy concert that they perform in the evenings, on the tops of the trees or the roofs of houses. Other birds, properly aquatic, that occur here, are the crested diver, the pelican, the cormorant, and almost every species of gull. Two kinds of leeches are found in this sea, the hog-leech and the dog-leech. The lurking places of these creatures have two apertures, one towards the south, the other towards the north, which they open and shut according to the changes of the wind.

Alexander the Great, with that attention which he was so ready to bestow upon whatever might be useful to commerce, gave, a short time before his death, directions to fit out a squadron in this sea, in order to survey it, and to discover whether it was connected either with the Euxine, or with the Indian Ocean. Seleucus Nicator, also, the first and most sagacious of the Syrian kings, at the time when he was assassinated, entertained thoughts of forming a junction between the Caspian and the Euxine seas by a canal, and of thus extending the trade of his subjects in Europe, and supplying all the countries in the north of Asia, on the coast of the Euxine Sea, as well as many of those which stretch eastward from the Caspian, with the productions of India. And many ages afterwards, under the auspices of Peter the Great of Russia, a canal was made at Vishnelt-Volotschk, by means of which a passage is had from the Caspian into the Volga, and thence, in conjunction with some rivers and lakes, into the Neva, and so into the Baltic. As to the actual commerce of this sea, ancient or modern, it is to be observed, that the maritime trade between the east and the west, which in every age has contributed so much to the opulence and power of the nations that have been fortunate enough to obtain the possession of it, was, in ancient times, long monopolized by Egypt, a country which, from its early and continued attention to naval affairs, had formed a powerful fleet, and obtained such a decided command of the sea, that it would have been vain for any other state to attempt to rival it in this trade. The Persians, in the mean time, though they had no intercourse by sea with India, yet being desirous to acquire a share in the valuable productions and elegant manufactures of that country, had then conveyed to all parts of their dominion by land-carriage. The part of these commodities destined for the supply of the northern provinces was transported on camels, from the banks of the Indus to those of the Oxus, down the stream of which they were forwarded to the Caspian Sea, and distributed through various channels over the different districts, bounded on one hand by that sea, on the other by the Euxine. The part of them intended for the southern and interior provinces, proceeded by land from the Caspian gates to some of the great rivers, by which they were circulated through every part of the country. While thus, however, in the several channels which they had respectively appropriated, the sovereigns and subjects of different states laboured with ardour and emulation to secure as far as possible to themselves the advantages of the trade with India, the power and consequence of them all was eventually swallowed up and lost under the devouring ambition and rapidly extending dominion of the Romans.

From that period, we hear little for many ages of any commerce, or other proceedings upon the Caspian. But in modern times, the Venetians and Genoese, as early as the 14th century, had begun to transport, by way of this sea, the Indian, Persian, and Arabian commodities with which they supplied the southern parts of Europe, through Astracan, to their magazines at Azof and Caffa. From Astracan, the goods were conveyed up the Volga, then by land to the Don, and afterwards forwarded down that river to Azof. The northern part of the European continent was, during the same period, likewise supplied with those Asiatic goods, which were sent by the Russian traders over Astracan, to their principal magazine at Wisby, a Hanseatic town in the isle of Gothland. Towards the end of the century, in consequence of the devastations produced by the wars of Timur, a transfer took place of this trade from Astracan to Smyrna and Aleppo; and the Arabian commerce, for which, in fact, these places lay more convenient, never returned thither, though a part of the Persian traffic was afterwards restored to its old channel. While the provinces of Casan and Astracan remained under the government of the Tartars, the camp of the khan was a mart for the Russian and Persian merchants; and as, agreeably to the customs of that people, the site of their camp was often changed, Astracan and Terek became at length two principal places of resort. This commerce, frequently obstructed and interrupted by numerous banditti, was, however, precarious until the conquest of Casan and Astracan by the Russians, opened a ready communication between Moscow and the Caspian Sea; and then Ivan Vassiliwitch II. having garrisoned Astracan with troops, rendered it the chief emporium of the eastern trade. This conquest having been effected previously to the end of the year 1554, soon after the discovery of Archangel, the English about that period obtained the czar's permission to pass through his dominions into Persia, and to carry on an exclusive trade over the Caspian. In 1558, Jenkinson accordingly, the first Englishman who navigated that sea, landed at Mangushlak upon the eastern shore, passed by land through the country of the Turcoman Tartars to Bokhara, capital of Great Bucharia, and returned to Moscow in the following year. In 1561, he again sailed over the Caspian, and proceeding to the coast of Shirvan, went by land to Casbin, and obtained from the Sophi permission to trade into Persia. Si-
milar expeditions were set on foot and conducted into the same parts by other merchants. The last of these was that under Christopher Burroughs, which was attended with many dangers; his ship being finally shattered by the ice in the mouth of the Volga, while the crew with difficulty escaped, and at length arrived at Astracan. Hitherto this traffic had been chiefly confined to the ports of Tumen, Derbent, Baku, and the coast of Ghilan; and having been much impeded by the banditti that frequent the shores of the Caspian, as well as by the wars which then prevailed between the Turks and the Persians, no English vessel during all that period, nor even for more than a century afterwards, ever appeared upon that sea. Indeed, for much the greater part of that time, the trade may be considered to have been altogether extinct; and no idea ever appears to have been entertained of its revival, till at length Peter I. having subdued the northern provinces of Persia, endeavoured to induce the English to engage anew in this commerce. The many unsuccessful attempts, however, that had been made in that department since the 16th century, and in which large sums had been lost, deterred them from entering into the views of that monarch; and so little, from various causes, chiefly the unwholesomeness of their climate, appeared now to be the advantage of possessing provinces which, at the time of their acquisition, seemed to promise very beneficial results, that, in consideration of obtaining the liberty of import and export duty free in all the harbours of the Caspian, with some other minor advantages, the empress Anne at length agreed to relinquish these provinces to Nadir Shah. Russia then gained more from them by trade, than before through the conquest and the possession of them; encouraged by which favourable appearance, as well as induced by other considerations, Captain Elton, an Englishman in the Russian service, renewed the project of instituting a British trade over the Caspian. Influenced by his persuasion, the British merchants of St Petersburg turned their attention to this commerce. A vessel was built for the navigation of the Caspian. It was loaded with the goods considered to be the best adapted for the Persian market; and in fine, a factory was established at Reshd, in the province of Ghilan. Even, however, in the outset, the symptoms appeared of an inauspicious jealousy, and a tendency to disagreement among those who were to be concerned in this traffic; and eventually, in consequence as well of disputes among the English themselves, as between them and the Russians, and at the same time, probably moved by views of ambition, Elton entered into the service of Nadir Shah, and assisted in constructing vessels, by means of which the Persian court seems to have entertained the idea of establishing their own supremacy on this sea. This proceeding reasonably gave umbrage to the court of St Petersburg, and Elizabeth, in 1746, withdrew her permission to the English merchants of passing through her dominions, on account of the Caspian commerce. On the death of Nadir Shah, who had for some time permitted the English to trade to Persia, their factory was pillaged, and their commerce annihilated. Elton, after various vicissitudes of fortune under those who, amidst the troubles which now began to prevail in this state, followed each other in rapid succession as the heads of its government, at length by a violent and premature death, paid the forfeit, either of his imprudence or of his crimes. The Russians, profiting by the loss of the English in this quarter, received no small advantage from the models which they left them, and from learning of them in those parts, as they had before done in St Petersburg, the use of the best materials for shipbuilding.

Considerably before this period, indeed, the natives of that country had entered into, and were now proceeding with no very unequal steps in the track opened by our merchants. Under Alexey Michaelovitch, Astracan became the centre of the Persian trade, to which place there resorted merchants from Bucharia, Crim Tartary, Persia, and even India. The vessels of the Russians, as has been already remarked, being rudely framed, without decks, and consequently exposed to frequent shipwrecks, the czar drew from Amsterdam several ship-builders, for the purpose of constructing others more calculated to weather the storms of the Caspian sea. His designs of improvement, however, were frustrated, in consequence of the rebellion of the Cossacks of the Don under Stenko Razin, and the devastations occasioned by it; and in fine, the trade of Russia was for the present annihilated. When this revolt was quelled, the greater part of the commerce of the Caspian fell into the hands of the Armenian merchants established in Astracan, who settled factories in both the Russian and Persian territories. During this whole period, neither the Russian nor the Armenian traders had, for the most part, penetrated farther than Niezabad, and their chief settlement was at Shamachie, till the year 1711, when that town, having been taken by the Leisges, the factory was destroyed. In 1721, Peter I. having obtained, as has been stated, the cession of the provinces of Dagestan, Shurva, Ghilan, and Mazanderan, the commerce was renewed. He established a Russian mercantile company trading to the Caspian, with a capital of 400 achins, or shares, of the value each of 150 rubles, or £30. The chief settlements were formed at Astracan and Kislar; but the right of property in those distant provinces having been resigned in the manner mentioned, the Russian merchants still retaining their exclusive privilege, now obtained the liberty of trading without payment of any duty to all the havens of the Caspian, and were allowed to build houses and magazines, subject to the single condition of obedience to the laws of the country. The benefit of the monopoly, with the other advantages enjoyed by this company, were confirmed to them by Anne and Elizabeth. Yet the commerce continued considerable till, in 1762, Catharine II. abolished their exclusive privileges, and permitted for the future all her subjects, without exception, to take part in the Persian trade. On account of the numerous banditti that infest the roads, she at the same time prohibited the inland traffic from Kislar and the other Caspian ports to Shamachie. For the benefit of the legitimate and authorised trade, two Russian consuls have their residence statedly at Baku and at Einzelles. By degrees, the Russian trade on the Caspian rose to considerable consequence; it has, however, been a
good deal injured by means of a contraband trade carried on in Shamachie and other inland Persian towns by the Armenian merchants, who, from their knowledge of the country and language, and from the terms on which, with these aids, they can make their purchases, have it in their power to undersell the Russians, in the parts which they severally frequent. Yet upon the whole, and owing chiefly to the various useful regulations introduced by the late empress, instead of the declining state into which it had for some time fallen, it has of late increased so much, that within the space of fifteen years, the average sum of the exports and the imports by the way of this sea, have been nearly tripled. The following is a general view of the state of this trade for several considerably distant years in the latter part of the last century. In 1760, the amount of the exports was £66,100, of the imports, £42,000, in all £78,100; with a balance against Russia of £6000. In 1768, the exports were £87,700, the imports £63,700; the amount of the whole, £151,400. Balance in favour of Russia £6000. In 1775, the sum of the exports was £125,400, of the imports £64,120; giving a total amount of £189,520, to which is to be added the farther sum of £10,000 for the traffic of Georgia and the nations of the Caucasus, making the whole sum £199,520; the balance, in respect to the part of this sum stated under the distinct heads of exports and imports, being in favour of Russia £61,280. In these statements, it is to be understood, that no account is made of the contraband trade, the amount of which is also considerable.

The marine of the Caspian Sea at present, consists of two frigates of 12 guns each, two cutters, and a transport. There are besides fifty-six merchant vessels, viz. a pink, a transport, five galliots of about 50 lasts burthen each, and forty-eight schooners from 10 to 30 or 40, and one of 60 lasts. There are moreover 138 roshivens, or flat-bottomed vessels, employed in fishing and taking seals, or in the Mankishlak trade with the Tukhmenes and Boukharians.

The fishery on the Caspian is the most important branch of this business in Russia. Not only does this sea abound with most valuable kinds of fish; but it is so commodiously situated in the centre of the empire, it has so much the advantage of easy communications by water, and the trade is prosecuted in so good a method, that nowhere in the empire is so much benefit obtained in this department, in respect either of internal consumption or of commerce. In fact, according to the observation of Pallas, the fishery on the Caspian is, in some views, as important to Russia as the herring, the cod, and the whale fisheries are to other maritime powers of Europe. That fishery on the northern shores of this sea is partly let out to Astracan merchants, whose great opulence is chiefly founded on it, and partly, in virtue of ancient privileges, belongs to the Uralian Cossacs, who claim this right, not only on the river Ural, but also for a space of 47 miles on each side of it. There are three principal seasons in which the fishing on the Caspian is prosecuted; the spring, the autumn, and the winter. As the sea is usually free from ice towards the latter end of March, the spring fishing usually begins immediately with the beginning of April. The business is usually undertaken by several contractors, each of whom has his particular station, or vataga, in a separate place, which commonly bears the name of the proprietor. At these vatagas, the kinds of fish that principally engage attention, are the several kinds of sturgeon, that properly so called, also the beluga and the sevruga. Shads and barbels are in an inferior degree likewise objects of request. The other smaller species of fish, which are found by a different class of adventurers to be well worthy of their care, are by those concerned in the greater fisheries disregarded. Each vataga prepared for the prosecution of this trade is occupied by from 50 to 80, or even 120 men, most of whom carry on a separate trade; there are also pilots, fishermen, salters, preparers of isinglass and caviare, and others. They have severally their small vessels of various dimensions and constructions, for the convenience of going out occasionally to sea; with a galliot for fetching provisions and salt from Astracan, and for sending away the fish that have been taken. Adjacent to the buildings for the accommodation of the people employed, several sheds are erected, where the roes are prepared, the isinglass dried, and the stock of fish properly kept. For preserving the salted fish, deep and well-secured ice-cellar of considerable magnitude are dug under ground, which are floored with thick deals, and have large reservoirs lined with planks, in which the fresh fish are pickled in a strong brine. At the two sides of these brine vats, are parts divided off, in which the fish, on being taken out of the pickle, are placed in layers and sprinkled with salt; behind the compartments in which the fish are thus laid, the space to the side of the cellar is rammed full of ice, for the better preservation of this easily perishable commodity. The distance of one vataga from another is indefinite; as are also, in some degree, the bounds in which neighbouring vatagas may fish. The taxes paid by these vatagas to the crown are rated by their quantities of prepared roes and isinglass; for every pound of isinglass five rubles, and for a pound of roes two rubles eighty copecks being paid into the caisse.

About the beginning of the fishing season in spring, myriads of little fish are observed pressing towards the shore, of which the ola particularly, a sort of scale-fish, is caught and kept alive in wells to serve the purpose of baiting the hooks, during the continuance of the season. This little fry is followed by prodigious swarms of ravenous belugas; the time for the capture of which is seldom longer than two full weeks; on which account the fishermen are obliged, during that period, to work day and night. In good years a vessel, while the swarming lasts, may within 24 hours bring up 50 or more of these large fish. The manner of taking them is by means of a machine, consisting of a rope 70 ells in length, to which there are attached 125 lines, each 1½ fathom long, with as many large angling hooks. This rope, with the number of hooks mentioned, is technically termed a nest; and 30 of these nests tied together commonly belong to a machine, which is therefore several hundred fathoms in length. Between every two nests there is tied a stone of some pounds weight: the two ends of a whole machine are furnished with wooden anchors; and generally the adjustments are in all re-
spects such that it may not easily be removed out of its place, and that no fish, when once caught, may have it in its power to escape. After they have been laid, these machines are visited twice in the day; the hooks are cautiously taken up along the rope; and a cord being passed through the gills of the fish caught, they are let down again into the water, in order that they may be brought on shore alive. They are now dragged with hooks to the beach, which is laid with planks, and are cut up in the following order: the lower part of the stomach, with the guts, are thrown away; the fleshy gutlet is salted for eating; the roe, which lies through the whole body adjoining to the entrails, is taken out with the hard and cast into tubs, in which it is carried away by the caviare makers; the float, or sound, which runs along the whole back, is given to the isinglass makers; then the cartilage of the back being cut off in order that the dorsal sinews may be extracted, these are washed, hung upon poles, and dried in the air; and the entrails being removed, the fat adhering about the milk and to the sides is scraped off with knives, collected, boiled down, and cleansed, in which condition, having a good taste, it is used occasionally instead of butter or oil. The fish, after these preparatory processes, are brought into the cellar above described, where they are first laid to pickle in brine, then stewed with salt, and laid up in courses one above another, to be preserved for use. These belugas are frequently of a great size. One is mentioned which is said to have measured 8½ arshines in length, (each arshine being 28 English inches,) to have weighed 70 pood or 2800 pounds, and to have yielded 20 pood of roe. They are not uncommonly taken of 1000 or 1500 lb. weight.

When the shoaling of the beluga has ceased, it is immediately succeeded by the train of the sevragas, which appears only once in the year, and also lasts not much above 2 weeks, but during that short space it is exceedingly numerous. At one vatagh, with a favourable sea breeze, it is usual to catch in a season sixteen and sometimes twenty thousand of these fish. The nets made use of for this purpose are so thick, that the machines are only a span wide: 25 of them are tied together, and laid at the depth at most of a fathom, as the sevragas frequent chiefly the shallow places. These fishes seldom exceed 4½ arshines in length; but their roes, as well as their sounds, are much more esteemed than those of the beluga, and consequently bear a higher price. The flesh is partly salted down, and partly dried in the sun.

The sevragas, as has been observed, make for the bays only in the spring season, which is the time at which they spawn. At this period the belugas are without roes, and proceed thither only in quest of prey. In the autumn and the winter, those latter fish therefore return thither again, either with a view to spawning, or to pass the winter. These two species of sturgeon, seeking, for the purpose mentioned, fresh or moderately salt water, repair annually at the stated seasons not only to the rivers, but also to the gulfs and bights of the sea; whereas the real sturgeon, requiring on the like occasions still greater freshness of water, proceeds always directly to the mouths of the rivers without tarrying in the bays. These fish, therefore, are caught only or chiefly at those vatagas, which are at the mouths of the Volga, and on the river itself; and a sturgeon is such a rarity at the fisheries on the bays of the sea, that, by a very ancient custom, it is the property of the person by whom it is drawn out of the water.

The autumn capture for the beluga, begins in the middle of September and continues through all October. The winter capture of the same description of fishes, begins as soon as the ice is set in on the sea, and lasts the whole of that season. The same machine is used for the purpose as formerly, but it is now set under the ice, apertures being with that view cut in it at the distance severally of 8 paces asunder, through which the rope is introduced by means of long poles. Where two nests are tied together, the machine is fastened to a cross pole, which rests on the brink of the aperture. For bait, there is provided a sufficient stock of obla fish to last during the winter, which are previously salted, with a view to their preservation. The belugas caught, are conveyed over the ice on sledges to the vataga, immediately frozen fresh, and carried to Astrakan.

Other fisheries of the same description with those now enumerated, and these also of considerable importance, are established on the rivers which run into the Caspian, particularly on the Volga and the Ural. The seal capture, which is carried on by the more opulent part of the Astracan merchants in the Caspian Sea, is found to be very profitable. Those animals are here very numerous. They crawl upon the islands, where the fishermen kill them with long clubs. One is hardly dispatched, when others come to his assistance and share his fate. They are exceedingly tenacious of life, and will endure more than 30 hard blows before they die. They will even live for several days after having received many mortal wounds. They are most terrified by fire and smoke, and, as soon as they perceive them, retreat with the utmost expedition to the sea. They become extremely fat, so as to look rather like oil-bags than animals. The principal seasons for taking them are the spring and the autumn. Many small vessels, at these seasons, go out from Astrakan in quest of them; and those which are killed, being immediately gutted and powdered with salt, are sent thither, where they are flayed, and their tallow melted. A sort of grey soap is here made of this fat, mixed with potashes, which is much valued for its property of cleansing, and taking grease out of woollen stuffs. The inhabitants of Astrakan, by salting their seals in the manner mentioned, immediately on the spot, gain this advantage, that the tallow is much cleaner and better than that of the seals taken at Archangel, or other places where a different mode of procedure is adopted.

Besides the great vatagas, the proprietors of them have fishing huts here and there on the sea coasts, where there is no capture of sturgeons, at which, mostly in summer, shad and barbels are taken with drag-nets. These two kinds of fish do not go into the rivers at that season, but keep about the sea shore, where they find a better nourishment. The shad here usually weigh 8 pood, and the barbel 1½ pood. The former sort of fish are extremely fat in summer; their roes are thrown away; but of the sounds an ordinary sort of fish glue is made.

The following is the estimated amount of the number of large and small fish taken annually in the lower branches of the Volga, and the inlets of the Caspian Sea.
The Caspian Sea, and of their value. The account is extracted from the joint returns of the principal proprietors of the fisheries, and those of the public brokers at Astracan, who are obliged to certify the exports of fish by permits. It exhibits the average of the returns for 4 years, admitting only the lowest prices during that period.

Of both belugas or great sturgeon, the number is stated to be 108,500. Each fish being reckoned at the price of only 2½ rubles, the value of these is valueless.

A thousand sturgeons produce about 7½ pood of isinglass; the above number consequently 776 pood, which valued only at 60 rubles a pood, is 46,560 rubles. The roe or caviare of 1000 sturgeons weighs 100 pood; or 4000 pound weight. The amount of the roe obtained from the whole will therefore be 10,350 pood, which at 3½ rubles, gives 36,225 rubles. Thus the entire product of the fisheries of the great sturgeon will amount to 341,535 rubles.

Of the small sturgeon, the number taken is estimated at 302,000, which, at 1 ruble 30 copecks, will give 392,600 rubles. The quantity of isinglass obtained from them, valued in a similar manner as above, will give 41,526 rubles; their roe or caviare 63,420 rubles; making in all accordingly the produce of this fishery, 497,545 rubles.

Of the sevrugas, the number obtained annually is stated at 1,345,000. Their price is reckoned to be 338,000 rubles. The return from these in isinglass is rated at 100,575 rubles; and in caviare, at 282,450 rubles; thus making the whole produce of the sevrugas 921,325 rubles.

In this manner, the whole value of the sturgeons of different kinds, caught in the waters of Astracan and the Caspian Sea, appears to amount to the annual sum of 1,760,405 rubles, according to the average price. In addition to this product, is to be reckoned that also of the smaller species of fish taken in these fisheries, such as carp, pike, and shad, which may be valued at half a million of rubles. The number of seals taken in the Caspian Sea, is to be also included under the head of the productive branches of industry. It is thus easy to perceive of how much consequence those fisheries, with the considerable ones also upon the rivers that run into the Caspian, must be in respect both to employment and provision to the people in the vicinity, as well as to those who live at greater distances from it.

CASSEL, the capital of the kingdom of Westphalia, is situated in the department of the Fulda, and on the river Fulda, which divides it into two parts, called the old and the new town, which are joined by a bridge. The old town, which is the largest of the two divisions, is very ill built. The houses are mostly old, and formed of timber, and the streets are narrow and irregular. The new town is subdivided into the upper and the lower. The upper portion, which is also called the French town, is ill built; but, in the lower part, the houses are elegant and well built, and the streets straight and spacious.

The principal public buildings and curiosities, are the Castle of Residence and its colonnade—the Palace—the Bath of Marles—the Museum—the Square of Frederick—the Arsenal—the Catholic church—the Foundling Hospital—the Anatomical Theatre—the Reformed Church; where there is a statue of the Landgrave Charles—the Foundry—the Palace of the Prince Guise—the Opera House—the buildings of the Orangery—the Observatory—the Menagerie, and the Place Royale.

The Museum, which was built by the Landgrave Frederick II., is a noble building. It has a façade of 290 feet long, with columns of the Ionic order, 36 feet in height. It contains a valuable collection of antique gems and ornaments, statues, busts, and cast models of Rome, and particularly all the Princes of Hesse, dressed in the costume of their times. In the Square of Frederick is a statue of the late Landgrave, by Nahl, erected in 1783. The Mange is a light and elegant building, and the library is a magnificent apartment, about 500 feet long by 40, and contains several valuable books and manuscripts.

The literary establishments of Cassel, are a society of antiquity; an academy of painting; a cabinet of machines and models; a college; the lyceum of Frederick; and the society of agriculture and the fine arts. The principal promenades are the park of Augusten; the garden of Bellevue, and the esplanade.

In the neighbourhood of Cassel is the beautiful castle of Wilhelmshöhe, formerly, Weissenstein, which is visited by all strangers. The fine cascade; the colossal Hercules of Winterkasten; the lofty jet d'eau; the Loewenbourg; the aqueduct; and the fall of water, are objects of general admiration. The garden of Freyenhausen, the chateau, gardens, and grottos of Wilhelmshöhe, are among the other curiosities in the neighbourhood.

The principal manufactures of Cassel are porcelain; delft ware; woollen stuffs; fine hats; ribbands; silk and woollen stockings; gold and silver lace; tobacco; wax candles; chocolate; buttons; and cards for playing. M. Kuttner reckons Cassel the fourth city in Germany, and inferior only to Vienna, Berlin, and Dresden. East Long. of the observatory 9° 53' 15", North Lat. 51° 19' 20". Population in 1811, 20,260. See Tynna's Almanach du Commerce pour 1811. Verzeichnis der hochfürstlich Hessischen Gemalde Sammlung in Cassel, 1783. Cassel und die umliegende Gegend, Cassel 1796, by M. D'Apel; Trotter's Memoirs of Mr For, p. 51. (π.)

CASSIA, a genus of plants of the class Decandria, and order Monogynia. See BOTANY, p. 209.

CASSIMERE. See CASIMERE.

CASSINE, a genus of plants of the class Pentandria, and order Trigynia. See BOTANY, p. 167.

CASSINI, John Dominic, a celebrated French astronomer, was born at Perinaldo, in the county of Nice, on the 8th of June, 1625, and was descended...
from a family, which has ranked among the senatorial families of Sienna since the time of Cardinal Cassini, who was archbishop of that city in 1426. After receiving the early part of his education under a private tutor, he was sent to the college of Jesuits at Genoa, where he made such a rapid progress in literature, that some of his Latin poems were published when he was only eleven years of age. In consequence of some books on judicial astrology having been lent to him by an ecclesiastical, when he was on a visit at the country house of M. Lercaro, the doge of Genoa, his attention was directed to the study of the heavens. He began to predict future events from the aspects of the heavenly bodies, and made numerous extracts from the astrological books which were put into his hands; but having accidentally read the work of Pic de la Mirandie against astrologers, he burned all the extracts which he had made, and abandoned for ever the dreams of astrology. He now devoted himself wholly to astronomy; and such was the rapidity of his progress, that in the year 1650, when he was only twenty-five years of age, he was invited by the senate of Bologna to the professorship of astronomy, which had been vacant for several years by the death of Cavallieri; a situation in which he continued for several years, devoting the whole of his leisure time to astronomical observations. From a series of observations on the comet of 1652, made with the Marquis of Malavisa, who had been instrumental in bringing him to Bologna, he concluded that comets were not of a meteoric nature as had been imagined, but that they were guided in their paths by the same laws as the planetary bodies; and he explains the motion of the comet by a circle described round the earth and beyond the orbit of the moon. These observations were published in his first production, which appeared in 1653, under the title of De Cometa anni 1652 et 1653. Muntigne, fol. In the same year he obtained a solution of the celebrated problem for determining geometrically from the mean and true place of a planet, the eccentricity of its orbit, and the place of its apogee, which had baffled the ingenuity both of Kepler and Bullialdus. In 1653, when the church of St Petronius at Bologna underwent a repair, Cassini obtained permission to draw the famous meridian line, which we have already described in our account of that city. This meridian line, which had been first drawn in 1575 by Egnazio Dante, was renewed in 1695 by Cassini, when a full account of it was published by him, entitled, La Meridiana del tempio di S. Petronia, tirata e preparata per le osservazioni astronomiche l'anno 1655, rivista e restaurata l'anno 1695. Bologna, fol. In the year 1657, Cassini went to Rome in the capacity of assistant to the Marquis Tamara, who had been sent by the senate of Bologna as ambassador to Pope Alexander VII. respecting certain differences which had arisen between the cities of Bologna and Ferrara, about the inundation of the Po; and such was the skill and judgment which he displayed on this occasion, that he was chosen superintendent of the waters of the state of Bologna. Marquis Chigi, the Pope's brother, afterwards appointed him in 1663, inspector general of the fortifications of the castle of Urbino, and he was also chosen engineer for all the rivers in the ecclesiastical state. Cassini was employed in settling with M. Viviani the difference which arose between Pope Alexander VII. and the Grand Duke of Tuscany, respecting the waters of the Chiana; and such was the personal regard which this pontiff entertained for him, that he frequently sent for Cassini to converse with him upon the sciences, and urged him, in vain, by the promises of preferment, to enter into the church.

During these occupations, which were rather foreign to the habits of a practical astronomer, Cassini found leisure to prosecute his favourite study. He observed almost all the celestial phenomena which occurred, he discovered the rotation of Mars upon his axis, and he formed tables of the motion of Jupiter's satellites. His various observations made in his native country were published in the following works:

5. Osservazione de eclipsi Solare fatta in Ferrara anno 1664, con una figura intagliata in rame, che rappresenta uno nuovo metodo di trovar le apparence varie che fa nel medesimo tempo in tutta la terra. Ferrara, 1664. fol.

* This work contains, among other things, a dissertation on the spots of Mars and Jupiter, and a reply to two brothers of the name of Serres, who maintained that Fontana had discovered the rotation of Mars.
Cassini, John.

Cassini's tables of Jupiter's satellites having accidentally fallen into the hands of the celebrated French astronomer M. Picard, he conceived a high opinion of the abilities of their author; and such was the fame of that work acquired, that Louis XIV. was anxious to number him among the members of the French Academy. Cassini, however, declined the invitation, which was transmitted to him, unless the consent of his superiors was obtained; and Pope Clement IX. and the senate of Bologna having yielded to the solicitations of the French king, Cassini was granted leave of absence for six years. In the beginning of the year 1669 he came to Paris, and in the same year he was appointed astronomer royal, and was admitted a pensioner of the academy. When his time of absence was about to expire, the Pope and the senate of Bologna insisted upon his return on pain of forfeiting all his emoluments and revenues, which he had hitherto been permitted to enjoy. The minister Colbert induced him to remain, and in the year 1673 he was naturalized, and entered into the married state.

The completion of the royal observatory in 1670, enabled Cassini to devote himself, without interruption, to practical astronomy. In September 1671, he began his laborious career, and during the period of 41 years he made more observations than was perhaps ever done by any individual astronomer. These observations are recorded in no fewer than 165 memoirs, with which he enriched the Memoirs of the Academy of Sciences, and they contributed greatly to extend the science of astronomy. Cassini made a set of regular observations on the equinoxes and solstices, and on the oppositions and conjunctions of the planets. On the 5th of October 1671, he discovered the fifth satellite of Saturn; on the 23rd December 1672 he discovered the third; and in the month of March 1684, he discovered the first and second satellites of the same planet. He had the merit also of discovering the rotation of the fifth satellite, the belts of Saturn and Jupiter, the spheroidal figure of Jupiter, the zodiacal light, and he was the first who gave a satisfactory theory of the moon's libration.

In the year 1685, Cassini undertook a journey to Bologna in company with his son, for the purpose of examining the meridian line in the church of St Petronius, which he had drawn in 1655, and he found that it had not sustained any variation in the course of 40 years. In 1700, he continued, to the very south of France, the meridian line which Picard had begun, and he published an account of the undertaking in the Memoirs of the Academy for 1701, under the title of De la Meridienne de l'Observatoire Royale, prolongée jusqu'aux Pyrénées. In the latter part of his life Cassini lost his sight, and he died without any disease on the 14th of September 1712, at the advanced age of 87. He had lost his eldest son at the battle of La Hogue; and he was succeeded in the observatory and in the academy by his youngest son, the subject of the following article.

The following works were left unfinished, or in MS. Nuncii Siderei Interpres. Magna periodus lunaris et Paschalis duo libris comprehensa, quorum primum magnam periodi fundamenta ejusque usum exponit, alter usum ejus civilium et ecclesiasticum. Une Cosmographie ou une description du Monde; en vers. Italien. Tables des Mouvements du Soleil et de la Lune. (o)

CASSINI, James, a celebrated astronomer, was the youngest son of John Dominique Cassini, and was born at Paris on the 18th of February 1677. After having finished his studies in his father's house, under the care of M. Chazelle of the Academy of Sciences, he was sent to study philosophy at the Mazarin College under the celebrated Varignon, who was then professor of mathematics; and so great was his progress, that, at the age of 15, he supported a mathematical thesis, which he dedicated to the Duke of Burgundy. In the year 1694, at the age of 17, he was admitted into the Academy of Sciences; and, in the year 1695, he accompanied his father to Italy, assisted him in verifying the meridian line at the church of St Petronius, measured the length of the Roman and Greek foot, and determined the latitude of several of the cities through which he passed. Upon his return from Italy he went to Holland, where he determined the latitude of several places; and discovered some errors which Snellius had committed in his measurement of the earth. Towards the end of the year 1696, he undertook a journey to England, where he became acquainted with Newton, Halley, Flamstead, Gregory, and Wallis, and after remaining some time, he returned to France with an additional ardour for his favourite science, and adorned with the title of Fellow of the Royal Society.

In the year 1712, James Cassini succeeded his father as astronomer at the Royal Observatory of Paris; and every volume of the Memoirs of the French
Academy contains numerous proofs, both of his assiduity as an observer, and as a physical astronomer. In the year 1705, he presented his paper on the method of determining the longitude of places, by the eclipses of the fixed stars and planets by the moon. His researches on the magnitude of the fixed stars, and their distance from the earth, appeared in 1717; and, in the same year, he published his Theory of the Motion of the Satellites of Saturn. In 1720, he published his work, entitled, De la Grandeur et de la Figure de la Terre. In his paper on the revolution of Venus round her axis, which was printed in the Memoirs of the Academy for 1732, he confirmed the results of his father's observations, by pointing out the mistakes committed by Bianchini; and this determination has been completely established by the very recent observations of M. Schroeter. His attention was next turned to the curious subject of the acceleration of the mean motion of Jupiter, and the retardation of that of Saturn; and he showed that the mean motion of Jupiter should be accelerated half a second every year, while that of Saturn was retarded two minutes in the same time; and that these quantities should increase for 2000 years, and afterwards diminish.

In the year 1740, Cassini published his Éléments d'Astronomie, accompanied with astronomical tables of the sun, moon, planets, stars, and satellites. The Elements of Astronomy were composed at the request of the Duke of Burgundy, who was solicitous to have in his own language an elementary treatise on that science. The astronomical tables, which were long reckoned the most accurate, were afterwards reprinted by his son, but with many errors, from which the original edition was free.

Although the attention of Cassini was chiefly directed to the study and practice of astronomy, yet the other branches of physical knowledge occasionally attracted his notice. Besides 172 memoirs on astronomical subjects, which were printed by the Academy of Sciences, he published eight upon the following subjects:

2. Reflexions sur les regles de la condensation de l'air. Id. 1705, p. 61. and p. 272.
3. Observations sur la lumiere des corps frottées. Id. 1707. Hist. 3.
4. Experiences sur les armes a feu differemment chargée. Id. 1707. Hist. 3.
5. De la necessite de bien centrer le verre objective d'une lunette. Id. 1710, p. 233.
6. Experiences de l'effet du vent a l'egoard du thermomètre. Id. 1710, p. 344.
7. Reflexions sur les observations du bâromètre qui ont été faites sur les montagnes du Puy-de-Dôme, du Mont-d'Or, et du Canigou. Id. 1740. Hist. 79.
8. Méthode de se servir des Miroirs concaves, de metal ou de verre pour tenir les metaux en fusion, &c. Id. 1747, p. 25.

Our author was employed, along with Maraldi and De la Hire the Younger, in completing the measurement of a degree of the meridian, which had been begun by Picard, and continued by Dominique Cassini; and he finished this work in the year 1718. The latitudes observed in several points, in an extent of more than six degrees, showed an inequality in these degrees; and M. Cassini maintained, that the degrees of the same meridian diminished towards the poles, and consequently that the earth was a prolate spheroid. This result, so contrary to the Newtonian theory of gravity, induced the French government to measure a degree at the equator and near the poles, the result of which overturned the opinion of our author.

In the year 1704, Cassini had been appointed master of accounts, and he discharged the duties of this office with such activity and zeal, that, in 1716, he was one of the small number of magistrates who were chosen to compose the Chamber of Justice.

While our author was on the road to his country house at Thury, he was unfortunately overturned, and, having become instantly paralytic, he died of his wound on the 16th April 1756.

Cassini was large and well made, and had a very interesting physiognomy. Distinguished by piety and benevolence, he was one of those persons who obtain that universal esteem to which they were justly entitled. In 1710, Cassini married Mademoiselle Ducharmoi, the daughter of the Countess of Sismon, by whom he had six children, one of whom died when young. His two daughters were well married, and his three sons rose to eminence in their respective professions.

CASSINI DE THURY, CÉSAR FRANÇOIS, was the second son of James Cassini, and was born at Paris on the 17th June 1719. He received his earliest instructions in astronomy and geometry from M.M. Maraldi and Camus; and when he was scarcely ten years of age, he calculated the phases of the total eclipse of the sun, which happened in the year 1727. At the age of eighteen, he accompanied his father in his two journeys, for the purpose of drawing a perpendicular to the meridian of the observatory from Strasburg to Brest; and, in the year 1735, he was received into the academy as adjutant super-numerary at the early age of twenty-one.

A general chart of France having been about this time meditated, it became necessary to traverse the kingdom with several lines parallel to the meridian, and to the perpendicular to the observatory. Cassini was charged with this undertaking; and, as the measurements taken by his father and grandfather were not exempt from errors, he undertook to draw anew the meridian of Paris, by means of a new series of triangles, smaller in number, and more advantageously arranged, than those which had been formerly used.

A full account of this survey was published by Cassini in the Memoirs of the Academy for 1744, under the title of Méridienne de l'Observatoire de Paris vérifiée dans toute l'étendue du royaume, par de nouvelles observations, &c. avec des observations d'Histoire naturelle faites dans les provinces traversées par la Meridienne. The series of triangles used on this occasion, passed along the sea coast to Bayonne, traversed the frontiers of Spain to the Mediterranean, stretched as far as Antibes, and round by the eastern frontier of France to Dunkirk. This map of triangles was terminated by two columns, on which were marked the longitude, latitude, and distance from Paris, of all the towns comprehended in the chain of triangles.
When the war broke out in Flanders in 1741, Cassini accompanied the king to that country, and took advantage of this opportunity of verifying the measure of a degree by Saclier. From the materials which he had collected, he prepared a particular chart of that part of Flanders which had been occupied by the French armies, and the king was so much pleased with its accuracy, that he expressed his desire to have a chart of France prepared in the same manner. M. De Machaud, who was then comptroller general, furnished the money which was necessary for this undertaking; but these advances were discontinued by his successor M. de Sechelles, and the King, out of regard to Cassini, announced to him personally this disagreeable intelligence; “Sire,” replied Cassini, “if you will only deign to say that you view with concern the suspension of this undertaking, and that you wish for its continuance, I shall take charge of the rest.” The king readily consented to this request, and Cassini immediately formed the plan of a company who should make the necessary advances, and repay themselves by the sale of the charts. This company was formed, and Cassini had the satisfaction of seeing his great undertaking accomplished. He published different works relative to these charts, and each sheet, the number of which was 183, was accompanied with an alphabetical table, containing the distance from the meridian, and from the perpendicular, of all the different places.

These charts of France inspired the sovereigns of other countries with a desire of having their own kingdoms surveyed, and, in 1760, the emperor invited M. Cassini to Vienna, for the purpose of continuing to that city the perpendicular to the meridian of Paris. On the 6th of June, 1761, he observed at Vienna the transit of Venus, an account of which he published in his *Voyage en Allemagne*, a work which contains many notices respecting the geography of the country, and the charts of Frich and Muller. He published a new map of that country, which represented a series of triangles from Strasburg to Tyrrau in Hungary.

In pursuance of his great plan, Cassini proposed to the British government to connect the general chart of France with that of the British Isles. This proposal was favourably received, and the trigonometrical survey of this country, of which we shall give a full account in another part of our work, has been carried on with the greatest ability by General Roy and General Mudge.

The attention of M. Cassini was not diverted from his astronomical studies, by the various geographical labours in which he was engaged. He published, in 1756, additions to the astronomical tables of his father. The comparison of a great number of observations of the moon with the tables, induced him to apply another equation whose period was 19 years. In 1770 he published three almanacks, which were accompanied by an universal instrument invented by the Prince de Conti. The papers which he printed in the Memoirs of the Academy, between the years 1765 and 1770, amount to 70, and are all upon astronomical subjects.

Though Cassini had naturally a strong constitution, which enabled him to undergo the greatest fatigue in the course of his geographical labours; yet, in the latter part of his life, he was seized with a habitual retention of urine, which rendered the last 12 years of his life particularly painful and distressing. In the month of August 1784, he was attacked with the small pox, of which he died, on the 4th September, in the 71st year of his age. He left behind him a daughter, and a son, the Count de Cassini, who succeeded him in the observatory, and, till about the end of the French revolution, continued to prosecute the study of his ancestors. The pleasures of a country life, however, have drawn him from these pursuits; and his son, who forms the fifth generation of the Cassinis, has exhibited no attachment to a science with which the name of his family will be forever associated. (a)

CASSIOPEIA. See Astronomy, p. 745.

CASSIUS, CAIUS, was a celebrated Roman, who sustained a most important part in opposing the revolutions which had been planned by Julius Caesar at a very early age. He was descended from ancestors who had made a considerable figure in the state; and as the tone of temper of some, if not of the same family, at least of the same name, bore a great resemblance to the ardour and impetuosity for which he himself was so distinguished during the whole course of his enterprising and eventful life, it has been affirmed, that one of them, Sp. Cassius, after a triumph and three consulships, was put to death by his own father, in consequence of attempting to encroach upon the liberties of his country. Of the truth of this circumstance, however, as well as that of many others in the earlier part of the Roman history, it is reasonable to doubt. Young Cassius is represented to have discovered at school a very high spirit of independence, and to have given intimations of that impetuous and unchangeable disposition, which never forsake him, even in those transactions which involved the fate of Rome itself. Faustus, the son of the dictator Sylla, had boasted of the greatness of his father; Cassius, whose family was actually hostile to Sylla with the other families in Rome, chastised his companion with as much freedom as if he had been the son of the meanest Roman citizen; and, in after life, he declared to Pompey, who had alluded to the story, that if Faustus were to refer to the same circumstance, he would repent the blow. At the usual age he was created quaestor, which was the first step of preferment in the state, and gave admission into the senate. In this capacity he served under Crassus in the Parthian war; and, upon many occasions, discovered not only his bravery, his great care that provisions and pay should be regularly distributed to the army, the more peculiar duty of his office, but he was also of the most essential service to the general himself, by the advice which he from time to time gave him; and it seems to be the opinion of ancient authors, that, had Crassus been more attentive to his counsel, he might have opposed more successfully that formidable enemy, and might have saved himself and his army from that disgrace with which they were overwhelmed. Upon the death of Crassus, B. C. 53. Cassius succeeded to the command of that shattered fragment of the army which remained after to complete a defeat. At the head of this body of troops he retreated through Syria, and though pursued by
the Parthians, the most formidable enemy the Romans ever engaged, he succeeded in fortifying himself in Aucticca. In this city he was besieged, but the enemy were unable to dispossess him, and he even obtained a considerable victory over them. In the civil contests that took place between Caesar and Pompey, and which terminated in the complete subversion of the republic, Cassius warmly espoused the cause of the latter. He had the command of Pompey's navy; but according to Caesar, (lib. iii. de Bell. Civ.) this was only nominal, for the real command was entrusted to Bibulus. The issue of the battle of Pharsalia, B.C. 48, is well known. The hopes of the Pompeian faction were completely extinguished, and the path to absolute power laid open to Caesar. Cassius, however, still entertained hopes of successfully opposing the usurper, and for this purpose directed his course with 70 ships to the coast of Asia; but Caesar had anticipated his design, and Cassius was thus frustrated in the plan he had formed. He therefore declared in favour of his opponent, as he probably was persuaded that opposition was vain. Of his sincerity, strong suspicions may be justly entertained; for when Caesar, by being created perpetual dictator, actually enjoyed the most arbitrary power that can be conceived, he, together with his relation Brutus, formed the scheme of assassinating the tyrant who had annihilated the liberties of his country. They succeeded in the attempt, and fled from Rome. Cassius joined Brutus at Athens, and having found means to collect a considerable body of troops, he made himself master of the Syrian province which had been assigned to him by Caesar. Dolabella had been exceedingly desirous to make himself master of Syria, but was under the necessity of retreating to Laodicea. Thither Cassius followed him, and having taken the city, was guilty of the most barbarous excesses. The history of Cassius at this period is intimately connected with that of Rome, we must therefore refer our readers to that article in our work, in which his different expeditions shall be detailed at length. In the mean time it may be necessary to remark, that he subdued the Rhodians, and that in the city of Rhodes he committed the greatest atrocities. He put 30 of the principal inhabitants to death, robbed the city of 8000 talents, demanded 500 more, and was guilty of the most rigid exactions throughout the whole of those provinces through which he passed. At Philippi, the united forces of Brutus and Cassius unsuccessfully engaged those of the triumvirs. Of the mode of his death nothing certain is known. He was found dead in his tent B.C. 42. He was a bold, resolute, turbulent man; and the unhappy times in which he lived, strengthened his natural passions. See Brutus; Plutarch; and Middleton's Cicero, &c.

CASSO, Casos, or Casus, the name of one of the Cyclades islands in the Mediterranean. It is about three leagues in circumference, and is surrounded with several islands of a smaller size. The part of the island which is cultivated is divided into portions, and shared among the inhabitants, who, by great toil and industry, have rendered it surprisingly fertile. Though the ground is stony, yet barley and wheat are raised, and a very good wine is obtained from the vines. The land is sown at the begin-

ning of the rainy season, which continues from October to February, and the crops are cut down in March. Excepting between October and February no rain falls, the air is remarkably pure, and the temperature is rendered delightful by the breezes from the sea. When their services are not required for the purposes of agriculture, the men are engaged in trade with the different islands in the Archipelago, from which they supply the deficiency in the produce of their own island. The women of the island, who wear a jacket, a sash, and a long cotton robe, are principally employed in spinning cotton, or embroi-
dering, and in making the fine linens which form their dress. Poultry, eggs, rice, and wine, are the principal articles of their food. The men dine together seated upon a carpet, and the women have a separate apartment to themselves. The principal amusements are dancing and music. "The population of this island," says Sonnini, "entirely com- posed of Greeks, is not considerable. The island is little frequented by shipping, its roads being difficult of entrance, and its shore dangerous of access. The inhabitants are but the more happy and free. The Turks seldom venture to go thither, to exercise the despotism with which they overwhelm the countries subject to their empire; and indeed those Greeks of Casso, more independent and more secure in their property, are more laborious than elsewhere." See Sava- ry's Travels, and Sonnini's Travels in Greece and Turkey, chap. x. p. 194. (π)

necia, and order Polyanthria. See Botany, p. 326.

CASTILE, (Old) a province of Spain, lies on the western side of the river Ebro, which, with the mountain of Docea, separate it on the east from Ar-
ragon and Navarre. On the north, it is bounded by Asturias and Biscay; on the west, by the king-
dom of Leon; and, on the south, it is divided from New Castile by the mountains of Guadarrama. It forms an irregular triangle, of which the western side measures 59 leagues, the north-east 51, and the south-east 53; and comprehends an area of 18,272 square miles. "Old Castile," says Laborde, "presents a succession of plains, or rather one expanse of down, surrounded by lofty mountains, and occasionally in-
tersected by other mountains of equal elevation, and diversified by hills, eminences, and gentle accelli." Its mountains are merely ramifications from the great Pyrenean ridge, which runs along the northern pro-
ces of Spain as far as the Atlantic, and consist chiefly of the mountains of Burgos, called also the mountains of Santander, the Sierra d'Oca, the Sierra de Gogollos, and the Sierra Piquera. These mountains contain several varieties of marble; and one in particular, which lies between Aspiaita and Vidana, is composed entirely of that substance, which is a black marble veined with white. Copper mines are found near d'Escary and Old Colemar; and in the vicinity of the latter place, is a bed of jet, and se-
veral muriatic pyrites. A transparent vein of quartz,
as fine as rock crystal, and forming a bed of about four inches in breadth, extends nearly half a league from south to north of Mata; and, about two leagues from Guadarrama, another vein of quartz mixed with pyrites, intersects a mountain of granite from one side to the other. The quartz, in this vein, detached from the rock, and grains of gold are easily distinguishable. Mount Arandillo, which constitutes a part of the mountains of Burgos, is composed entirely of calcareous rock; and, in its centre, exhibits impressions of the large horns of the cornua ammonis, and that species of shells commonly called St. James. On the top of the mountain is a thick saline lake, from which salt is procured by evaporation, in the proportion of seven pounds of salt to one quintal of water.

Old Castile abounds with mineral waters. Among its cold springs, are the celebrated lakes so well known by the name of Fuente de Bocío, or Lagos de San Vicente, and Lagos de Santa Casilda; and of its tepid springs, the principal are those of Arnedillo, whose source rises at the foot of the mountain Encineta, about a mile from the town, Barco d’Avila, Banos, which was well known to the Romans, and Alcaraz.

This province is watered by numerous rivers, among which are the Xalon, the Monubles, the Queiles, the Duero, the Carion, the Tormes, the Cayar, the Ebro, the Alhama, the Arvedillo, the Araja, the Lagartera, the Iregua, the Tiron, the Pizuerga, the Zidacos, the Arlanzon, the Arlanza, the Henarex, the Carneca, the Valtaia, the Abion, the Uzero, the Castillo, the Dueraton, the Burejo, the Nazerilla, the Ora, the Paz, the Tueva, and the Oja. The plains and valleys are fertilized through which they pass, and though the soil is frequently rocky, and scarcely susceptible of culture, yet in some places it is highly favourable for the purposes of agriculture, particularly in the district lying between Rodrigo and Burgos. There the harvests are most luxuriant, and every species of grain is produced in great profusion, and of excellent quality. Cultivation, however, is much neglected throughout the province. The ground is merely scratched with a light plough; but notwithstanding this slight preparation, the heat of the climate, and the dryness of the atmosphere in this country, such is the inherent humidity and richness of the soil, that the crops are seldom known to fail; and so plentiful is the increase, that a third part of the harvest is considered as sufficient for the consumption of the province. It is to this profusion indeed, that we must, in a great measure, attribute the backwardness of the natives to agricultural improvements. The overplus of their crops, owing to the difficulties of conveyance, can seldom be converted into wealth. Their only method of exportation is on the backs of mules, and the roads are in general so wretched, that some of them are even scarcely practicable to these sure-footed animals. Part of the great road which leads from Bayonne to Madrid, intersects this province, and passes through the cities of Burgos and Valladolid; but the cross roads are no better than they were four centuries ago. They are narrow, steep, and rugged, sometimes miry, and often impassable to horses. The pass of Guadarrama, which is the nearest point of communication between Old and New Castile, was, till about the middle of the last century, so steep and difficult, that it could not be attempted without danger. But by the care and munificence of Ferdinand VI. a road was formed, beginning at the village of Espinar, by which the ascent was rendered safe and easy. In gratitude for this service, a marble monument has been erected to his memory, which represents a lion resting on a column, with this inscription:

FERDINANDVS VI. PATER PATRIAE
VIVAM UTRIQUE CASTELLAE
SUPERATIS MONTIBUS
FECIT
ANNO SALUTIS MDCCXLIX.
REGNLI SUI IV.

It stands on the summit of the mountain, which is called the Puerto de Guadarrama, and from it the eye can take in at once the whole extent of country included in the sister provinces. The difficulties of exportation, however, in this province, would be almost completely obviated by the completion of the canal of Campos. This work was begun in 1753 by the same prince, and was intended to reach from Fontibre, two leagues from Reyenos, to the river Pisuerga below Valladolid, and then passing by Segovia to join the Duero. But after it had been cut for several miles, it was suddenly stopt, and has never since been resumed, though its accomplishment would require neither extraordinary labour nor expense.

Old Castile produces a considerable quantity of wine, but it is inferior both in strength and flavour to that of the southern provinces. Fruits are in general very scarce, except in the canton of Burela, which is indeed covered with luxuriant orchards, and well wooded with elms, poplars, and chestnuts. But this district is the only one in the province which can boast of such plantations. In the other districts, the appearance of trees is chiefly confined to the banks of the rivers. Many of the extensive plains are almost entirely bare of foliage; and in some places, particularly between Cabezanz and Rodrigo, they are not embellished with a single shrub. Madder has of late years become a favourite object of cultivation in this province, and is produced in great quantities in the vicinity of Burgos, Segovia, and Valladolid. It employs more than a hundred mills, and furnishes annually about seven or even eight thousand quintals. Wool, however, is the staple commodity of Old Castile, and constitutes an important article of foreign exportation. Innumerable flocks of sheep, which winter in the plains, browse during summer on the mountains, where they find a rich and luxuriant pasture. Their wool is equal in quality to any in Spain; and the cloth of Segovia, into which it is sometimes wrought, is famous throughout Europe. Immense numbers of cows also feed upon these mountains, but such is the ignorance or indolence of the inhabitants, that their produce is turned to very little account; for though this province alone could almost supply excellent salt butter for the whole kingdom, yet it produces little more than what is requisite for its own consumption; and Spain is compelled to draw that necessary article from other countries.

While Old Castile continued to be the residence of
its sovereigns, and was animated by their presence, it held the first rank among the provinces of Spain for opulence, as well as for the excellence and variety of its manufactures. But since the removal of the court to Madrid, its prosperity has most rapidly declined. The manufactures of woollen and linen cloths, for which it was formerly so distinguished, are now almost annihilated. The greatest part of its wool is carried to France, where it is fabricated into cloths and caps, many of which return to Spain for sale; and the half of what is manufactured at Segovia is sent to Madrid and some other places in New Castile. Paper, hides, and leather, are also exported to the same province; white glass to Arragon; and a little wine to Biscay. Its imports, however, are more considerable, and consist annually of about 400 quintals of almonds, and 15 quintals of dried figs; 12,000 loads of rice, paper, needles, brass-nails, silks, and oil; 700 quintals of flax, and 12,000 of hemp; 800 pieces of stuff; 720 dozen pairs of worsted stockings; besides saffron, cutlery, salted pilchards, linens, wire, nets, printed calicoes, shoes, and iron utensils.

The character of the inhabitants corresponds with the depressed state of their province; and, according to a late writer, they bear in their swarthy complexion the expression of poverty and dejection. They appear to have little relish for the pleasures of society, and are more remarkable than any of their countrymen for that gravity and hauteur of manner, which is the general characteristic of their nation. They have scarcely any intercourse with each other, and the few amusements in which they engage are always of a solemn and sombre cast. In their conduct, however, they are honest, temperate, and sincere; "their morals," says M. De Laborde, "are incorrupt and ingenuous; they are upright in conduct, strangers to artifice, and unpractised in cunning or duplicity; they are naturally obliging; probity is their birth-right; and they are so disinterested, and so perfectly free from all affectation, that they may be justly stiled, the honest people of Spain." From this general character there are some exceptions in particular districts. The inhabitants of the valley of Mena, who boast of being descended from the ancient Cantabri, still retain a considerable share of their ancient courage and vivacity; and the mountaineers of Burgos have a great resemblance to those of Biscay, both in habits and manners. The dress of this description of inhabitants is indeed quite peculiar; and that of the women in the villages bordering on the province of Biscay, still exhibits the fashion of the 16th century. It consists commonly of a brown gown, with slashed sleeves, close at the collar and wrists, and bound round the waist with a large girdle and buckle; the hair is braided in tresses, and hangs down behind; and the head is covered with a black silk hat, called a montera.

The population of Old Castile scarcely amounts to one half of its former number. It is estimated at present at 1,190,108 persons, among whom are 146,036 nobles, 9013 vicars and secular priests, 5774 monks and nuns, 1865 advocates, and writers, 5760 students, and 37,183 domestics.

The principal places in this province are Burgos, the capital and an archbishop's see; the episcopal cities of Osma, Siguenza, Avila, Valladolid, Segovia, Calahorra, and Soria; and the towns of Lo-
supposed to be the most elevated land in Spain. It is of considerable extent, reaching eastward to Aragon and Valencia, and is diversified with many fertile valleys. The Sierra de Molina occupies the north-east point of the province; and the Sierra D'Alharazin, which runs a little north of it, stretches toward the south-east, when it forms a junction with the Sierra de Cuenca. The Sierra de Gudarama, which constitutes the northern boundary of the province, is derived from the Pyrenees.

All of these mountains contain treasures of intelligence, which would amply reward the researches of the mineralogist and botanist. Their recesses are as yet unexplored; and the traveller trampes at every step upon tribes of plants, which, however beautiful and useful, are scarcely known to the natives of Spain. On the mountain of Barbaxeda are a copper mine and a bed of coal; and on a lofty part of the same mountain are the lakes of Tobar and Beteta, which are both above four hundred fathoms in depth. They abound with trench, and are frequented by flocks of teal, wild-ducks, and other aquatic birds. Hyacinthine stones are found in their vicinity; and near Maranchon are fragments of pisolithes, blemnites, and other bivalved fossil shells, resting on a bed of calcareous earth. At Bonaco de Sierra, about two leagues north of Cuenca, are several kinds of variegated marble, among which are a yellow marble veined with violet, a yellow marble striped with pink, and a marble of a variety of colours; and at the foot of the Guadarama mountains was found a large emerald, which is now employed in polishing mirrors in the glass-house of St. Idefonso. The mountain of Las Conterras contains a salt mine, which is said to have been wrought from the time of the Romans. It is called the salt pit of Minglanilla, and consists of a series of deep caverns, into which the descent is by 200 steps cut in the rock. It gives employment to thirty men, and its produce belongs exclusively to the king.

In the mountains of this province are several curious caves, some of which are evidently the remains of mines long ago forsaken. Those most worthy of notice are in the Sierra de Cuenca, viz. the cave of the Greeks, the iron cave, and the cave of Peter Cotillas. “This last,” says Laborde, “is remarkable for the variety and beauty of its concretions, which compose stalactites of every description; to the eye they present striking similitudes of the human figure, of dogs, adders, pyramids, and columns; by the light of torches they are resplendent; some of them, by their transparency, resemble crystal; water is constantly dripping from every part of this cavern, which, in all probability, is the relic of an ancient mine.”

Among the abundance of mineral waters in New Castile, the principal cold springs are those of Alameda-Sagra, Vacia-Madrid, Cevica, and Anover, which are all saline, and the two first are highly cathartic. The thermal waters are those of Sacedon, Corcoles, Trillo, and Buendia. Of the principal rivers which run through this province, three are navigable, the Tagus, the Iaco, and the Guadiana; and the smaller ones are, the Henarez, the Gaya, the Cabriel, the Oiana, the Guercaro, the Cauda, the Zuia, the Bedija, the Xiqueta, the Lozoya, the Guadarrama, the Albercho, the Xarama, the Molina, the Manzara, the Cabrilla, the Tietar, the Tacua, the Tortoles, the Guazaon, the Guadiera, and the Moscas. This last, which rises in the mountains of Cuenca, and flows from thence to Valera, has its waters impregnated with salt.

These rivers are well adapted for the purposes of irrigation, and might be converted into valuable sources of fertility. The soil, though rich and fertile, is much parched, and requires nothing but moisture to adapt it for every species of agriculture. But the indolence of the inhabitants is a complete bar to all improvement. The rivers are allowed to flow undisturbed in their native channels; and though the beneficial consequences of irrigation in this province were long ago ascertained by Michael Alvarez Oporto, and it was demonstrated by his son, in 1687, that even the little river of Narez was adequate to the fertilization of 80,000 fanegas of land, yet agriculture still remains in the same state, without any attempt at profiting by such proofs. Many of the cantons, however, are under tolerable cultivation; but others are completely neglected, though capable of great fecundity. Among the former are, the country lying between Guadalaxara and Alcala de Henarez, the district of Torrelaguna, the rich plain of Requena, and the vale of Aranjuez; and among the latter are, the lands commencing on the frontiers of Aragon, and extending for twenty leagues to Torrijas; also those between the Bravo and the river Albercho, and the country near Alcorcon, on the road leading from Madrid to Talavera de la Reyna.—Wheat is the staple produce of the province, and indeed, except a little barley, it is the only grain which is cultivated. It yields most abundant crops, wherever its culture is made an object of attention. In the valleys lying beneath the Sierra de Cuenca, and in the environs of Madrid and some other towns, as well as in the plain of Talavera de la Reyna, &c. the harvests are most luxuriant, yet the quantity produced by the whole province is scarcely sufficient for the consumption of the inhabitants. Very little flax is raised here, though the soil is well adapted to its cultivation. Hemp, however, is more plentiful, particularly in Alcaria; and the country of Huete alone produces yearly the average quantity of five or six thousand arrebas. Saffron is planted in various parts of New Castile, particularly between Madrid and Cuenca. It is in great demand over all Spain, especially in the Castilian provinces; and consequently it is considered as a profitable object of cultivation. Its consumption, however, in some places, is rather diminished; and the 40 quintals which were formerly produced in Huete are now reduced to five.

The greatest part of the province is equally destitute of foliage with Old Castile. Woods are very rare; and even for several leagues round the capital a tree is scarcely to be seen. An extensive tract of 40 leagues, from Aranjuez to the confines of Valencia, is almost completely bare, without a shrub or leaf to break the naked uniformity. The fertile plain between Guadalaxara and Alcala de Henarez is also devoid of trees; and the country through which the great road leading from Portugal lies is equally naked. “There is not a tree to be seen,” says Mr Swinburne, “from the Sierra Morena to Toledo, nor from the banks of the Tagus to Madrid: a few dwarfish evergreen oaks, huddled together in nooks
of hills, and some stumpy olive plants, scarce deserveto the name of trees. A few particular spots, however, are more favoured. In the plain of Requena, trees are cultivated with considerable care and success; and some of the mountains, particularly those of Cuenca, are clothed with indigenous pines, and various kinds of oak. Poplars are abundant at Talavera de la Reyna; and there are woods of green oak in the environs of Torrija. The banks of the rivers are, in general, embellished with elms, poplars, and willows; and between the village of Flores and the river Henarez, is a forest of the quercus coccifera, producing the precious worm which supplies the carnation tint. Fruit trees are very scarce; and though the soil, with the means of irrigation which they possess, is very favourable for their culture, yet this province draws most of its fruits from Valencia and Arragon. Vines are cultivated in several places; but the wine of New Castile, though good, is often thick, and sometimes hard, and is considered as inferior to that of Arragon and the southern provinces. In some cantons, plantations of olives are both numerous and flourishing, especially between Cebolla and the Guadarama, and the southern parts of the province. The fruit is excellent, but the oil both of New Castile and Arragon is excorable, owing entirely to the method of preparing it; for were it properly extracted, it would be equal to any in the kingdom. Considerable quantities of honey are gathered in this province; and that of Alcaria and the Sierra de Cuenca is reckoned the best in Spain. On the mountains of Cuenca alone, the produce of 1773 was 9334 arbas of honey; and 156 of wax.

The manufactures of New Castile consist chiefly in woollen stuffs. The cloths of Brihuega are excellent in their quality, but they are surpassed by those of Guadalaxara and Vigonia. Very little linen is made here; and its manufacture is confined almost entirely to Toledo and St Ildefonso, which employ only about 30 looms. Extensive manufactories of silks and girdings, however, are established at Requena, Toledo, and Talavera de la Reyna; where are also fabricated plain and figured velvets, of mixed colours, and embroidered with gold; taffetas, satin, silk serges, silk stuffs, gold and silver stuffs, and silk ribbons. At Requena alone these manufactures give employment to nearly 800 looms, and the annual consumption of the three places is estimated at 100,000 pounds of silk, 4000 merks of silver, and 70 marks of gold. Besides these, the other principal branches of manufacture are, calicoes, laces, and tapestries; silk, cotton, and worsted stockings; hats and caps; porcelain and delf ware; pikes, swords, and cutlery ware. There is also a royal manufactory for mirrors, which was carried on at the king's expense. Most of its manufactures, however, are scarcely adequate to the demands of the province; and it is indebted to other districts for many articles of comfort and luxury, of ornament and use. A few of its stuffs are carried to Seville and Cadiz, and thence exported to America; but its cloths and woollens are inferior to those of England and France, and cannot stand in the same market. Its silks, which are exposed to sale at Madrid, are also undersold by the French silks, as well as by those of Catalonia and Valencia.

Considerable improvements have been recently made on the roads of this province, which have greatly facilitated the transportation of goods between the different districts. Some of these roads are broad and handsome, but almost universally incommened with dust. They are sometimes planted with trees on each side, and are frequently intersected by rivers, over which are several well constructed and magnificent bridges. Many of the cross roads, however, are still scarcely passable, being rough, narrow, and often dangerous.

Though New Castile is the residence of the court, and comprises within itself every thing calculated to produce opulence and splendor, a fertile soil and a salubrious climate, yet its general characteristics are poverty and ignorance. Industry, science, and the liberal arts, are confined entirely to the capital, where they flourish under the influence and protection of the sovereign. But the traveller has scarcely left the city, when he finds himself transported, as it were, to a different region. The luxury, wealth, and activity of Madrid emit not one ray beyond its walls, to cheer the poverty and sloth with which it is surrounded. While the capital is fostered by the hand of power, the province is left to languish in indigence and obscurity. The means of instruction are denied to the majority of the inhabitants, and but niggardly supplied to others. The universities of Toledo, Alcaia de Henarez, and Siguenza, are (excepting those of the capital) the only public institutions in the province for the advancement of literature. The mechanical arts are equally neglected; and there is scarcely a native of New Castile who is distinguished as an artisan. Those of the capital are either foreigners or Catalonians; and among the literati are to be found fewer Castilians than the natives of other provinces. It is not, however, the want of capacity which renders the Castilian inferior in these respects to the other inhabitants of the peninsula, but rather a native indolence arising from habit, and the want of sufficient encouragement to exertion. He still retains the prejudices of his warlike ancestors, who, devoted entirely to the exercise of arms, looked upon agriculture and the arts as ignoble and inferior objects; and though the arts of peace have been long established in many of the other provinces of the kingdom, the prejudices of the Castilian has been perpetuated by indolence and the scarcity of instruction. "With superior capacities for reflection," says Laborde, "the Castilian thinks much, but demonstrates little, and acts less; he is rather slow in yielding his confidence, but when he trusts at all, it is with his whole heart and soul; he is neither prompt in enterprise, nor disposed to acquire the regular habits of industry. There are perhaps not many active occupations he is likely to pursue with success; his aptitudes are to science, particularly to such abstruser branches as are connected with speculation and research; his conceptions are strong and vigorous; his judgment solid; his imagination vivid and vivacious; he devotes himself completely to the objects of his pursuit, but he is seldom capable of embracing more than one at the same moment; his genius only requires culture and encouragement; but he possesses not the power to obtain knowledge, and the government fails to afford him the means of instruction."—"The, New Castilian," says the same author, "possesses qualities of genuine excellence; he is honourable and humane, sober and temperate, and revolts from every species of falsehood.
and duplicity. In his temper he is more docile than the native of Old Castile, who pertinaciously retains the inflexibility of his ancestors, whilst the other readily assimilates with the character of the neighbouring provinces. In general, the observer may trace in him a complexion resemblance to the country he approximates; he is most civilized in the environs of Madrid; most useful in the borders of Andalusia; most active and industrious on the confines of Valencia; most arrogat and rude on the frontiers of Aragon and the Sierra de Cuenca; most indolent in the neighbourhood of Estremadura; whilst generosity, nobleness, and benevolence, are the bonds which unite him to Old Castile. In particular, we should select for praise the inhabitants of Alcaria, distinguished by their frankness and simplicity, their cheerful love of labour, their social affections, and ready hospitality.† The steady loyalty, the decorous gravity of deportment, the cautious prudence, and the fortitude in adversity, which have distinguished his forefathers for many centuries, still distinguish the Castilian of the present day. The frequent revolts in Catalonia lead him to characterise the Catalanian as a rebel, and to cherish against him a deep-rooted hatred; while the sentiment is repaid on the part of the Catalanian with contempt. On the promenade, while others are walking backwards and forwards, the Castilian takes his seat on one of the benches, and never rises but to return home.

Some of the towns and districts of this province are distinguished by local customs and amusements, as the mondás of Talavera de la Reina, the festival of the nights of Prado, the mass of Aginaldo, and the custom of burning Judas in effigy. The guitar is their favourite instrument; but the pandero and zambomba are also much in use, and are peculiar to Castile; the former is generally accompanied with sequilllas, and the latter with the voice, but is used only from All-Saints day to Christmas. The music of both is harsh and monotonous. Of the national dances, which constitute a principal amusement of the Castilians, the quarcha is peculiar to themselves. It is danced by a single person, to the sound of the guitar, and the steps are formal and precise, greatly resembling the Dutch minuet.

The population of New Castile bears no proportion to its extent; and according to Laborde, has been sensibly diminishing during the last century. Of many flourishing villages, scarcely a vestige remains; and 195 deserted chapels perpetuate the names of as many once populous hamlets, which have been long left without an inhabitant. According to the estimates of 1787 and 1788, the total inhabitants of the province, without including the monks, amounted to 940,649, among whom were reckoned 5443 priests, 8794 monks and nuns, 12,687 nobles, 2123 advocates and writers, 2859 students, and 46,742 domestics.

New Castile has two cathedral chapters, five collegiate chapters, two abbeys, four establishments of military orders, 1301 parishes, 375 religious houses, 108 hospitals, eight monks’ hospitals, a supreme military government, four provincial military governments, four provincial intendants, three universities, fifty schools, six cities, 754 towns, and 382 villages. Its chief places are Madrid, Toledo, Cuenca, Talavera de la Reina, Illesca, Zurtia, Tremblequin, Villa Nueva de los Infantes, Consuegra, Alcolea, Guadalaxara, and Alcala de Henares.

This province, early in the fifth century, was conquered from the Romans by Altholphus, king of the Alani, who fixed his residence at Toledo, and laid the foundation of a Gothic dynasty, which lasted for 300 years, and ended with Rodero, who fell in the battle of Xeres in 711, when opposing the invasion of the Moors. This battle was followed by the subversion and desolation of the Gothic empire; and this province continued under the subjection of these intruders till its reunion with Old Castile in the 11th century. See Old CASTILE, and SPAIN. See also Laborde’s View of Spain, vol. iii. p. 56–324; and Swinburne’s Travels through Spain, vol. ii. p. 114–243. (p)

CASTLE, an edifice designed for defence against hostile assault.

The state of military architecture is, in every country, strictly commensurate with the advancement of the arts. We can trace its regular progression from the condition of the defenceless savage, who shuns his more powerful enemy by retracting to the fastnesses of the mountains, down to the construction of towers and battlements which the most skilful engineer can devise for the repulsion of the assailant, who has all the destructive engines of war at command. Nevertheless, this is a subject which has experienced uncommon neglect, and the elucidations it receives are compelled to give from scanty materials and the memorials of former ages.

When mankind, in savage life, begin to manifest inimical designs against each other, the weaker retire to eminences of the earth; they pile bulwarks around them, or form earthen circumvallations, and rows of palisades. Their bulwarks, as civilization improves, are converted into rude constructed towers; after which are erected edifices gradually enlarging into castles, and lastly, appearing in spacious areas, encircled by buildings serving alike for convenience and defence. That such are the different gradations, is not only testified by modern experience, but by ancient history, and in particular by that of our native islands.

One of the simplest kinds of regular entrenchment that can now be found, is among those South American Indians, who are just verging towards the first degrees of civilization. Retiring to the top of a hill, they dig three or four ranges of masts around it, each strengthened by a parapet, from whence they can safely annoy an assailing enemy. Sometimes the exterior circumvallation exceeds a league in circuit; the inner parapet or bank is always higher than the outer one, and their dwellings stand in the centre of the whole. Not very dissimilar from this, was the custom of our ancestors during the Roman invasion soon after the birth of Christ. Tacitus, in speaking of the resistance offered to Ostiorius, says, Tunc monibus arduis et si qua clementer accedis poterant, in modum valli saxa preestrit; that is, they secured themselves on rugged mountains, and defended any accessible parts by ramparts of stones. The remains of such an entrenchment, now called Moel Arthur, exist on the top of a mountain in Wales. On the only accessible side void of precipices are two ditches of great
depth, with corresponding ramparts guarding the approach, and the summit has been levelled into a smooth terrace, where the natives assembled, or like the South American Indians, dwelt in their huts. The black and white Catter Thun in Scotland, so distinguished, it is said, from their different colours, are also ranked among the earliest means of defence adopted in that country. Both of these, from the advantage of position, are of great strength, and crown the summit of two hills. The black Catter Thun is of a circular form, consisting of various concentric earthen ramparts, from one side of which issues a rivulet that has made a deep gully in its descent to the level ground. Perhaps the black catter thun is of somewhat more labourous construction; it is of an oval figure, consisting of a stupendous dyke of loose white stones, whose convexity from side to side is 122 feet. It encloses a flat area of ground, 436 feet long, by 200 in breadth, which was consequently either the site of a considerable number of edifices, or received a large body of men. The whole outside is encircled by a cavity resulting from the disposition of the stones. Two deep ditches, of which only vestiges of the second remain, encircle this ancient post, one at the base of the mound of stones, and the other about an hundred yards lower. Foundations of small circular and rectangular buildings are yet perceptible, as also the site of the well. Other entrenchments, apparently of the same kind, are seen in different parts of Scotland; and analogous to the catter thun, is the celebrated circumvallation now called the Herefordshire Beacon, situated on the highest of the Malvern hills. Here the summit is of an oblong irregular figure, 175 feet long by 110 in breadth, quite level, and surrounded by a high steep rampart of stones and earth, and a very deep ditch. Lower down the hill are two irregular areas stretching east and west, each defended by a high bank and deep ditch, and ramparts still further down contributed to complete the system of defence.

Varieties are found in the construction of the simple fortifications, in lofty places where greater labour has promoted the convenience of the defenders. One situated on a high hill in Wales is protected by three stone walls on the only accessible side; the upper ones 15 feet high, and 16 broad. The space at the top consists of an irregular area, full of small rude mishapen cells, some round, some oval, and of different dimensions. Square or oblong cells are likewise seen; one of the former is at least 30 feet long, and several of the round are not less than 15 in diameter, but such cells are of smaller size in other fortifications.

Successive ditches and ramparts were to be overcome before the assailants could reach the concentrated strength of the defenders. On the top of a high hill in Cornwall is such a fortification, called Caer-bran, surrounded first by a deep ditch 15 feet wide, edged with stone, through which is a passage to an outer rampart of earth 15 feet high. Within is another great ditch, three times as wide as the former, and then a rude stone wall, completely encircling the summit of the hill.

People, therefore, in the most barbarous ages, found their account in selecting lofty situations for defence, just as the South American Indians practise, and as is witnessed among the islanders of the Pacific Ocean. The latter, we know, establish their fortifications on rocks or promontories washed by the sea, and which are scarcely accessible by land. The path is intercepted by deep ditches and strong palisades, while the spot chosen on the top of the height will contain but a few huts within its limits. Hence the fortresses of these islands have originated on steep and precipitous rocks, such as Edinburgh, Stirling, and Dumbarton castles, and that of Dunamase in Ireland, besides many others.

Although mankind have usually established themselves on heights, there is one rude kind of edifice found in low grounds in Scotland, which, common consent having denominated the most ancient castle of our forefathers, must not be omitted here; and similar structures are said to exist in foreign countries. These are called Duns, all at this day in ruins, but still exhibiting the general outline of the parts which composed them. Each is the ruin of a cone without, but perfectly circular within, consisting of large flat stones deposited on each other, without mortar or cement. Whether they had any roof, or what was its particular form, is uncertain. It is conjectured, that they might have been divided into stories, and there is always a door close to the ground. The internal diameter of a dun is from 20 to 30 feet, and the walls are of great thickness at the base. Dun Dorndilla is one of the most entire, if a ruin may be called so, that remains; and its measurements have frequently been taken by distinguished antiquaries. This ruin is somewhat less than 30 feet in height, though the surrounding rubbish shews that it must have originally been considerably more. Its internal diameter is 27 feet, and its circumference nearly 150. There is no external aperture found here, or in other edifices of the same description, except the door; but towards the inner court are several openings, to transmit light to cavi ties in the centre of the stone-work. This would lead us to infer, either that such buildings had no roof, or that it was not completely closed at the highest part, if of a conical form. Three successive rows of narrow galleries, or passages above each other, are formed in the thickness of the wall of Dun Dorndilla. They are mutually connected by steps, also within the wall, and lighted from the apertures in the circumference of the inner area. Each gallery is somewhat lower than the height of a man, just wide enough for a passage, and floored with large flat stones, which unite and bind the whole building together. Independent of the apertures, there are other recesses in the wall, which do not penetrate through to the internal galleries. An edifice still more remarkable, called Dunalisaisgigh, or Dun-Alisaig, is also seen in Scotland, on the Frith of Dornoch. It is conical, like the others, built of large rough dry stones in equal layers, each of which contracting an inch and a half as the building rises, produces its peculiar figure. Here the diameter is 30 feet, the circumference 164, and the thickness of the wall 12. About nine feet above the ground, a circle of stones projects into the area, broad enough to walk upon; and one step above these, there are four doors which enter into the chambers of the second story, which communicate by stairs with those below. Both the stories of chambers are as the former, in the heart of the wall, and receive light by apertures to the interior; but their figure and disposal are very different. Entering the door of the
edifice below, a narrow passage on the right introduces the visitor to a small oval cell, and there is the same to the left. Other three entrances from the internal area, at equal distances, likewise lead to small oval cells of a similar description; therefore, each cavity in the wall consists of two oval cells, connected by a narrow passage, from one side of which an entrance communicates to the court.

Some analogous edifices are of larger dimensions, enclosing a much greater space within their circuit, and their walls rising to a considerable height. The latter, however, is by no means proportioned to the diameter of the area, so far as we are at this day enabled to judge. A rude constructed building, consisting of dry rough stones without cement, stands on one of the Orkney Islands; the walls of which are still 45 feet in height, though the interior circle does not exceed 20 feet in diameter. The conical shape is continued only about two-thirds of the edifice, and it is thence cylindrical to the top. A stair of steep narrow steps in the heart of the wall, which is sixteen feet thick, leads to the summit of the ruin; and the whole building is encircled by four or five stories of galleries also in the wall, interrupted only by the ascent of the stair. Broad thin stones serve for the roof of one row, and for the flooring of the next; and light is admitted from the court, by three perpendicular rows of small square apertures.

Such edifices are not invariably situated in low grounds; one which has elliptical chambers, like Dun-Alishaig, stands on a precipitous rock, overlooking the river Brora. But they are not less to be considered as places of defence, from being commanded by adjacent eminences. All that their inhabitants had to dread, was probably being within arrow flight, or the range of a spear, both of which are extremely inconsiderable, when precision is to be relied upon. But though we must necessarily ascribe their erection to a period of remote antiquity, it is difficult to conceive by what means their uncivilized tenants would accomplish it. The doors are in general such as we at present use; but the lintel of some consists of a huge triangular stone, six feet long in each side, and four in thickness. Nay, it is said, that part of the wall of one is composed of a stone 29 feet long and 9 feet thick. We are thus minute in describing these very ancient edifices, as they exhibit remarkable peculiarities, and because an evident similarity pervades the whole, indicating a common origin from the same people.

It is not probable, that the pillar towers found in Scotland and Ireland, and also we believe on the continent, were designed for military purposes; yet intelligent persons have maintained a different opinion. Thus we shall only remark, that they were of great height, extremely slender, and of skilful architecture. Some are 90, 100, even 130 feet high, though not exceeding 15 in diameter at the base. The door is always at a considerable height above the ground, sometimes 8, 10, or 15 feet, and without any remaining communication or means of ascent. We shall afterwards see, that one great precaution in constructing castles, was placing the entrance far above the ground.

It cannot be supposed, that our ancestors remained insensible of the advantages which the regular entrenchments and fortifications of their Roman invaders afforded, and possibly might combine them with their own national modes of defence. Single fortresses, in all countries, naturally arise in place of simple mounds or bulwarks; and those which were thrown up for temporary use, at length became so many encircling walls of strong materials, which could afford protracted resistance to a foe. Sometimes the Romans erected temporary towers on the verge of their encampments during their progress through an enemy's country; and if their operations were to be permanent, these were constructed of stone.

On ascending to an early period, we find an interesting specimen of ancient fortification, far exceeding that of the Scottish dun, in Launceston castle, Cornwall. The remains of a central tower stand on the top of a conical hill, which are of a circular shape, 18 feet of internal diameter, with walls 10 feet thick. About the distance of six feet from the exterior, this tower is encircled by a wall 12 feet thick, lower than its top. After another interval of six feet, is a second encircling wall; beyond which is a third, or breast-work, now in ruins. A circular wall is said likewise to have surrounded the base of the hill, which is judged to be above 70 yards in diameter; and still further off, one more, fortified by towers, and guarded by a ditch on the outside. The area occupied by the three concentric structures on the top of the hill, is about 31 yards in diameter. Some antiquarians date the formation of this edifice anterior to the Roman invasion of Britain: whatever may be the truth in this respect, the difficulty of an enemy surmounting the successive entrenchments can easily be conceived.

In foreign countries, either exposed to hostile invasion or liable to intestine commotion, there are castles constructed on a similar plan. Indeed, we may here remark, that there is scarcely any exclusive or peculiar fashion adopted by one nation which is not at some ancient or modern era seen in another. Rucks, islands, and precipitous heights washed by the sea, have always been favourite situations. The Mingrelian princes in Asia dwell in strong towers, thirty or forty feet high, which are encircled by a second wall of stone. We are likewise told of the fortress of Irivan in Persia, built on the verge of a steep precipice, and surrounded by three walls. The ancient and modern castles, that is, those which exist in modern times, for we cannot tell the precise date of their era, are protected by similar means of defence. Herodotus describes Ecbatana in Media, as being built on a lofty hill, and surrounded by seven walls. All these were of different colours, and each exceeded the height of that adjacent to it. Within the central inclosure, was the residence of the king. It has been argued that Launceston castle in Cornwall, was perhaps built after some design introduced from the East, by those nations frequenting the British coast in quest of tin. This, however, is not a necessary conclusion, because the varieties in fortification in the same country are conspicuously displayed, according to the prevailing sentiments of the people respecting their capacities of resistance. Thus we see round or square towers standing single or combined, encircled by walls or moats, or destitute of both; small, capacious, low or lofty, all as chosen by individuals diverging from common rules, or adopting improvements. But irregularities so numerous
and so great are exhibited, that we can scarcely reduce the different edifices under any certain classification. Our attention shall chiefly be directed to the castles of this and the neighbouring island.

Mr King has appropriated the erection of British castles to nine successive eras. 1st, The small strong Anglo-Saxon tower, one remove from the northern dun; 2d, The large and improved castles of Alfred; 3d, The round Norman keeps, on high artificial mounts; 4th, The beautiful towers of Gundulph about the time of the conquest; 5th, Mixed buildings, where architects were not restrained by any fixed principles; 6th, The magnificent piles of Edward I. derived from foreign countries, uniting the accommodations of a palace with the strength of a castle; 7th, Palaces as completed by Edward III. absorbing the military architecture of castles; 8th, Spacious mansions for residence, and embattled only for the purpose of ornament; 9th, Palaces properly so called. These he considers as including “all the regular successive alterations from rude barbarity to civilization.”

Instead of illustrating the peculiarities of these different fortifications, we shall confine ourselves to some miscellaneous observations on several fortresses with whose structure we are acquainted, and on the means of defence.

The castles with which this island abounded, were, in general, erected by individuals; but we are told they were originally so few in number, that an invading enemy was enabled to over-run the country. From passages in the life of Alfred, it has been inferred that he built only wooden towers; and it has been concluded, that castles walled with stone, designed both for residence and defence, are not of greater antiquity than the conquest. Then it is affirmed by our older historians, that the whole kingdom was harassed with building castles by command of the sovereign; and the turbulent condition of the succeeding reigns contributed to increase them more and more. They served as well for a receptacle to the lawless, as a protection for the orderly part of the community; but from the powers usurped by the rude and ignorant owners, they at length became the residence of so many petty tyrants.

Stephen is reported to have encouraged the erection of castles in the earlier part of his reign, and no less than 1115 were built before its close, so that the face of the country was entirely covered with them. However, the licentious conduct of those who inhabited them becoming intolerable, a treaty was entered into with Henry Duke of Normandy, whereby all constructed within a certain period should be destroyed. Many were therefore raised to the ground, and subjects were prohibited to erect others without special licence. Probably the means of obtaining the royal permission was not of difficult attainment, and in the subsequent reigns, subjects continued to build castles until they came to be no longer considered indispensable to safety.

It has appeared extraordinary to some, that so many castles could be erected in England within so short a time as from the conquest to the end of Stephen’s reign; but let us consider what was done in Ireland during the reigns of Elizabeth and James. The former obliged every grantee of forfeited land to build a fort or castle for the protection of his family and tenants, and the stile of fortification was to be proportioned to the extent of his grant. Lord Aubigny having obtained 3000 acres, built a strong castle 50 feet long by 28 in breadth, five stories high, flanked by four round towers; adjoining to it was another fortification, 60 feet square, flanked by two turrets 15 feet high. This castle stood where five public roads met, and kept the neighbouring country in awe. In a few years one hundred and sixty-eight fortifications, great and small, arose in the six northern counties; and it has been calculated that there were, most likely, not fewer than three or four thousand in the whole island.

After all the intermediate stages of military architecture, to which the labours of individuals, or even of uncivilized states, gave birth, we at last find the completion of strong and extensive edifices, artfully constructed, and secured against the warlike assaults of an enterprising enemy.

A large portion of ground, sometimes extending to many acres, was enclosed within the precincts of a castle, which consisted of various important parts. First, the barbican, or watch tower, an advanced post, stood beyond the moat by which the castle was encircled. On the verge of the moat was a wall, called the wall of the outer bailey. A vacant piece of ground, contained between it and another wall, was called that of the inner bailey. Within this second wall were the different edifices appropriated to the garrison; and the citadel, or keep, the main place of refuge and security to the defenders. The walls were strengthened by round or square turrets, properly disposed; and we read of ingenious contrivances, among those of the most ancient construction, for communications among the besieged. The city of Byzantium had seven towers, from one to another of which sound could be transmitted, and in such a manner, that no confusion or interruption ensued. In like manner, we find flues or cavities among the remains of some of the castles of this kingdom, which it is likely were intended for no other purpose.

The barbican, which constituted the sole entrance into the castle, was connected to the moat by a drawbridge, so that it might fall into the hands of an enemy without great danger to the besieged.

The ditch, which was either wet or dry, was frequently of great breadth and depth; if dry, subterraneous passages from the castle sometimes communicated with it, through which cavalry could issue. Here there was another drawbridge connected with the external rampart or wall of the outer bailey, which was lofty, flanked with towers, and had an embattled parapet, pierced with chinks, to give a view of the surrounding objects. The entrance to the outer bailey, and also to the inner, was through a strong gate, situated between two towers, and rendered yet more secure by a ponderous portcullis, sliding like a window sash in a groove of the wall. It was not one gate only which protected the garrison; two or even three, single or double, are seen in ancient castles, each with its iron portcullis: all which had to be forced before access could be gained to the interior.

The keep, or dungeon, which our modern poets absurdly call the donjon, in imitation of the barbarous French of ancient times, frequently, and perhaps most properly, stood in the centre of the whole
structure, on an eminence. But its place was by no means uniform; and it is very often situated at an angle of the inclosure, or sometimes at one side. Its figure was round, square, or polygonal; its height and diameter indefinite. The walls were always of great strength, even eighteen or twenty feet thick; it was guarded by a moat, and its entrance was through a machicolated gate, that is, where there were gratings or apertures above, through which melted lead or scalding water could be poured on the assailants, or heavy weights, that could be retracted by chains, employed to crush them below.

In vulgar acceptation, the keep is now understood to be the place formerly devoted to the confinement of prisoners alone, and that it was invariably a subterraneous dungeon: but, on the contrary, it was always a lofty tower, and the residence of the principal persons of the castle. We know not whence the name of dungeon originates; but we cannot coincide in the conjecture of those antiquarians, who think it is from the scanty light received through the narrow apertures of thick walls. If the keep was small, a single apartment occupied each story; in large castles, it was a round or square tower of four or five stories, each containing more than one apartment, with turrets at the angles of the latter, in which were stairs. Frequently in the centre of the ground floor there was a well of terrific depth; and there were also frightful vaults below for the reception of prisoners. The stories were divided by strong arches or simple flooring, and the summit was usually crowned by a platform and embattled parapet, whence the garrison could descry the approach of their enemies.

To prevent the access of missile weapons, the only windows were narrow loop holes, or long chinks in the wall, which in itself was of such thickness, as to admit of chambers or stairs in its substance.

Very great varieties, however, are exhibited by the keeps of successive ages, or perhaps of the same; and considering it as the ultimate place of refuge to the besieged, we cannot be surprised that their utmost skill and efforts were lavished on its structure. All single towers unconnected with walls or circumvallations, come under the general name of keep, for in fact a keep is nothing but a tower. Strength was more the object than convenience; and if in any situations the accommodation of the defender was studied, it was in such a way that the security of the castle might not be endangered. Thus, in the lower stories, nothing but long narrow loops and orielts admit the light; and where there are windows, they are cautiously placed so high as to be beyond the hazard of projectiles, or if one should enter, it will strike the interior arch in the substance of the wall. There are instances where the loop is contrived obliquely inclining downwards, so that if a missile weapon entered, instead of reaching the interior of a chamber, it was conducted up to the roof beside the loop itself, on which its force was spent.

The keep of Coningsburgh castle in Yorkshire is of remote antiquity, and has been ascribed by several antiquarians to the fourth or fifth century. It rises from a low mount at one angle of the area that formerly constituted the whole castle. From the surface of the mound, the diameter of the tower gradually decreases until about 18 feet in height, where there is an entrance by a flight of steep narrow steps to the inte-
neither was the dungeon for confinement of prisoners always under the principal tower. The walls of Cockermouth Castle in Cumberland form nearly a square, about 600 yards in compass, flanked by several square towers. Within are two courts; and on each side of the gate entering into the second are two deep dungeons, vaulted at the top, with a small opening, through which the prisoners were lowered down: two narrow slits, level with the ground, admitted the provisions, light, and air. Each dungeon is capable of containing 50 persons. Such dungeons were sometimes in the vestibule of the entrance into the tower; but little regard was paid to the conveniences of those unfortunate captives, who fell into the hands of their enemies: and numerous examples are recorded of their being starved to death from mere negligence.

Castles, large or small, enclosing courts within their precincts, are common throughout the island, and at the same time exhibit great irregularity of structure. The castle of Kildrummy, in the north of Scotland, was of a pentagonal form, and defended at each angle by a strong and lofty tower; the remains of one is still judged to be 50 yards in height. It contains a spacious court, exceeding an English acre in size; and there are indications of a subterraneous passage, for communicating with a deep glen below, through which, it is affirmed, both men and horses could reach a stream flowing in its centre. Before the use of cannon, this place is said to have been thought impregnable.

Enlarging the extent of castles admitted of an irregular assemblage of buildings, and as the successive owners attended to both convenience and defence, their alterations and additions frequently exhibit a confused, and sometimes an unsightly pile. Many were so spacious as to have churches or chapels, we believe even monasteries, attached to them, and great halls were fitted up for the hospitable entertainment of retainers, or dependents on the proprietor. The great hall of Naworth castle, which is a large square pile, surrounding a court fortified by square towers and battlements, is an hundred feet in length. In Raby castle, which is an extensive irregular edifice, with square towers, built in 1378, is a hall nearly of equal dimensions with the former, in which 700 knights, who were vassals of the family owning it, are said to have assembled: and, as is well known, the unfortunate Queen Mary, by a cruel sentence of the English court, was beheaded in the great hall of Fotheringhay castle.

The ancient castles of Britain and Ireland, and in most parts of the continent, were built of stone and lime; but the latter, by mixture with water, was reduced almost to a fluid state, and uncommon quantities poured into the walls. A strong and durable bulwark was thus produced which the lapse of succeeding centuries is required to impair.

The walls of the spacious castles built by the Moors, are formed of mortar only, and entirely without stones. Having undergone the necessary preparation, the mortar is rammed hard into moulds, first for a foundation; when this is done the moulds are removed, and receive another supply, which is also allowed to harden; and by successively shifting the moulds higher and higher, the wall gradually rises, and by the quality of the mortar, and the influence of the sun, becomes as hard and durable as stone.

Block houses, or wooden towers, were also frequently erected, though rather for temporary use than permanent fortifications; nor is the use of them unknown in modern times.

The style of the ancient castle was necessarily such as to be best calculated for defence against the usual engines of war, and the repeated assaults of an enemy. Perhaps a considerable time elapsed before the first invented cannon supplanted the catapults, mangonel, trebuchet, and warwolf, which were all employed to discharge enormous stones against the besieged. These machines could throw a weight of two or three hundred pounds; and an instance is related where a certain general being displeased with the purport of a mission from a neighbouring enemy, loaded his engine with the messenger, and threw him within the lines. While showers of stones were discharged against the besieged, battering rams were forcibly impelled against the gates, and moveable towers, pushed forward on wheels, enabled the assailants, from different stages, to mount the walls. Fire and mining were both employed, and the defenders successively driven from their strongest posts: thus, in four assaults by Henry III. on Bedford castle in 1224, "the barbican was taken by the first, and by the second the outer ballium. The old tower, on the third attack, was thrown down by the miners, whereby with great danger they rendered themselves masters of the inner ballium, through a chink. At the fourth assault the miners set fire to the tower, so that the smoke burst forth, and the walls were rent by broad fissures, which compelled the garrison to surrender." While the attack was going on, the besieged were not idle: the stones projected by the assailants were returned; if the force of the battering ram was directed against the wall, wool packs were interposed; likewise logs of timber were thrown down to crush the enemy, or their machines were destroyed by immense weights falling upon them. While the besiegers attempted to force the gates, burning sand or boiling lead were poured upon their heads; and, if they did succeed, a ponderous portcullis, descending in its frame, opposed their progress.

It was not of less importance in ancient times to individuals, that it is now to a nation, to prevent an enemy from gaining a fortification. The unfortunate defenders were generally put to death, and to an ignominious one in proportion to the bravery they had displayed in resistance. This horrible custom, practised only by a few modern barbarians, is of ancient date. Joshua, the leader of Israel, murdered his captives in cold blood. Alexander the Great having besieged Arimazes, a soldier who had established himself on a mountain with 30,000 men, gained the strongest posts above his enemy. Arimazes offered to surrender, on condition that his own and his followers lives should be spared; but the victorious monarch rejected terms of capitulation. Therefore Arimazes having descended with his relatives and chief men, Alexander cruelly scourged them, and then crucified them at the foot
of the hill. Mankind are too sanguinary to shun such examples; and there are repeated instances, as at Bedford, Rochester, and many other places, where the vanquished garrison were promiscuously hanged by their ferocious conquerors.

Where petty states are confined within narrow limits, a uncommon number of warlike edifices will always be found, both to guard against internal divisions, from which unsettled governments are never free, and to serve as a security against mutual invasions. But from the prevalence of the feudal system in these kingdoms, they were alike the protection of the tyrannical overlord, and the unprincipled marauder, who subsisted by the booty acquired from his defenceless neighbours. A savage herd of retainers was sometimes kept, to enable the lawless owner to resist his native sovereign, or to aid him in wanton oppression of his own vassals, or those of others. Invested with absolute powers and privileges, he could with impunity condemn an offender, real or imaginary, to a dungeon, or even inflict a capital sentence upon him; and it was judged an act of clemency, if his sentence extended only to suspension of the culprit a few hours by the heels, instead of by the neck on a gibbet. If remote from the seat of administration, as in Ireland, where the people are still in an uncivilized state, or in the northern parts of Scotland, it was scarcely within the power of government to root out the turbulent chieftains. No sooner were hostile measures manifested against him, than his whole clan, by one common voice, arose, and formed of themselves an army for his defence; he retreated to the fastnesses of the hills, or fortified himself in his castle in some wild and inaccessible quarter, where he bid defiance to his assailants.

From the total change in warlike operations, the abolition of the feudal system, and the greater civilization of this island, the castles in the hands of private individuals have gradually been allowed to decay. A long protracted interval of internal peace renders them unnecessary to the crown, and the watchful eye of the police guards the safety of the subject, without his seeking places of refuge. Those that still remain, are rather calculated for ostentation than defence: We should therefore view the burwarks that surrounded our ancestors with double interest, and felicitate ourselves on existing in times, when they are no longer required for our personal security.

CASTS. These are impressions, figures, or statues, formed of plaster of Paris, sulphur, metals, or other substances.

Sculptures of every description are so tedious and expensive, that a more speedy and economical method is adopted, of obtaining resemblances in plaster of Paris. This is attended with the convenience of the materials being easily procured in a state of preparation for immediate use as an impalpable powder; and nothing more is required than an addition of water to reduce it to the consistence of thin paste or cream.

A mould is always necessary for a cast, in whatever substance it is made, and it is formed according to the nature or figure of the subject. In taking a cast from a medal, for example, it is to be laid on a smooth surface, and encircled by a hoop of card or paper, of the breadth desired for the thickness of the mould. The plaster, reduced to the consistence of thick cream, is then to be poured over the medal, and allowed to dry. Thus a mould is formed, which is hollow, to receive the cast. Its surface must be brushed over with a camel-hair pencil, dipped in olive oil; observing if there are any holes, previously to fill them up by a similar expedient, with thin plaster, which will also prevent holes in the cast. The mould is next to be surrounded with a card or paper hoop, as broad as the thickness of the cast, and the plaster, reduced almost to a fluid, poured in. By allowing it to dry, the cast is formed, and many successive casts may be obtained from the same mould.

If the subject be larger than a medal, we must use a wooden frame, within which the subject is laid, as a certain degree of strength is necessary to resist the pressure of the fluid plaster. It is essential to observe, that immediately after being reduced to the proper consistence, the plaster must be poured on the subject, as by standing it becomes unfit for use.

This, however, is a method adapted only to the most simple impressions, and where none but one side or surface is to be taken off. If there are several surfaces, the mould must be divided into such a number of parts as circumstances may require. Supposing a cast of a round or angular subject is desired, the plaster must not be reduced nearly to fluidity as before, but to the consistence of paste. This is to be applied by the hand as a coating on the subject, and slightly pressed, so as to be adapted to all its different parts, and then cut through in several places with a very thin-edged knife. After being of such consistence as to retain the impression, the pieces are allowed to become completely dry, having, previous to the division, received various pencil marks, that they may be more easily united for the cast. Considerable dexterity is necessary in dividing the pieces of the mould asunder, and in properly adapting them for the cast they are to receive. After being completely dried, they are to be well greased and united, and the plaster, as before, reduced almost to a fluid state, poured in so as to fill the whole cavity. The mould is then taken off, and the cast appears.

Large casts are generally hollow, both to be lighter and to save the materials. In that case, a wooden core is suspended within the mould, with the thicker end outwards, so as to be more easily with-
drawn. If the cavity be of an irregular figure, the core may consist of clay also suspended within the mould by cross wires, or otherwise, and afterwards picked out by a sharp pointed or hooked implement.

In casting a bas relief from wax, or to obtain another cast of the same substance, the figure desired is first to be modelled on wood or glass, and being surrounded by a frame, plaster is poured over it. This is allowed to dry, and when removed, serves to receive the cast. If dipped in water, and suddenly withdrawn, the wax poured in will not adhere, and comes out quite clean.

Delicate and beautiful casts are obtained in sulphur, which, of late years especially, has been successfully employed to preserve representations of the most elegant sculptures of antiquity. The mould, for a cast of this description being formed of plaster, is repeatedly dipped into half a pint of boiled linseed oil, mixed with an ounce of spirit of turpentine, by which the surface is hardened. A quantity of sulphur being melted in an iron ladle over the fire, and allowed to flame for five or six minutes, is taken off, and after cooling a little, is poured into the mould; and the cast having stood a few minutes, may be taken out. Adding a third part of vermilion, and stirring the mixture well together, will produce a cast of a fine red colour. When the cast is taken from the mould, it should receive a polish, from being rubbed over with clean cotton.

Small metallic casts were easily obtained from moulds of plaster, clay, or sand, the latter of which are preferable for those of larger size. In all cases, particular care must be observed to have the mould perfectly dry, otherwise the cast will be disfigured by blow-holes or pores, and the safety of the artist endangered by explosions, from the rarefaction of the fluids remaining unexpelled. Yet as very few casts of considerable size are to be obtained free of blow holes, these must necessarily be filled up, either by screwing in a portion of the same substance, or beating it in. The latter is the better method, as the interstice is more completely filled up; but instead of simply filling up the pore in the cast taken from the mould, the defect is more completely cured, by enlarging it somewhat more, and then beating in a piece of metal. If the cast has to undergo a considerable change after coming from the mould, it should be beat over the whole surface with a hammer of a few ounces weight, which will close all the small blow-holes, and fit it for receiving a suitable polish. This method cannot be adopted where a complete and perfect figure from the mould is desired.

Equal quantities of pumice-stone and plaster of Paris, with a third of clay, is considered a suitable composition for moulds to receive small metallic casts; or two parts of fine brick-dust, added to four of plaster, and mixed up with water until of the consistence of cream. Supposing a small animal, a bird, frog, or lizard, is to be imitated, the subject, after being moistened with spirit of wine, is to be suspended by threads, in a trough or frame, which must then be filled with the composition. But a channel to the cavity which the subject occupies must be preserved by a strong thick wire, proceeding from its extremities, to above the surface of the composition. This, when withdrawn, will leave a conduit for receiving the metal. Other vents are necessary, in all moulds, large or small, for allowing the included air to escape. The subject thus remaining inclosed, and the wires being withdrawn, the mould must be gradually exposed to successive degrees of heat, until becoming red hot, whereby the subject will be totally consumed, and a cavity left, corresponding to the space occupied by its parts. But as some particles of dust or ashes may remain after every precaution to discharge them, the cavity should be filled with mercury, by which means they will rise on the surface, and may be poured out along with it. The mould, when converted to use, must be rendered very hot, and gently struck after receiving the metal, that access may be gained to all its parts, and the expulsion of air facilitated. After being allowed a sufficient time to cool, the cast is removed.

Metallic casts of large subjects, are great and important works, wherein the concurrence of many different circumstances are essential to the success of the artist. The ancients were well acquainted with the various methods practised in casting in bronze, as appears from the beautiful reliefs still preserved to us, and the description of the busts and statues of divinities in their temples. It has been conjectured, however, that none of them were of extraordinary size; that they were in general little if any larger than life, and that the colossus, celebrated as one of the wonders of the world, could only have been formed of plates of metal. Some of the moderns have peculiarly excelled in this branch of the arts, and have themselves minutely laid down the rules whereby to obtain a successful metallic cast.

Here, as in all other cases, a model of the cast is built on a skeleton, composed of wood or iron, exhibiting the angles and curvatures of the figure desired. The famous artist, Benvenuto Cellini, affirms, that this skeleton should be covered, to nearly the size of the figure, with clay, well beaten together with a quantity of rags, by an iron rod, and the mixture thus kept several months to macerate. It will then form a paste, which may be wrought up with the hand, and is fashioned into shape. When sufficiently baked, and having been allowed a considerable time to dry, that no contraction may ensue on subsequent heat, this rude resemblance of what is to be cast is covered with a coating of wax, not less than an inch thick, on which the artist impresses the exact form of what the cast is meant to exhibit, and varnishes over the surface. A mould is next prepared of plaster, or of a mixture of clay and sand, which it is exceedingly difficult to procure of suitable quality, and from this cause the works of skilful statuaries have failed; and being applied around the model, is allowed to become perfectly dry. This mould, it is evident, is to receive the cast, but a different proceeding from taking it to pieces is employed to obtain a cavity. It is perforated by innumerable channels through the clay to the surface of the model, which also are all filled up with wax. The greater the number, the more is the chance of success.

When the model is thus completed, and surrounded by the mould, it is lowered down into a pit, by means of a crane, and a brick wall, capable of resisting considerable pressure, built around it. There it is exposed to a moderate degree of heat, by which
the waxen coating is melted from within the mould, and runs off by conduits, but, at the same time, leaves the interior surface corresponding with the outline which it occupied. For a statue larger than life, two days and nights are required for the operation, during which time it is necessary that the heat be moderate, or otherwise the wax might boil up against the mould and injure it, though the varnish contributed to render it smooth and equal. It is likewise necessary that the pit be somewhat deeper than the height of the figure, in order that the metal may rise above it, and avoid the imperfections which would otherwise arise.

All the previous preparations being completed, a brisk fire is kept up in the furnace, and the metal reduced to a state of perfect fusion, the channel of communication is opened, and it begins to flow. The numerous conduits introduce it to the interior of the mould, and the space before occupied by the wax is speedily filled. After the cast has stood a day or two to cool, the mould is taken off, and it is elevated from the pit by a crane, when it appears altogether covered by spines. These are the metal which filled the channels of communication; and by their removal, and the subsequent polish, the work is brought to perfection.

It has been maintained, that the ancients were such masters of this branch of casting, that they could take figures from the mould free of spines, and so clean and perfect, as not to require finishing by the chisel or the file. But this has been denied by the most intelligent among the moderns, and certainly it would be granting the artist a wonderful degree of skill to suppose it the case.

Casts of all different shapes and sizes may be obtained by practising this method in detail. Some statues weigh one or two thousand pounds or more, according to the size and thickness of the metal. One of Louis XIV. at Paris, weighing above 60,000 pounds, was obtained from a single mass of fused metal, which flowed fifty feet between the furnace and the mould. See Dossie’s Handmaid to the Arts; and Benvenuto Cellini Due Trattati dove veggono infatti segrati nel Gettare le Figure di Bronzo. (c)

CASTS, INDIAN, denote the four grand tribes, or orders, into which the population has been divided from the remotest antiquity. The Hindoos records afford no authentic documents to ascertain the origin of this singular arrangement; and the earliest Greek authors who treat of the history of India, content themselves with mentioning the fact without attempting an explanation of its origin. The information of the Greeks does not seem to have been very correct on this subject; for Strabo, Diodorus Siculus, and Adrian, affirm, that the Hindoos were divided into seven castes, or classes: their mistake has probably arisen from confounding with the casts, the various employments allotted to different classes in the community, and from which they are strictly forbidden by the Hindoo laws to depart. No fact is more clearly ascertained, than that there never have existed but four casts in India. The first, or that of the Bramins, (see BRACHMANS,) was deemed the most sacred; and the members of it, had it for their province to study the principles of religion, to perform its functions, and to cultivate the sciences. They were the priests, instructors, and philosophers of the nation. The members of the second order, (the Ketri,) were intrusted with the government and defence of the state. In peace they were its rulers and magistrates; in war were the generals who commanded its armies, and the soldiers who fought its battles. The third, (the Byse,) was composed of husbandmen and merchants, and the fourth, (or Soodra), of artisans, labourers, and servants.

When any person has been guilty of egregious misconduct, such as neglecting or violating the precepts of his religion, he then becomes an outcast from his tribe, and is subjected to a species of excommunication, which brings along with it the most terrible consequences. The persons thus excommunicated are denominated Pariahs, and sometimes Chandals, and their condition is inconceivably wretched. “No person of any cast will have the least communication with them. If a pariar approach a mayor, i.e. a warrior of high cast, on the Malabar coast, he may put him to death with impunity. Water or milk are considered as defiled even by their shadow passing over them, and cannot be used until they are purified. It is almost impossible for words to express the sensation of wileness that the name of pariar or chandala conveys to the mind of a Hindoo.”

Robertson’s Disquisition concerning India: Appendix.

Though it is impossible to fix the period when this division into casts took place, yet it is easy to conceive the circumstances under which it has originated. It must have been established at a time when the regal and sacerdotal offices were united in the same individual; for nothing but the sacredness attached, in early ages, to the priestly character, combined with absolute authority on the part of the person who was thus revered, could have given birth to such a monstrous institution, so contrary to reason, and so subversive of the natural rights of man. This evidently carries back the origin of the institution into the remotest antiquity; for it was only in the primitive ages of the world that this formidable union of regal and sacerdotal power existed in the person of the same individual. When once the division into casts was established, we need not be surprised at its continuance. The human mind needs a stimulus to excite it to any efforts of excellence; and when this stimulus is not only withheld, but positive discouragements applied, we can only expect the mind to remain in a state of torpor and lasting immaturity. This effect has been produced to a very great extent on the immense population of India. The mind being chained down to some grovelling employment, above which it is forbidden to aspire, must seek comfort from dismissing even the consciousness of exertion, and the desire of improvement: and the favoured few, who are permitted to explore the sources of knowledge, being secure of respect altogether independent of their abilities, or attainments, have but little inducement to pursue the rugged paths of science.

By the numerous subdivisions into what may be called professional classes (for every individual is bound by the law to follow the profession of his ancestors,) a considerable degree of perfection in the mere mechanical operations of art may be expected. In this respect the Hindoos have made some approach, to that minute division of labour which has had so much influence in promoting the success of
the arts and manufactures in civilized countries. But none of these pleasing associations occur to the mind on contemplating the perfection of Indian workmanship, which never fail to present themselves on considering the improvement of the arts in other countries. In the latter case, the proficiency of the artist is in general an indication of enlargement of understanding, and of scientific attainments; in the former, it is rather a proof of mental degradation, when we consider that mechanical dexterity in the arts has arisen from the restriction of the faculties to one minute point, beyond which they are not permitted to wander, and in which they have attained perfection by expending all their energies in one unconnected object.

Dr Robertson having inadvertently said in his *Disquisition concerning India*, that "what now is in India, always was there, and is likely still to continue;" some writers have set to work to prove him, without doing him the justice to acknowledge that he himself has corrected the assertion in a note, and admitted that very considerable changes have taken place in Hindoo customs and manners. We are happy to have it in our power to state, that the influence of the pernicious system of casts which has so long prevailed in India, is almost daily diminishing, and in many cases is scarcely felt. This is so contrary to what has been so frequently asserted on the subject, that it is necessary for us to produce our authority, which we hope will appear decided and unexceptionable. We quote from Mr Colebrook’s *Remarks on the Husbandry, &c. of Bengal*; a gentleman who was long a provincial judge in India, and who is well known for the accuracy of his information on every subject connected with the customs and literature of India. "They (the Hindoos) are, as it is well known, divided into four grand classes; but the three first of them are much less numerous than the Soodra. The aggregate of Brahmins, Kettis, and Byses, may amount at the most to a fifth of the population; and even these are not absolutely restricted to their own appointed occupations. Commerce and agriculture are universally permitted; and under the general designation of servants of the other three tribes, the Soodras seem to be allowed to prosecute any manufacture. In this tribe are included not only the true Soodras, but also the several castes whose origin is ascribed to the promiscuous intercourse of the four classes. To these also their several occupations were assigned; but neither are they restricted by rigorous injunctions to their own appointed occupations. For any person unable to procure a subsistence by the exercise of his own profession, may earn a livelihood in the calling of a subordinate cast, within certain limits in the scale of relative precedence assigned to each; and no forfeiture is now incurred by his intruding into a superior profession. It was, indeed, the duty of the Hindoo magistrate to restrain the encroachments of inferior tribes on the occupations of superior casts; but under a foreign government this restraint has no existence. In practice, little attention is paid to the limitations to which we have here alluded; daily observation shows even Brahmins exercising the menial profession of a soodra. We are aware, that every cast forms itself into clubs or lodges, consisting of the several individuals of that cast, residing within a small distance; and that these clubs, or lodges, govern themselves by particular rules and customs, or by-laws. But though some restrictions and limitations, not founded on religious prejudices, are found among their by-laws; it may be received as a general maxim, that the occupation, appointed for each tribe, is entitled merely to a preference. Every profession, with few exceptions, is open to every description of persons; and the discouragement arising from religious prejudices, is not greater than what exists in Great Britain, from the effects of municipal and corporation laws."—*If these facts and observations be not considered as a conclusive refutation of the unfounded assertion made on this subject, we must appeal to the experience of every gentleman who may have resided in the provinces of Bengal, whether a change of occupation and profession does not frequently and indefinitely occur? Whether Brahmins are not employed in the most servile offices? and whether the Soodra is not seen elevated to situations of respectability and importance? In short, whether the assertion above quoted, (respecting the influence of the cast in preventing improvement in commerce and agriculture,) be not altogether without foundation." *Remarks on the Husbandry, &c. of Bengal*, p. 171.

From this passage it will appear that another assertion made by Dr Robertson, and by almost all other writers on Indian casts, is without foundation. He says in the Appendix to his *Disquisition*, "though the line of separation be so drawn, as to render the ascent from an inferior to a higher cast absolutely impossible, and it would be regarded as a most enormous impolicy, if one in a lower order should presume to perform any function belonging to those of a superior cast; yet in certain cases the pundits declare it to be lawful for persons of a high class to exercise some of the occupations allotted to a class below their own, without losing their cast by doing so." This is so far from being the case, that no forfeiture is incurred by intruding into a superior profession, and the Soodra is permitted to prosecute any manufacture, under the designation of servant to the superior casts, by which he frequently rises to wealth and eminence; whilst the lazy Bramin, who rests satisfied with his divine indefeasible right to pre-eminence, sinks into poverty and merits contempt.

The institution of casts, and the restriction to particular professions, have always been regarded as the chief obstacles to the improvement of India. From what we have stated, however, it does not appear that they are so formidable as is generally apprehended. The natives themselves find it impracticable to observe these restrictions; the inconvenience of which is so great, and their absurdity so glaring, that the only wonder is, that they have maintained their ground so long. Our European settlers, however, and those in particular who have at present the greatest power in India, have uniformly acted as if it were essential to the safety of their government to uphold the present system of degradation and superstition. The three superior casts, the Brahmins,
Ketri, and Byse, scarcely amount, when taken together, to a fifth part of the population; and yet for the sake of these, the great mass of the people must be doomed to perpetual ignorance and servitude. This certainly is monstrous; but it is the natural system of despotism which founds obedience, as well as devotion, in ignorance. We cannot hope to see these evils remedied, till Britain, or whatever other foreign power obtains the dominion of India, find it expedient to circulate other laws respecting it than those of gain; but in the present state of things, it is found more convenient to employ the established engine of superstition, than to communicate liberty and happiness to so many millions of the human race.

CASUARINA, a genus of plants of the class Monocotyledons, and order Monandria. See Botany, p. 320.

CATACOMBS, are subterraneous galleries and chambers appropriated for the reception of the dead.

Most nations emerging from barbarity have testified a pious anxiety respecting the disposal of their dead, and have erected monuments to perpetuate their remembrance. Some, instead of at once committing bodies to the earth, where they might return to their pristine dust, have deposited them in natural caves, or formed artificial excavations below the surface, where they might be preserved entire from decay. Such was the practice of the Egyptians, which led to the construction of catacombs; and more recently, the Guanches, or aborigines of the Canary islands, adopted an easier expedient of depositing their dead in caves, where three or four hundred bodies may be seen collected together.

The most ancient catacombs with which we are acquainted, are those of the Theban kings; as they can be traced during a period of 5000 or 4000 years. In the age of Diodorus, long after the city of Thebes itself was destroyed, it appears that 17 of 47, the original number, still remained; and Strabo also speaks of about 40 sepulchres of the Theban kings.

The Egyptians, believing that if the human body could be kept entire, it would be revisited by the soul, contrived, by means of embalming, to preserve it from decay. Then it was deposited in catacombs excavated in the earth, to await the return of the animating principle. Hence resulted those wonderfully extensive and intricate subterraneous galleries and chambers which have remained to the present day.

Excavations are always found in the vicinity of the most extensive cities; and they are also seen in remote and sequestered places. But those of Thebes, from the reputed splendour of the city, have been viewed with peculiar interest during many succeeding ages.

The whole chain of mountains in the neighbourhood of Thebes is penetrated for almost three-fourths of their height, by an incredible number of openings, leading to an immense labyrinth of catacombs. Those of the kings, of which the same number can probably still be recognised as described by Diodorus, occupy a deep ravine, flanked by the bed of a torrent, in the centre of the mountain Lybicus. They are between six and seven thousand paces from the banks of the river Nile, and were gained by an artificial passage.

Proceeding along the valley, the traveller unexpectedly discovers openings in the ground, with a gate-way in a simple square frame; an ellipse bearing

a beetle, or the figure of a man with a hawk's head, Catacomb. is seen in the upper part, and beyond its edge two figures kneeling in the act of adoration. Each gateway in the valley is an introduction to a gallery, leading to the royal sepulchre. At the distance of forty paces within is another gateway opening to a second gallery as broad as the first, and 24 feet in length; and to the right and left of these galleries are small chambers. A third gallery succeeds, communicating with a chamber 18 feet square, above the level of the other apartments; from it is an entrance to a gallery, which, added to a subsequent one, is 64 paces in length. At their extremity is a corridor of 16 paces, leading to a chamber eleven paces square, connected by a short gallery to another chamber of the same size. The royal sarcophagus is next seen, in a spacious saloon twenty feet square. But beyond this is even another chamber, of still larger dimensions. Hence the intricacy of such subterraneous passages may be conceived, the total length of the excavation here spoken of being 255 paces. It is not to be understood, however, that all the catacombs of the kings are of the same dimensions. As equal opportunities have been wanting to ascertain the fact.

The whole sarcophagi have long ago been violated, and the bodies of the kings carried away or destroyed. But their enormous size, and the rugged way through which they were necessarily conducted, must excite our admiration. One consists of a huge mass of granite, 16 feet long, six broad, and eight high. The lid is also a single block of stone, bearing the effigy of a king. The sarcophagus has been worked in the place which it now occupies; which would seem to add to the difficulty, already incredible, of conveyance over the mountains, and along the passages below. But the ancient inhabitants of that territory had always some stupendous work in view, and which it would require ages of our comparatively feeble faculties to accomplish.

Though all the royal sepulchres have been violated, the French traveller, M. Denon, found the fragment of a mummy in one, and also an ancient patera. We believe that nothing besides has for ages been discovered here, which shews how carefully the later Egyptians, or more modern Arabs, have ransacked them.

The whole extent of catacombs is covered with hieroglyphics and paintings, generally in fresco, of the most fantastic figures, from which the grotesque of the Romans is supposed to have been derived. But the preservation of these figures is wonderful, considering how probable it is, that four thousand years may have elapsed since their execution. The paintings were as fresh, to all appearance, as on the day when they were executed, in eight lately visited, except in two places where they were injured by the access of rain. It is said that the Romans endeavoured to remove one of the royal sarcophagi from its site, and levelled the ground below it, to facilitate their undertaking.

The other catacombs in the same chain of mountains are usually on a similar plan, especially those conjectured to have been appropriated for the poor. From an opening towards the east, a passage about 20 feet long proceeds in a straight line, or turns off at an angle, supported by pillars or pilasters. At the
Catacombs.

The extremity of this gallery is a pit from 40 to 60 feet deep, communicating with long subterraneous passages, rudely shapen in the rock, which terminate in a chamber about 30 feet square.

The catacombs of the more opulent ranks of the ancient Thebans, or their immediate successors, were lower on the mountain. In proportion as the height of the excavation increases, they are more richly decorated: the colours of the paintings are brilliant, and the sculptures elegant and well-defined. Among the innumerable subjects displayed throughout the catacombs, one chamber is devoted to warlike weapons, another to the implements of husbandry, or a representation of agricultural operations. All ordinary occupations or amusements are exhibited; hunting, fishing, trafficking, and the like. Yellow figures are executed on a blue ground in the royal catacombs, with as much taste as modern edifices would require. Headless trunks are seen; black men who had suffered decollation, and also their executioners holding a sword coloured red. Sometimes religious or funereal processions are exhibited, sometimes games or imaginary subjects. The most singular and apparently absurd figures are displayed. Those of men larger than life, or dwindling to a pigmy size, men with the heads of birds or beasts, or asses raised on their hind legs. It has been conjectured, that the history of each of the ancient Egyptians deposited in the catacombs may be traced on the walls, and that the paintings represent their occupations in life.

Mummies are still found in the Theban catacombs, not in niches, but resting on beds formed entirely of small images of baked earth. They are swathed up, and lie in regular order on the ground. Almost the whole of these cemeteries have been rifled of their contents, either in search of treasure, or for the sake of obtaining the resin with which the head and belly of the mummies are filled. Hence the passages are obstructed by heaps of bones and decaying fragments of mortality, and it is rarely that an entire mummy is discovered. Nevertheless there are still some, such as those just mentioned, which until lately were undisturbed; and on removing the bands in which they were swathed, some rolls of the ancient papyrus, in good preservation, were found. The nails both of the hands and feet are gilt in many mummies, and sometimes two rolls are seen, which are supposed to contain a certain form or order of prayers for the deceased.

A mountain in the neighbourhood of the ancient Eileithia, is also penetrated by numerous catacombs, the entrance to each of which is guarded by two figures armed with clubs, in the sides of an arch which forms the gateway. In one of these recesses are statues of men and women as large as life. But it is chiefly by paintings, as before, that the walls are ornamented; and while the different operations of life are performed, persons are always present, apparently recording them in writing. Here are seen men harnessed to draw the plough, bird-catchers, vessels under sail, and the performance of music. The larger human figures are about eighteen inches high, the smaller only eight. The men are painted red, and their clothing is a girdle encircling the waist, which falls to the knees: the women are painted yellow, and are attired in a tunic reaching from the bosom to the ankles. The children are naked.

From the anxiety with which mummies were sought by European nations, the Arabs have made a kind of property of catacombs, and frequently prevent the access of the curious; or practising an imposture on them, a mummy is secretly conveyed to a well known catacomb, and the deluded traveller taught to believe that he is its original discoverer.

Next to the Egyptian catacombs, the most extensive with which the moderns are acquainted are those of ancient Rome. Though their antiquity perhaps is not equal to that of some others dispersed throughout the world, an unusual interest is excited by their containing the remains of a people, who had rendered themselves so illustrious, and whose history is so familiar to our knowledge.

The Roman catacombs are of great extent. Some maintain, that, entering close to the city, they stretch several leagues beyond it; but the precise destination and limits of these, if they actually do exist, are not ascertained. Some others have for centuries been frequently explored: in the course of which a zealous antiquarian, Anthony Bosio, who has amply elucidated this subject, ventured to pass entire days within them, had provisions carried there, and, notwithstanding the danger of the enterprise, traversed their utmost extremities. Yet the hazard of this is great: persons have been known to lose their way; and the passages are of such intricacy, that it is unsafe to penetrate their recesses without a clue.

The catacombs of Rome, like those of most other places, are long, narrow, subterraneous galleries, crossing each other at right angles, or passing off obliquely. Chambers at each side occasionally appear, and a glimmering of light is admitted by openings above, distant by intervals of 300 yards or more. But in the interior it is dark as night. The excavations are invariably under the earth, in the puzzolana whereon the city is built; they are necessarily narrow to preserve the roof, and, in some parts, are vaulted. Nevertheless the earth frequently detaches itself from above, and obstructs the passages, or totally blocks them up. There are cavities along each side, which have formerly been appropriated for the reception of lamps; and deep niches penetrate into the walls, wherein the bodies of the deceased were deposited. These niches are invariably in proportion to the size of the individual; those of women and children being smaller than the rest.

The bodies are regularly arranged in one tier of niches above another, along the sides of the galleries, each niche of sufficient capacity according to the number it was required to contain, and closed at the foot by a single brick. In general, the galleries can admit of a man traversing them with facility, and there two or three rows of niches are seen: in some places they are more lofty; and Bosio relates, that one which he discovered was so high, as to receive eight or ten bodies above each other in the sides. Parts of the same gallery, however, were so low, that he had to advance bending downwards, or crawling on his breast, to the different streets and passages; probably the consequence of the superincumbent earth having given way.

The cement by which the tombs are closed, unless
CATACOMBS.

where yielding from too great desiccation, is yet entire; and on removing the brick to inspect the interior, the skeletons of the deceased appear in good preservation. In elucidation of this fact, let us quote the words of an adventurous explorer, who recently penetrated these gloomy mansions. “The brick obstructing the aperture of a catacomb being removed, a body, apparently that of a young woman, was discovered. Even yet all the teeth were preserved in her jaws. Her bones were totally covered with stalactites, exhibiting a most singular spectacle; for the light, reflected by the motion of the torches, seemed to animate the body, and the image of the spectator was multiplied a thousand fold, by the most extraordinary portion of the skull.” Another tomb was opened, wherein a skeleton, turned towards the east, was seen. The hands were crossed on the breast, and but few teeth were in the jaws; it seemed to be that of an old man. When my guide stretched one arm to the head, and the other to the feet, designing to raise the skeleton, it immediately fell into a whitish humid dust. Nothing except the substance of the teeth, which were eleven in number, remained: the whole skeleton had vanished from view.” It may here be remarked, that it is proved by numerous instances, while the remainder of the body is utterly decomposed and resolved into the elements, the teeth continue entire, their enamel white and perfect. But though it be also known, that the human hair remains an extraordinary time in preservation, none is seen in the catacombs of Rome. Skeletons are observed there, the hands of which are not crossed on the breast.

The catacombs of Rome, besides the tombs, contain edifices, which, in the days of the most prevalent superstitions, were churches, and where, it is probable, the mysteries of the earlier Christians were celebrated. Many inscriptions are still extant, and elegantly sculptured sarcophagi have been obtained from these catacombs. But above all, they abound with paintings in fresco, representing, like those of Egypt, an infinite variety of subjects: and sepulchral lamps, as also vases and lacymatories, are frequently discovered in tombs which have escaped the pillage of the more barbarous ages.

We shall not here attempt to describe the sarcophagi, as two of beautiful workmanship in Parian marble have occupied the attention of Bosio and other antiquarians: one bearing the name of Junius Bassus, the other that of Probus and Proba, both of the fourth and fifth century. Some others removed from their original site, now serve for baptismal fonts in Rome. The inscriptions are generally short and expressive; or explain the kind of tomb acquired by the deceased, whether a bicalum to contain two bodies, or a triacum for three; and accordingly the bones of two or three individuals are still recognised in several of the niches. These inscriptions are chiefly on black or white marble, some are in gilding, and some painted red. Their grammatical errors, and orthographical peculiarities, have presented great difficulties to a learned member of the academy of Cortona, by whom the catacombs were visited in 1805; but he had referred to the works of Mabil¬

lon, to the treatise on the Diplomatic Science by the two Benedictines, and especially to manuscripts of genuine antiquity, his difficulties would have easily been solved. It is chiefly religious subjects that are painted in the catacombs, and these principally in the cubicular or lateral chambers. By religious subjects, we mean those which are taken from scripture history, such as Moses striking the rock, Abraham about to sacrifice his son, or Daniel in the lion’s den. Jonas swallowed and vomited by the whale, is a favourite subject. Descending later, Christ is seen amidst the doctors in the temple, or restoring Lazarus to life. But, by a strange association, Orpheus is at the same time depicted with his lyre, and the beasts of the earth flocking around him to listen to his strains. Bosio has particularly specified a painting of the naked bust of a young man of comely appearance. His skin tends to an olive colour, he has large blue eyes and fair hair, a thin scantly beard, and a large nose. On each side, is a full length female figure with a written roll in her hand; and on an arch above him, triumphal cars, drawn by several horses abreast, and driven by charioteers, bearing a palm branch, and a crown or garland. There are besides, figures of victory in the air, and other emblems. Here also, as in the Egyptian catacombs, the common operations of life are represented: funereal repasts, bearing burdens, teams of oxen dragging weights, children gathering fruit, or engaged in puerile sports.

Burnt bones mixed with ashes are found in vases. Glass, and earthen vessels and instruments of torture, have all been recovered from the catacombs.

With respect to the precise era when these cemeteries were constructed, and the persons for whose reception they were appropriated, we are opposed by many uncertainties. Some ascribe them to the ancient Romans, others bring them to a period about the birth of Christ, and there are not wanting intelligent antiquarians, by whom they are considered as devoted almost solely for a secret deposit of those who suffered martyrdom, while the rage of persecution threatened the extermination of Christians. It is possible that all the three opinions are right. Though cremation was general among the Romans, we do not learn that it was universally practised: Children were not burnt, nor those in a state of servitude; and besides, if we may credit Pliny, this custom was introduced long after the building of the city. Inscriptions prove, that many who were not Christians were interred here; and numerous emblems, epitaphs, and histories shew, that it was a sepulchre for Christians, among whom were martyrs. The academician of Cortona saw a skull, which he conjectured to have been violently separated from the vertebra of the neck; and Bosio, to whom we have so often referred, relates, that in opening a tomb, he found a skull cleft by a hatchet, still sticking in it, and observed others apparently fractured by violence. It was not uncommon to bury the implement of death on the deceased; a custom ascribed to the Jews on interment of malefactors. In another part of the catacombs there was found a horrible kind of pincers, with which the flesh was torn from the bones of martyrs; and also vessels full of concrete blood, which crumbled to earth, but on being wetted immediately shewed its crimson hue. Some of
in particular, being an object of veneration, has been
embalmed in thousands in the extensive catacombs
of Memphis. The galleries there divide into many
branches, with recesses on each side, about six feet
by eight in size, containing rows of baked earth-
en urns or pots, somewhat of a conical form, all a-
long the walls. In each of these, which is from 12
to 20 inches high, is a mummy of the sacred bird,
frequently in perfect preservation, and exhibiting all
the original colours of the plumage. The pots are
regularly arranged, tier over tier, in regular order.

Almost all catacombs have been violated in search
of treasure, and they have sometimes been converted
to less pacific purposes than for mansions of the dead.
It is not long since a formidable band of robbers was
organized in those of Rome, by a Portuguese lead-
er, who, on the day of their admission to his corps,
impressed certain mystic characters on the arm of
each with a hot iron. They stored up provisions
for several months, and have been known to remain
above fifteen days unseen in their subterranean re-
treats among the tombs. After committing innum-
erable depredations, their leader having endeavoured
to save a Portuguese gentleman who was attacked, some
of his party were displeased, and fired upon him:
he returned their fire; they fled, and the whole se-
parated, never to meet again. The French, also,
during their invasion of Egypt, frequently took up
their abode in the catacombs. See Diodorus Siculus,

CATALONIA, a province of Spain. It occupies
the north-east extremity of the peninsula, and
is bounded on the north by the Pyrenees, which
separate it from France; on the east by the Medi-
erranean, on the south by Valencia, and by Arragon
on the west; extending from east to west about 40
leagues, and 44 from south-west to north-east. This
province is almost throughout extremely mountain-
ous, but interspersed with many rich and well-culti-
vated plains and valleys, which are watered and fer-
tilized by numerous rivers. Its mountains, however,
are merely branches of the Pyrenees, which, stretch-
ing far into the country, form second-rate mountains,
of which the chief are, Mon-Negre, Valgorguina,
San-Gran, Alsinellas, Requesens, Monseny, and
Montserrat. Of these, Montserrat is the most re-
markable, both for its situation, its appearance, and
the composition and arrangement of its rocks. It is
about 3300 feet above the level of the sea, and ap-
ppears to stand completely insulated and unconnected
with any other mountain, rearing its base and rugged
head above a hilly country, like a pile of Gothic
spires. Its huge cliffs shoot up to a stupendous ele-
vation, and their blanched and naked summits are
split into a variety of shapes. Some of these rocks
are composed of limestone of different colours, ce-
mented together by sand and a yellow calcareous
carth, and others of freestone and white quartz.

4 K.
mixed with touchstone; indeed, the whole of Montser-
rat is evidently formed of that species of aggregation,
known to naturalists by the name of pudding-stone.

Though most of the mountain appears barren
and arid, yet the interstices among the cliffs pre-
sent the most luxuriant vegetation. These spaces
are filled with close woods and deciduous trees, in-
termingled with aromatic shrubs and flowers, which
are nourished by the rich earth which is dissolved,
and washed down from the rocks by the rains. The
great variety of plants with which these woods ab-
ound, would amply satisfy the curiosity of the bo-
tanist. There are few evergreens in Europe, that
may not be found here; and when Mr Swinburne
visited Montserrat in 1775, the apothecary of the
convent had a list of 437 species of plants, and 40
of trees, which grew in its clefts. There is, however,
a great scarcity of water. It is even supposed that
there is no spring in the whole mountain; and the
streamlets which are sometimes seen to descend from
its sides, are said to proceed from reservoirs formed
by the rain in the crevices of the rocks, and running
in a bed of porous stones that lies across the middle
of it. Besides the convent of Montserrat, which is
situated in a large cleft on the eastern face of the
mountain, there are fifteen hermitages scattered over
its surface, some of which are placed on the very
pinnacle of the rocks, and in cavities hewn out of
the highest cliffs. Between Figueras and Gerona,
are two mountains standing together, which are re-
markable for their uniformity. They are both of
an equal height, and of a pyramidal form; and, accord-
ing to Mr Bowles, have all the signs of ancient vol-
canoes. But the greatest curiosity of this province
is the mountain of Salt, in the vicinity of Cardona,
which is about 500 feet high, without a cleft or
crevise, and nearly three miles in circumference.
It is composed almost entirely of salt, which is very
white, except a small quantity of a reddish and of a
bluish cast; and its side, which stands close to the
river Cardonero, is nearly perpendicular. Of the
substance of this mountain, the inhabitants of Car-
dona make a variety of articles for sale, such as al-
tars, figures of saints, crosses, chandeliers, salt-cellars,
&c. which are as clear as crystal, but cannot be sup-
posed to be equally lasting.

The other mountains of Catalonia contain nu-
merous and valuable minerals. Marbles are found in
great variety, and are wrought to a very considerable
extent. There are several iron mines near Alius and
Taull; lead mines near Tortosa; and of its numer-
ous coal mines, that of Clansa is the best. Am-
thysta, topazes, and coloured crystals, are found
near Vicq, which are manufactured and sold by the
goldsmiths of Barcelona, and there are also mines of
antimony, copper, tin, alum, vitriol, silver, and one
of gold. Among its mineral waters, the most re-
markable cold springs are those of Monistrol, Vall
de Ebron, Tortosa, and Rivas: and its principal hot
springs are at Caldas, Garriga, Gerona, Esplugues
and Torello.

Catalonia is watered by twenty-six rivers, of which
the chief are the Ebro, which is the largest, and is
very important for its navigation, the Segra, the
Llobregat, the Cervera, the Fluvia, the Ter, the
Muga, the Tordera, the Bezos, and the Noya.

Though the soil of this province be more ungrate-
ful, and more interrupted with mountains and rocks
than that of any of the other provinces, yet agricul-
ture is here better understood, and more successfully
and universally practised, than in any other part of
Spain. The plains and vallies are intersected by nu-
merous canals, for the purposes of irrigation, in
which the Catalonians particularly excel, and which
is attended with the most beneficial consequences. In
some cantons, indeed, this art is carried to very great
perfection; and a regular police is established for
conducting and distributing the waters. Every pro-
prietor enjoys the right of irrigating his land for a
limited time, according to the extent of his property;
and for this privilege he pays an annual duty, which
is expended in keeping up the canals, and in paying
the salaries of the commissioners. The districts most
remarkable for fertility and cultivation, are, the coun-
try about Lerida, the plains of Urgel, Vallez, and
Iqualada; the environs of Cervera, the Campo de
Tarragona, and Ampurdan. The industry of the
Catalonians, however, is not confined to the plains.
The mountains are improved by their skill and la-
bour; and even craggy cliffs, which seem to have
been destined for ever to be the habitation of the
chamois, are converted by their exertions into vine-
yards, cultivated fields, and valuable forests. In
many places they carry up earth to fix the young
vine in, and rather than suffer a good patch of soil
to remain useless, they sometimes let one another
down from the brow of the rock by ropes. Plant-
ing is a favourite improvement, and a principal ob-
ject of attention with the Catalonian landlords. They
vise with each other in multiplying trees of every
kind. Plantations of beeches, elms, poplars, pines,
and oaks, are consequently numerous and thriving;
and cork trees are so plentiful, that Catalonia is able
to supply the whole of Europe with this important
article. Fruit trees of every description are reared
in great abundance, particularly in the beautiful gar-
den on the banks of the Segra, the Llobregat, and
the Ampurdan, and between Matava and Barcelona;
and oranges, lemons, figs, almonds, filberts, apples,
walnuts, and chestnuts, are common throughout the
province. Grain of every kind is raised here, but
the crops are liable to frequent burstings and mild-
dew, and the wheat harvest is seldom sufficient for
the consumption of the inhabitants, who are obliged
to draw supplies from other countries. The cultiva-
tion of rice has of late considerably decreased, from
the idea that it produces an effect upon the atmo-
sphere very prejudicial to the health; and the people
of Ampurdan, who were its first victims, in a mo-
moment of irritation, destroyed most of their rice fields.
The vintage in Catalonia is, in general, uncommonly
plentiful, and the wine in the east part of the pro-
vince is excellent. That in the west and north parts
is rather of an inferior quality. The best red wine
is made at Matava, and the best white at Sitges.
Olive trees are in great abundance; but mulberries,
though they thrive well, are much neglected; and,
consequently, less silk is produced here than in
many of the other provinces. The cultivation of
flax and hemp is also inconsiderable; and the wool
which it produces is altogether insufficient to supply
the manufactories of the provinces. The principal
productions of Catalonia, with their average annual
quantity and price, are contained in the following Table.

The roads in this province are in general bad, and notwithstanding the industry of its inhabitants in other respects, they are almost totally neglected. There are very few bridges, and in rainy weather the traveller is liable to be constantly stopped by the rivers, which, in that season, descend in torrents from the mountains. Goods are conveyed in carts drawn by four or five mules, yoked in a line, which carry immense weights; and the Catalans are reckoned the most expert and careful drivers in Spain.

Catalonia, from the remotest times, has been famous for its manufactures; and here every profession that is connected with the useful arts is so much honoured and respected, as in the other provinces it is despised. Its woollen and cotton stuffs, silks, velvets, and linens, were celebrated even in the 13th century; and though its manufactures and commerce afterwards met with several severe checks, and were almost annihilated in the 16th and the beginning of the 18th century, yet from that time their revival has been gradual and constant; and it is now the most active and industrious province in the kingdom. Besides cloths of almost every description, it has manufactures of all kinds of stockings, lace, tape, nets, ribbons, &c.; also iron ware, cutlery, earthen ware, and shoes, for exportation; and above 200 mills are employed in making paper, which produce annually about 480,000 reams, estimated at 160,000 sterling. These articles, together with its natural productions, supply Catalonia with many valuable exports; and its great extent of coast and excellent harbours, render it peculiarly favourable for an extensive commerce. Its inhabitants have indeed profited by these advantages. The sea-ports are filled with ships, and peopleed by traders and seamen, who are equally industrious with their brethren in the interior. Of its coarse cloths and serges, the greatest part is made up into clothing for the troops, and sent to the different provinces of Spain; the fine cloths are carried to Madrid, Arragon, &c. Two-thirds of its linens, cotton-velvets, nankeens, and muslins, are exported to the colonies; about one-twelfth and a half is kept for the consumption of the province; and the remaining two-twelfths and a half are sold in the markets of the peninsula. About 10,000 dozen of silk-handkerchiefs and sashes, manufactured at Manresa, are annually sent to Arragon, Biscay, and the two Castiles, and 55,000 to America: 20,000 quintals of cork, and 470,000 reams of paper, are exported to different parts of Europe: England receives 20,000 sacks of nuts; 10,000 pipes of brandy are sent to the same place; 4,000 to Guernsey and Alderney, and about 20,000 to Holland and the north of Europe: 8,000 loads of oil are carried to France and Holland, and 4,000 loads of wine to Italy: 200,000 pairs of shoes go to America, and 500,000 are distributed in the interior of the kingdom; and of 24,000 pairs of worsted stockings furnished by the town of Vic, one half pass into the adjacent provinces. A considerable quantity of silks and silk stockings, are exported to the New-World, which also receives fire-arms, iron-ware, printed calicoes, laces, &c. The sweepings of houses which are shipped annually from Barcelona, amount to nearly 60,000 ducatas. The following Table gives an exact account of the quantity and value of its principal exports.

Total exports £1,286,839 3 8
CATALONIA.

The imports of this province consist chiefly of corn, wool, and silk. From 400,000 to 600,000 quarters of wheat are supposed to be annually imported from America, Sicily, and the north of Europe; and in 1775 Canada alone sent about 80,000 quarters. It receives 10,000 quintals of wool, and 80,000 lbs. of silk, from Arragon; 100,000 lbs. of silk from Valencia; and Lyons silks, Gange and Nismes silk-stockings, fine cloths, linens, essences, perfumes, pot- matus, jewellery, and millinery, from France. England furnishes it with superfine cloths, herring, and cod-fish; and Holland with a few spices. The amount of these, however, is far from being equal to its imports. About 1000 vessels are almost constantly employed in trade, and the government can depend upon 18,000 Catalonian seamen, who are registered, and always ready for any emergency.

The spirit of industry which pervades Catalonia, has led its inhabitants to turn their exertions to the useful rather than to the liberal arts; and, as mechanics, they are in general preferred to those of any other province. The sciences, however, have not been entirely neglected; and among the Catalans have arisen several writers upon natural history, theology, medicine, and law, of no inconsiderable merit. Besides public libraries, and schools of different kinds, there were formerly two academies in this province, under the title of Gay Science; one at Barcelona, founded in the 14th century, by John I. King of Arragon; and the other at Tortosa, in the beginning of the 15th, where verses were recited and prizes decreed to the victors. The duration of both, however, was but short; and since their declension, the Catalans have made very little progress in the fine arts; for excepting the works of Volfortonga, nothing striking in their poetry is known. In their dispositions, the Catalans seem to be influenced by the nature of their country. They are proud, hardy, and impetuous, of a brown complexion, strong features, and brawny limbs; and their chief characteristics are activity and a spirit of independence. They are indefatigable in the prosecution of their schemes. No obstacles can deter, no dangers can terrify them. Their natural vivacity, their enterprising spirit, and their love of money, lead them to every quarter of the world; and there are few sea-ports in Europe, India, or Spanish America, where Catalans are not to be found. As soldiers, their bravery and firmness has been always conspicuous, and has been often displayed against the most fearful odds. In the beginning of the 18th century, they withstood the united armies of France and Spain; and in 1714, the inhabitants of Barcelona made one of the most vigorous and desperate defiance that is recorded in history. On a forlorn hope, or for a coup-de-main, the Catalans are excellent; but they are in general averse to the strictness of regular discipline. When treated with kindness and mild words, they are docile and obedient; but they rise against the slightest appearance of authority or subordination. The Catalans possess a haughtiness of demeanour, and authoritative tone, peculiar to themselves. They look down upon the rest of their countrymen as their inferiors; the loyal Castilians, in particular, they regard with aversion; and to their ancient enemies, the French, they bear a lasting and invincible animosity. But though high-spirited and overbearing, they are distinguished for their honesty, steadfastness, and sobriety. Most of the principal families in Madrid have Catalans at the head of their affairs; and as muleteers and callelleros, they are scattered over every province of the peninsula. "The desire of wealth," says Laborde, "makes them industrious; emulation makes them active, leads them to every part of the world, and enables them to brave the perils of long voyages; and glory blinds them to every kind of danger. When they love, they love warmly; but their hatred is implacable, and they have rarely sufficient strength of mind to stifle their resentment. But we are not, therefore, to imagine the Catalan disposed to mischief; he is not so naturally. He works himself into a rage, and is loud, but seldom commits acts of violence. In a political point of view, the Catalan is restless and facious; he is forever sighing for a liberty, or rather independence, which he has often attempted to acquire, and which has so frequently impelled him to take up arms. But as devoted in his attachment, as terrible in his hatred, he is ready to make every sacrifice for a prince who knows how to gain his love." With all their eagerness for money, the Catalans are capable of the most disinterested generosity; and during the late revolution in France, multitudes of French refugees of all ranks, whose loyalty had driven them from their country, were received, consoled, and protected by the republican Catalans. Instead of the mantle and Mayo jacket common throughout Spain, the usual dress, in almost all ranks among the Catalans, is a close coat in the French fashion, and the peasants on the mountains wear a double-breasted vest, with a kind of wide great coat, called a gambeto, which reaches only to the knee. Their ancient and favourite slouched hats, white shoes, and large brown cloaks, were long ago prohibited. Catalonia has a language distinct from the other provinces of Spain. It is the ancient Limousine tongue, but disfigured by hard terminations, and by a sharp and disagreeable pronunciation, which gives an appearance of greater roughness and asperity to the Catalan character than in reality belongs to it. This language is spoken throughout the province, but with considerable variations in the different districts, and is preferred to the Castilian. It is purest on the mountains, but greatly mixed with Castilian in the large towns. Its harshness, however, is completely lost in the mouth of a Valencian, whose pronunciation renders it soft and harmonious, and though in the towns of Valencia, the Castilian is always used, yet the Limousine in some parts of that province has preserved its ancient purity.

The population of Catalonia since the beginning of the last century has been upon the increase. In 1718, it amounted to 407,192; in 1768, to 732,506; and in 1788, to 814,412, which is nearly its present state. Among these are 6608 priests, 5801 monks and nuns, 1260 nobles, 6908 students, 1020 writers and lawyers, and 20,963 domestics.

Catalonia contains an archbishopric, 7 bishoprics, 8 cathedral and 18 collegiate chapters, 22 abbeys, a grand priory, and 16 commanderies of the order of Malta, 2738 parishes, 284 religious houses, 84 hospitals, a university, fifteen colleges for the education of youth, 14 cities, 283 towns, 1806 villages, 22 fortresses, and five ports. Its principal towns are
CATALONIA, the capital, Tarragona, Urgel, Lerida, Gerona, Saloua, Vicq, Tortosa, Figueras, Aulot, Igualda, Reus, Mataro, Villa Franca de Panades, Cervera, Manresa, and Palamos.

Catalonia, with the rest of Spain, was overwhelmed by the invasions of the northern barbarians in the beginning of the fifth century, and continued under the dominion of the Goths until 712, when it was compelled to yield to the Saracens. The Saracen power in this province, however, was not of long continuance; for before the conclusion of the same century, they were completely expelled by Lewis le Debonnaire, the son of Charlemagne. It was then erected into a province of France, and was governed by counts or viceroys, removable at pleasure, until Godfrey or Wifred the Haairy was created hereditary count of Barcelona; and the sovereignty of the province bestowed upon him and his heirs for ever. As soon as it became a separate power, it rose to respectability among the independent nations of Europe; and besides Catalonia, the counts of Barcelona comprised under their dominion, Roussillon, Cerdagne, the country of Foix, and a great part of Languedoc. At this time Catalonia was divided into vigneries or jurisdictions, each governed by a visier, or lieutenant, who enjoyed a very considerable authority; and when its count, Raymond V., succeeded to the crown of Aragon in 1137, by his marriage with Petronilla the heiress of that kingdom, it still continued to be governed by its own states, which shared in the legislative power with the sovereign. These states were composed of the three orders, the clergy, the nobility, and the commons, whose power consisted in proposing to the king such laws as they thought necessary, and in sanctioning those that originated with him. This privilege was continued even after its union with the crown of Spain; but it was gradually undermined by the viceroys, and at last completely withdrawn by Philip V., who allowed them to retain merely the empty right of sending deputies to the states general of the Spanish monarchy. Catalonia, during its union with Aragon, was engaged in repeated, and sometimes lengthened rebellions. It frequently opposed the most obstinate resistance to the commands of its sovereign; and even often attempted to choose a foreign prince as its ruler, or to erect itself into a republic. But notwithstanding its exertions for independence, it continued under the dominion of Aragon, and afterwards of Spain, till 1640, when the Catalans, enraged at the arrest of their deputies at Madrid by the command of Philip IV., flew to arms, and declared themselves free. Being unable, however, to maintain their freedom, they gave themselves up to France; and in 1641 proclaimed Louis XIII. count of Barcelona. But even the power of Louis was insufficient to support them against Spain. They were reduced in 1629, by Don John of Austria, and in 1659 their submission was confirmed by the treaty of the Pyrenees. The most desperate and obstinate struggles, however, which the Catalans made in defence of their privileges, was in the war of the succession, when attaching themselves to the cause of the Archduke Charles, they resisted every offer of accommodation from the French; and when at last deserted by the king, whom they had chosen, and by every foreign power, they stood alone, and single-handed maintained the contest against the united efforts of Spain and France. By this war the province was drained of its wealth, and almost depopulated, as many of its inhabitants preferring exile to submission, emigrated to foreign countries. Its manufactures and commerce were destroyed; and when Barcelona capitulated in 1714, Philip V., received a country without resources. Every privilege was abolished, and heavy taxes imposed in order to defray the expenses of its reduction. But though depressed and impoverished, it in a short time recovered its activity and energy; and its trade being relieved from the impolitic and paralyzing taxes of alcavala cientos and milliones, under which many of the other provinces of the Spanish monarchy labour, it soon rose to its present state of wealth and splendour. Except a few partial insurrections, the Catalans have submitted to the yoke, with sullen apathy; and such is their character of pride and independence, that several of their nobility had constantly refused to accept of any titles and dignities, till the last journey of Charles IV. into this province, who, by his kind- ness and manners, greatly conciliated its inhabitants; See Spain and Barcelona. See also Laborde's View of Spain, vol. i. p. 1-136; Swinburne's Travels in Spain, vol. i. p. 16 and 39; and Townsend's Travels, vol. iii. (p)

CATANA. See Catania.

CATANANCHE, a genus of plants of the class Syngenia, and order Polygamy Eequalis. See Botany, p. 289.

CATANIA, a city in Sicily, the ancient Catina, situated in N. Lat. 37° 30', E. Long. 15° 19', at the foot of Mount Etna, in the Valley of Noto, one of the three districts into which the island is divided, and on the shore of the Ionian sea.

Whether we consider the political revolutions which this city has experienced, from its earliest history down nearly to the present times, or those awfull convulsions of nature which have so often buried it in ruins, Catania must equally claim our attention. In treading upon classic ground, however, it is with regret that we narrow ourselves to the limits which must be observed, lest a subject of particular interest should betray us into a trespass upon other articles, which, though of less moment, must not be omitted. Wherever the earth is inhabited, we find man invariably attached to the spot of his nativity, identifying himself, as it were, with the soil, however few its inhabitants may be; but the force of the principle is infinitely more striking, where we have the fortune to witness the happy effects of the construction of the man of the very lava that had swept away in its course the mansions of his forefathers, upon a foundation that he has often felt shaken by earthquakes, in the midst of surrounding monuments of desolation. Such are the circumstances in which Catania stands. In addition to these, it has undergone every vicissitude to which a city was exposed, from having frequently arrived at sufficient opulence and splendour, to excite the cupidity of barbarians, and the envy of the powerful and ambitious.

Catina, one of the most ancient cities in Sicily, was founded in the time of the Sicaniens, who were driven from it by the Siculi, at the period of their land
CATANIA.

ing from Italy; then a Grecian colony, from which they had been expelled. From them Sicily derived the name it still retains. Having established themselves in possession of Catina, they enacted wholesome laws, under which it prospered, until Gero the first of Syracuse, growing envious of their prosperity, and confident in his own power, attacked the city, which he soon sacked. He removed the inhabitants to Leontium, now Leontini, and supplied their places with new settlers from the Peloponnesus. So ambitious was Gero of the reputation of founding cities, that he attempted to abolish the name of Catina, calling that place Etna, and himself a citizen of Etna. His death, which happened in the first year of the 79th Olympiad, afforded a favourable opportunity, which the Sicilians eagerly availed themselves of, to drive the Grecian intruders from their territory. After succeeding in their enterprise, they entreated their countryman Carcondas to quit the asylum to which he had fled, in Italy, on the conquest of Catina by Gero, and to return to his native city, to assist them in framing laws for their government; and the result evinced the wisdom of the measure, for Catina again prospered. It next fell a prey to the Carthaginians, who proved themselves the greatest scourge it had hitherto experienced. In the 93d Olympiad, Dionysius, tyrant of Syracuse, obtained possession of Catina, through the perfidy of Archilaus, the prefect of the place. The tyrant plundered the city, and laid it desolate; he sold the inhabitants for slaves, and gave their lands to others.

The Roman yoke was the next which this ill-fated city was destined to feel. While Sicily was a province of the empire, it flourished; but on the decline of that power, it fell a prey to the Saracens: and from the period of their expulsion by Roger the Norman invader, it shared the chequered fortune of the island, until its settlement by treaty upon the second branch of the royal family of Spain, now the only branch of the once powerful house of Bourbon, from whose hands the sceptre has not been wrested.

Catina was laid in ruins by an earthquake in the year 1693; and upon the situation which it occupied, the present city was built, the lava serving at the same time for a foundation as well as a quarry, from which stone was dug for its construction.

Situatéd upon a declivity, and a level at its base, the aspect of Catina is magnificent and imposing, from the number of public buildings, the width and regularity of the streets, and the size of many of the dwellings of individuals. There are upwards of fifty religious edifices of different descriptions, including churches, convents, and monasteries. The cathedral, dedicated to St Agatha, was founded in the year 1094, and richly endowed by Roger the Norman; but it has often suffered dilapidation from earthquakes, and its appearance is said to be greatly altered from the repairs it has received.

The Benedictine convent of St Nicholas, which occupies a large space in the higher part of the town, is a spacious mass of building, capable of accommodating more than twice the number of its inmates. The size and splendour of the convent bespeak the opulence of its order. Nobility of birth is an indispensable requisite, exacted by the rule of the convent from those who are candidates for a share of its comforts. It is not easy to reconcile this with the profession of a religion, the essential doctrine of which is humility. In the church of the convent there is an exquisite organ, which has been rated inferior only to the celebrated instrument in Antwerp. The museum, occupying one wing of the convent, contains many valuable curiosities, the most interesting of which have been found in Sicily and Italy. As it is within the convent, men only are admitted; but they are readily admitted at suitable hours.

The church, though very splendid, is decorated with paintings of little merit, representing chiefly miracles. In one, St Benedict is seen flying through the air, without the uncrowned appendage of wings, holding in his hand a youth suspended by the hair. The writer of this article was told by one of the brothers, that the boy was a Christian captive, who lamenting the loss of his religion, prayed fervently to the saint, while discharging the office of cup-bearer to the sultan. Benedict propitiously heard his pious importunities, and quick as lightning descending through the dome of the apartment, seized the boy by his flowing locks, flew off with him, and landed him in safety in his father's house, in as short a time as any magician in the Arabian Nights could have done, leaving the Grand Turk in astonishment to lament his rapta Ganyemedis honores.

In the Sanctum Sanctorum of this church a most precious relic is shown, which a heretic observer might readily mistake for a rusty fragment of a ten-penny nail; but the miraculous power with which this piece of rusty iron is endowed, irrefragably proved it to be no other than one of the identical nails that pierced Our Saviour at the crucifixion. When a stream of molten lava, some years ago, threatened destruction to the convent, the relic was brought from its deposit, and held up in menace to the demon of the lava, which accordingly was immediately turned from its impious course.

One of the breasts of Saint Agatha, the patroness of Catania, is preserved to this day, from the time that she suffered martyrdom in defence of her faith and her honour, at the early age of fourteen; from the shrivelled remains of her, we are entitled to suppose that she was full grown. Many other sacred morsels of saints of both sexes, which, though equally well authenticated, we shall not enumerate, sanctify this place. Narrow streets with lofty houses, has very often been reprobad as an error in the construction of towns in warm climates; the modern Catania, however, shews that the greatest possible inconvenience results from the streets being made very wide, and the houses low. They are so spacious, that the buildings scarcely afford any shade, consequently the heat and glare of light produced by the direct rays of the sun, together with the reflection from the lava, of which both the street and buildings are formed, are intolerable.

The palaces of the nobility are begun upon so magnificent a scale, that few of them are finished. In making this remark, we are forcibly struck with the uniformity of national character, apparent in some circumstances, notwithstanding the changes that have taken place in the government and laws of a country. Plato said, that when a Sicilian sits down to supper, he eats as if he never were to eat again; when he builds a house, he builds as if he never were to die. Had the philosopher lived in the present times, every
one must have recognised the likeness of his portrait.

We have said the palace of the nobility, because in Sicily no man of rank inhabits a house; neither does the country produce what in England is called a gentleman. These palaces are built in a square, with one side to the street; the first upper floors are occupied by the proprietor, for none of the nobility reside upon their estates. They contain large apartments for show, and generally pretty small rooms for use. If a stranger makes his visit at the time of a meal, he will certainly find the family in a small dirty apartment, with pyramids of macaroni piled before each, upon a table-cloth bearing stains of oil, of an older date than yesterday's supper, attended by a half lousy servants. The scene is changed on gala days, the spiders are dislodged from gilded apartments, by prescriptive right their own, and the powdered menials are decked out in laced liveries. The lower part of the palace forms a striking contrast to an English eye, but it is, nevertheless, in a state of Italian consistency, filthy and dirty, and silken rags; here cobblers and all sorts of mechanics of the lowest orders are to be seen at work in their cells, when driven in by the heat, or on the pavement, when the coolness allows them to breathe a purer air.

Catania is chiefly resorted to by the nobles, whose fortunes do not enable them to shine at the royal residence in Palermo. The city is superabundantly stocked with priests, monks, nuns, and beggars. Any one passing through a Sicilian town, might readily believe that it contained the aggregate of decrepitude and deformity of Europe. The industrious inhabitants are few, the fruges consumere nati numerous.

In the square before the cathedral a gigantic elephant, the ancient symbol of Catania, of lava, with an obelisk upon his back, on the sides of which hieroglyphic characters are carved, stands, having withstood the concussions of many earthquakes.

The prince of Biscari, the great man of the place, has a choice collection of specimens of Carthagenian, Grecian, and Roman architecture, mosaic work, and statues; a very perfect collection of Tuscan and other vases and lamps of infinite variety of form; bronzes, volcanic specimens, and an assortment of cameos and intaglios of the most exquisite workmanship. There are also many excellent monuments of the arts, which have escaped the ravages of time, in iron and other metals, such as pieces of armour, harness, keys, &c. Instead of confining themselves to the display of what they are almost unirrellved in, the vanity of the Biscari family has led them to disfigure their museum, by the introduction of busus naturae, and disgusting anatomical preparations.

We are told that Catania contains 80,000 souls; but we cannot give them credit for half that number of inhabitants. It is the see of a bishop, much of whose ample revenue is drawn from the snow sold from Etna. There is an university of much repute (in Sicily) in this place, where the three learned professions are taught. The students destined for the church far outnumber those of physic or law, the reason of which is very obvious: nearly one-third of the landed property of the island is in the possession of the church and the religious orders, many temptations are therefore held out: the higher classes accordingly, very frequently force their daughters, who are not fortunate enough to get married, to take the veil; and as younger sons could not pursue any profession without degrading their illustrious family, they take the vows to obtain a provision for life, and to partake of the good things of this world which the church has to offer. The lower classes flock to those convents which admit people not of noble descent, some from zeal, others to advance in the scale of rank, and many from indolence, to eat the bread of idleness rather than earn it by labour. Of the poorer students for the church, many are educated at the expense of the bishop.

It may amuse such of our readers as are so curious to know the progress of the sciences, to lay before them a few points to illustrate the state of medicine as practised in Sicily; in this view, we shall transcribe some dogmas from the Institutiones Medicinae of the present professor of that science in the university of Catania. "Ungues pedum et digitorum lini- miti, vomitum excitant, (it would indeed be very extraordinary if they did not,) et valent contra epilepsiam, lethargiam, hydropem et intermittentes fibres, &c. Urina interna assumpta et recens et tepida ab 

It may gratify the adherents of that northern light in physic, John Brown, to learn, that their hero has divided the faculty in Sicily into two parties, in each of which, symptoms are to be traced evincing the existence of a malady well known amongst doctors, though undescribed by nosologists, viz. the odium medicum, in as genuine a form as ever Germany exhibited. A preliminary to a consultation has more than once been the question, How does opium operate? and we have often read a most excellent application of the true Brunonian answer, written with charcoal in large characters, on the outside of a wine house in the plain of Catania, Non sedat opium, followed by the appropriate exclamation, Viva il celeberrimo Brown.

How the laws are taught in this university we are not competent to say; but we have seen enough of their administration to form a pretty accurate judgment of their practical application, from which we are inclined to doubt the possibility of the jurisprudence of the petty states of Barbary being upon a worse or more uncertain footing. A very few years ago, two atrocious murders were committed in the course of one week: the bishop's cook was most sacrilegiously stabbed when officiating at his own altar, namely the kitchen dresser; and a travelling guide was shot in the dusk of the evening, at the door of a wine house, by a companion, with whom he had had a dispute the day before. Many examples might be cited, to show how prone the Sicilians are to commit murder, under the impulse of passion, which is no way restrained by the laws. Although assassination is very frequent, a capital punishment hardly ever is inflicted, and, if it were to take place, the process is so tedious, that the crime would be forgotten before the criminal suffered. We were still more surprised to observe, that the perpetration of two murders in so short a time, called forth no expression of indignation on the part of those whom we may suppose to have been more enlightened, no
one even mentioned the circumstance as an extraordinary occurrence; nay more, the police of the place made no effort to apprehend the murderers, because, as one of the senators sagely remarked, “it would be fruitless, for a man always runs off when he assassinates another.” Such deeds make no other impression than what arises from the dread of their own career being cut short in the same way.

In digging through the lava some years ago, an extensive theatre of Grecian architecture, built of lava, and founded upon lava, was discovered. There are remains of hot and vapour baths in several places.

The principal exports of this city, are the means of producing heat and cold, the snow and fire wood which Etna furnishes, to Malta and other places; the various sorts of macaroni, which are well manufactured here, and sold under the general term of paste; silk, which is also manufactured here.

The amusements are, as in every Italian town, a conversazione, which much more frequently signifies a party assembled to play at faro, sharo, or other games of chance, than for the purpose of rational conversation; sometimes an opera, and a masquerade on Sunday during carnival, in the prince of Biscari’s theatre; an academia, wherein the professori meet the virtuosi, not in the old-fashioned way of the Greek philosophers, querere verum inter syllas academia—no, be it known to the reader, that academia is neither more nor less than a concert, the professori the performers, and the virtuosi the audience.

The ancient Catina produced Carondas the legislator, so much commended by Plato; and Stesichorus the lyric poet, who introduced singing with the accompaniment of the cithara into the chorus.

The Scamatus, now the Giarata, sung by Theocritus, flows through the plains of Catania at some distance from the town. The Naphtha lake, the seat of the oracle of the Palici, hardly second in repute to that of Delphos for its responses, is in the neighbourhood of Catania.

From Catania, Adrian the emperor ascended Etna, “ut solis ortum visere.” But this city is so often mentioned by the ancient writers, and the natural phenomena that characterise it are so intimately interwoven with the allegory and fable of ancient mythology, that every stream and fountain in its neighbourhood bear record of its antiquity.* (w)

CATECHU. This is a substance which has been long known under the name of terra japonica, being believed to be an earth that came from Japan. It is, however, now known, to be an insipissated vegetable juice, which its name is said to indicate, cate signifying a tree, and chu juice.

There are two varieties of catechu, one comes from Bengal, and the other from Bombay. These differ from each other very slightly in their chemical characters, but may be distinguished by the particular appearance of each. In general, catechu has a pale reddish brown colour, is friable, possesses a lamellar structure and rough fracture; specific gravity about 1.39; taste bitterish and astrinquent, leaving a disagreeable sweetness; it is insufible, does not deliquesce, and does not exhibit any sensible change in consequence of exposure to the action of the atmosphere.

The Bengal catechu may be distinguished from that which comes from Bombay, by being of a darker colour, more nearly resembling chocolate on its exterior surface, and by exhibiting a streaked appearance of chocolate and reddish brown internally. The texture is more uniform, and the fracture more resinous and shining. Its specific gravity is somewhat less, and it is also more friable.

Sir Humphry Davy, at the suggestion of Sir Joseph Banks, analysed both varieties, and the results nearly correspond. We shall give a general statement, which may be considered equally applicable to both, previous to the details of the analyses. Catechu is almost soluble in hot water; the solution is of a deep reddish brown, and reddens the infusion of litmus. By long decoction a solution is formed, which yields, by evaporation, about 4th of its whole weight of solid matter.

The presence of gallic acid and tannin were also distinctly proved, by the black colour produced by sulphate of iron, and by the copious precipitate by animal gelatine.

Catechu contains a peculiar extractive, and a substance resembling mucilage. The last is left pure by the action of alcohol, which dissolves all the other matters. The extractive, when completely freed by washing from the tannin, is slightly astringent, and very sweet when chewed for some time. It is soluble both in water and alcohol, and acquires a deep colour by exposure to the air.

The following are the exact results of the analyses.

It has been said to be derived from various trees; but it is certain, that it is most usually obtained from the Acacia catechu of Wildenow, which grows abundantly on the mountains of Hindostan, and which is there called Coira.† It seldom exceeds twelve feet in height, and one foot in diameter. It is covered with a thick coarse bark, and divides into many branches at its top. The leaves are alternate on the young branches, and are composed of from 15 to 30 parts of partial pinnas nearly two inches long, each having about forty pairs of linear leaflets beset with short hairs, with a small gland on the leaf stalk between the bases of each pair of the pinnæ. There are two short recurved spines at the base of each leaf.

The flowers are male and hermaphrodite, and spring from the axil of the leaves on close spikes four or five inches long. The calyx is tubular, hairy, dividing into five oval pointed segments. The corolla

---

* The Editor has been indebted for this interesting article to a gentleman who resided a long time in Catania.

† This tree belongs to the Linnaean class Polygania, and order Monocidae. Natural order of Linnaeus, Lomentacea; of Jussieu, Leguminose. See Botany for the generic characters.
tubular, monopetalous, and twice the length of the calyx. The filaments are numerous, twice the length of the corolla; anthers roundish; germin oval, supporting a slender style of the same length with the stamens, and terminated by a simple stigma.

Fruit lanceolate, compressed, pod smooth, brown, margin thin. It contains six roundish flattened seeds.

The following is the mode of preparation, as narrated by Mr Kerr, who was formerly assistant surgeon to the civil hospital at Bengal.

"After falling the trees," says this gentleman, "the manufacturer carefully cuts off all the exterior white part of the wood. The interior coloured part is cut into chips, with which he fills a narrow-mouthed unglazed pot, pouring water upon them until he sees it among the upper chips; when this is half evaporated by boiling, the decoction, without straining, is poured into a flat earthen pot, and boiled to one-third part; this is set in a place to cool for one day, and afterwards evaporated by the heat of the sun, stirring it several times: when it is reduced to a considerable thickness, it is spread upon a mat or cloth, which has previously been covered with the ashes of cow dung; this mass is divided into square or quadrangular pieces by a string, and completely dried, by turning them in the sun until they are fit for sale.

Catechu is imported into this country in bags, and occasionally in small chests that contain 3 or 4 cwt. each. Both varieties are mixed up together in the same package.

Catechu is used in India in some processes of dyeing. It is a chief ingredient in the betel composition, which is so generally chewed by the natives of the East. The Indians also use it as an ingredient of an ointment, in high repute for curing sores.

In Europe, it is chiefly employed for medicinal purposes. Its astringency renders it peculiarly valuable in some cases of dysentery and diarrhoea, when astringents are indicated. From the quantity of tannin which it contains, it may become a very valuable article in the preparation of leather.

CATHERINE II. Empress of Russia, was born at Stettin May 1, 1729. She was the daughter of Christian Augustus, prince of Anhalt-Zerbst-Dornburg, and of the princess of Holstein; and was originally denominated Sophia Augusta Frederica. Under the judicious and prudent tuition of her mother, who was distinguished for her talents and beauty, she displayed at an early age a taste for learning, and devoted much of her time to literary and philosophical studies. In 1744, she visited, with her mother, the court of Petersburgh, and received from the Empress Elizabeth the most flattering marks of regard and esteem. This princess had been betrothed, and affectionately attached to her uncle the prince of Holstein-Eutin, whose premature death alone had prevented the accomplishment of the marriage; and the appearance of Sophia awakened in her the tender remembrance of her loss. The affection which she cherished for her betrothed husband, the now expressed towards his niece; and scarcely was Sophia settled in the court of Elizabeth, than the plan was formed of uniting her in marriage with the Grand Duke Peter, and of thus raising her to that throne which had been intended for her uncle, but which death had prevented him from ascending.

In the prospect of her exaltation, Sophia formally renounced the doctrines of Lutheranism, in which she had been educated, and embraced the religion of the Greek church, when, at the same time, she assumed the name of Catharine Alexievena. On their first introduction, the young pair were pleased with each other. They were both handsome, and a mutual attachment seemed to be formed, which promised the happiest consequences. But an unexpected circumstance occurred, which not only retarded for a while their union, but which completely alienated the affections of the princess. The Grand Duke was seized with the small-pox, which, being of a very malignant nature, so disfigured his countenance, that Catharine could not behold him without disgust. Ambition, however, was a stronger passion in her heart than love. She had sufficient art to conceal her dislike; and submitted, with apparent cheerfulness, to the nuptial ceremony. Her mother and the empress were both delighted with the alliance. But the abilities and accomplishments of Catharine very ill accorded with the weakness of her husband. She soon began to perceive that her hand had been given to one upon whom she could place neither her affections nor esteem. His follies and vices were to her a daily cause of shame and regret; and she often blushed at beholding him so unworthy of her. Peter, on the other hand, blushed at the superiority of his wife. He felt constrained in her presence. Her company was forsaken; and his days and nights were generally spent in the midst of his dissolute companions. Mutual disgust and jealousy was the consequence, which both parties took so little trouble to conceal, that it soon became apparent to the whole court. But Catharine consoled herself with the hope of a crown; and while the grand duke was indulging in drinking and gaming, she was busily employed in acquiring partisans among the nobles, and in laying the foundation of her future power.

Pleasure, however, was not forgotten, though it never was allowed to interfere with her plans of ambition. She revelled in all the wantonness of an unprincipled and debauched court. Her amours with Soltikof, the prince's chamberlain, were notorious, and her partiality was so un guardedly expressed, that Peter alone was blind to his shame. Such, indeed, was his indifference, that he vindicated before the empress the innocence of Soltikof. Catharine had the address to profit by his folly, and pleaded also the cause of her paramour and of her own honour with such eloquence, that Elizabeth was led to discredit the various reports which were circulated against her, and to receive her again into favour. Emboldened by success, Catharine renewed her correspondence with the chamberlain, which continued without interruption until his removal to Hamburg.
Catherine

as minister plenipotentiary from Russia. His absence, however, and the arrival of the young Count Stanislaus Poniatowsky at the court of Elizabeth, soon produced a revolution in the affections of Catharine. Soltikof was forgotten, and the young Polander had scarcely declared his admiration, than he was admitted into all the familiarities of a favoured lover. This new intrigue was carried on with as little secrecy as the former, and soon spread throughout the court.

The enemies of Catharine were loud in their sentences. The indignation of the empire was awed, the jealousy of Peter was alarmed; and the grand duchess was about to be overwhelmed with infamy and disgrace, when she was extricated from her difficulties by the extreme fondness of Elizabeth for the young Paul Petrovitch. When no offer of accommodation would be listened to by the empress, except upon the most mortifying conditions, Catharine asked leave to retire to Germany. This request, she had reason to believe, would not be granted, as her departure would expose her son to the hazard of being afterwards declared illegitimate; and consequently by awakening the feelings of Elizabeth, who was now in her dotage, for her favourite Paul, a concilia
tion was immediately effected. The storm, which threatened to burst upon her head was thus dissipated; and to the astonishment of the court, she appeared at the theatre by the side of the empress, who treated her with the most marked and friendly attention.

But the death of Elizabeth and the accession of Peter opened a new field for the genius and exertions of Catharine. She had little to expect from a husband, whom she had so deeply injured, and openly despised; but she had in some measure fortified herself against his power, by her influence with some of the most distinguished nobles of the empire, and had attempted to conciliate the popular favour by an exterior of piety and devotion. The first measures of Peter's reign, however, gave her no uneasiness. He, who when grand duke was dissipated, capricious, and impetuous, was no sooner seated on the throne, than, to all appearance, he was transformed into a temperate, equitable, and enlightened monarch. He retained in his places the great officers of state, and was particularly kind to such as had been at

ached to Elizabeth. All his former animosities seem to have been forgotten. The grand duchess was treated with marked attention, and received the most flattering testimonies of confidence and esteem. Her opinion was consulted on all affairs of importance. He seemed to delight in her conversation; and to repose himself on the strength of her under

standing. Catharine, however, knew too well the temper and disposition of her husband to be deceived by this change in his conduct. He possessed neither judgment nor energy sufficient for the government of a great empire. Inconsistency and levity were the predominant features in his character, and consequent
ly she could have little dependence on his kindness; but was always prepared against the dropping of the mask which he had assumed for ambitious and selfish purposes, and which accorded so ill with the weak
ess and versatility of his mind.

Peter no sooner supposed himself firmly established upon the throne, and secure of the popular favour, than he resumed his former habits. The greater part of his time was spent in dissipation. His appa
rent respect for Catharine was turned into indiffer
ence, and sometimes to rudeness; and while his mist
ress, the Countess Woronosof, was publicly distin
guished by his attention, she was often subjected to
the most humiliating neglect. The countess even boasted of her power over the Czar, and of his in
ention to raise her to the throne of Russia. He
himself took no pains to disguise it; but often hinted
his resolution of repudiating Catharine, and of publish ing her infidelities; of declaring illegitimate her
son Paul Petrovitch; and of adopting as his succes
or the Prince Ivan, who had been dethroned by
Elizabeth. Informed of these designs, Catharine was not idle in adopting measures for their prevention.
She had long seen that her only safety was in the de
thronement of her husband, and her own exaltation;
and had proceeded by slow but certain steps to the
accomplishment of her purpose. She had opposed to
his harshness and neglect, the utmost address and
dissimulation. She affected an air of resignation and
piety; accosted the poor with kindness, and attended
daily prayers in the churches of Petersburg. Her
situation excited the compassion of the populace, and
by her arts she soon gained their affections, which
the Czar, by his follies, was rapidly losing. She had
also been assiduous in drawing to court, and attach ing
to her interest, men of courage and intrigue; and
did not hesitate in disclosing to a few, upon whose dis cretion she could depend, her intention of ascending
the throne. But her plans were laid with such se crecy and art, that to each of her accomplices, the communication was at first distinct, and each acted without the knowledge or concurrence of another.

Catharine herself, in her retirement at Peterhoff, an imperial palace on the gulf of Finland, whither she had been dismissed, animated and directed them all;
and impelled by the designs of Peter and the hope of absolute power, she prosecuted her schemes with
a wisdom and dispatch, which could not but be at tended with the most fortunate result. The chief conspirators were Gregory Orloff, a man distinguished
for his courage and strength, but possessing nei ther the advantages of birth nor education; Lieu tenant General Villebois; Hetman Kurilli Kazu
mofsky; Prince Volkonsky; Count Panin; the Arch bishop of Novgorod; Lieutenant Passick; and the
Princess Dashkof, all determined and active charac ters. But Catharine was also aided in her purpose
by the indolence and indiscretion of the Czar, who, confident of security, was wasting his days in the midst of his profligate and artful companions; and by delaying the execution of his own designs against the empress, hastened his destruction. Even when he was informed that a conspiracy was on foot, he dis regarded the intelligence, and could not be prevailed upon to seize those who were suspected.

When the plot was sufficiently matured, and the conspirators had resolved upon the dethronement of the Czar, they chose the anniversary of St Peter and St Paul, as the most proper opportunity of seizing his person. This anniversary was to be celebrated at Peterhoff, and the conspirators awaited only the arrival of the Czar to complete their purpose. But before the appointed time the plot was discovered, and Passick, one of the principal actors, was im mediately arrested. The conspirators were struck with
consternation. Peter was for the present secure from
their power; and the first step of their design was
frustrated. But all was not lost. They were only
driven to hasten their measures, and they determined,
that very night, before the Czar could be informed
of their proceedings, or take any steps for preventing
them, to carry Catharine to Petersburgh, and pro-
claim her sovereign of all the Russians.

Catharine, under pretence of leaving the apart-
ments of the palace free for the approaching festival,
but in reality with a view of facilitating her escape
to Sweden should her plot fail, had retired to a re-

dote summer-house, called Montplaisir, situated at
the extremity of the garden on the shore of the gulf.
Here she had concerted with her associates the mea-

ures which were to be pursued, and remained in
quiet expectation of the result. But about two
o'clock in the morning, she was aroused from a pro-

found sleep by the unexpected entrance of a soldier,
who delivered a note from the Princess Dashkof, and
said, "your majesty has not a moment to lose, get
ready to follow me." Catharine was at first thu-

nstruck, but immediately recollecting herself, and

summoning all her resolution, she disguised her dress
so as to elude the observation of the sentinels about
the palace, and with her attendant Ivanova hastened
to the carriage, which Alexius Orlof, one of the
conspirators, had ready at the garden gate. They
set off at full speed, and after some interruption,
arrived safe at Petersburgh by seven in the morning.
A small band of soldiers hailed her arrival with joy-
ful acclamation; and swore to die in her defence.
Others soon followed their example, and in a few
hours, the whole city was in motion. The troops
declared their allegiance on a crucifix; and in the
midst of a vast concourse of spectators, Catharine
was crowned, in the church of Kasan, by the Arch-
bishop of Novgorod, who proclaimed her sovereign
of all the Russians, and declared Paul Petrovitch her
successor in the empire. The Te Deum which follow-
ed was accompanied by the shouts of the multitude;
and when Catharine returned to the palace, crowds of
the inhabitants flocked thither to take the oath of
fidelity, among whom were many of the principal
nobility, who cheerfully joined their homage to that
of the multitude.

Thus was a most important revolution effected
without bloodshed; and before the evening, Catharine
saw herself in possession of a well fortified capital, a
devoted populace, and 15,000 chosen troops. But
of the consequences of this revolution; the de-

thronement and murder of Peter III.; the assassina-
tion of the unfortunate Ivan; and those wise and vi-
gorous measures, by which she supported her usur-
pation, extended the boundaries of her empire, and
raised it to its highest glory, we must refer for a
particular account to the article Russia. Instead,
therefore, of anticipating here what will be more pro-

perly introduced under that head, we shall only ob-
serve, that her policy, in almost every instance, was
dictated by a spirit of ambition and vanity, which
often led her to promote or to sacrifice the hap-
niness and interest of her subjects according as it suit-
ed her own views of aggrandisement. The object of
all her public conduct was the advancement of her
own fame. To this end her attention and exertions
were continually directed. She affected to imitate
and rival the most illustrious deeds of former mo-

narchs, and was incessantly engaged in measures that
might attract the reverence and admiration of the
world. She laboured, like Frederick of Prussia, to
render her capital the seat of literature and the

sciences; she encouraged commerce and manufac-
tures; reformed abuses in the state; and cherished,
to the end of her life, the favourite and mighty pro-
ject of expelling the Turks from Europe, and of
reigning in the ancient capital of the eastern empire.

But notwithstanding all her exertions for promot-
ing the welfare of her people, the system of favour-

itism, by which her government was administered,
often proved most destructive to their happiness.
This system had been followed by the former em-
press, and was strengthened by the nature of Catha-
rine's situation. She had usurped a throne, and her
accomplices aspired to become her equals. From
these some of her principal favourites were chosen;
but others were merely fortunate adventurers, chiefly
distinguished for their beauty and accomplishments.
Of the former, the chief was Gregory Orlof, a man
of rough expression and brutal manners; and among
the latter, was Potemkin, whose splendid talents,
elegant manners, and military exploits, are still re-
membered in Russia with enthusiasm. Whoever en-
joyed the protection of the reigning favourite, could
exercise the most undisguised tyranny and injustice.
Every dependent was a petty despot, who could
trample upon his inferiors, and violate the laws with
impunity; and thus her administration, which, with-
in the immediate circle of her own influence, was
mild and temperate, was at a distance arbitrary and

oppressive.

Catharine, from the commencement of her reign,
was almost constantly engaged with schemes of fo-

reign aggrandisement; and during a long and pros-
perous life, she annexed to her dominions, by her
arms or by intrigue, the Crimea, the Kuban, and
part of the frontiers of Turkey; Courland, and Se-
migallia; and nearly one half of Poland, besides im-
mense tracts of country in northern Asia. She had
also penetrated into Persia, and taken Derbent; and
by her treaty with Great Britain and Austria in
1795, called the "triple alliance," she looked with
confidence to the conquest of Constantinople. But
she was stopt in her ambitious career by a fit of apo-
phecy, which carried her off on the 10th of Novem-
ber 1796. On the morning of the preceding day
she was in good spirits, and having taken her coffee,
had retired to her closet: but remaining longer than
usual, her attendants were alarmed, and upon enter-
ing her apartment, found her lying speechless on
the floor! Dr Rogerson her physician, being imme-
diately called, ordered her to be bled, which gave
her some relief, but she lingered only until the fol-
lowing evening, when she expired in the 66th year
of her age, and the 35th of her reign. Her remains
were laid in state by the side of those of her unfor-
tunate husband, and a true love knot, which reached
from one coffin to the other, bore this inscription in
Russ characters, "Divided in life—united in death."
They were then deposited in the same tomb, in the
church of St Alexander Nefsky.

Catharine was of a middle stature, rather inclined
to corpulency, and well proportioned; but her erect
walk and dignity of demeanour gave her a tall ap-
Catherine II.

Catherine II. had an aquiline nose, a chin somewhat long, an agreeable mouth, auburn hair, and blue eyes arch'd with black and thick eye brows. "Her physiognomy," says one of her biographers, "was not deficient in expression, but that expression never discovered what was passing in the soul of Catharine, or rather it served her better to disguise it." Dissimulation, indeed, was the occupation of her life. She had been early practised in its arts, and she gained the favour of her people more by her hypocritical devotion, than by any other action of her reign. Though an infidel in principle, and a disciple of the new philosophy; though she often expressed her contempt for the doctrines and ceremonies of the national religion, and even held its ministers in abhorrence, yet she sometimes condescended to enter into its most childish superstitions. She not only attended the churches during public worship, and prayed with all the semblance of a sincere and fervent pietist, but she was punctual in the most superstitious practices of the Greek religion. On her journey to Moscow in 1775, she carried with her a great number of little figures of saints, which she distributed in churches and chapels on the road; and even performed a pilgrimage with all her court, to a convent situated about 40 versts from that city, walking on foot the whole way. The garb of religion was assumed by her merely for purposes of policy, in order to gain the affections, or to attract the reverence of the ignorant multitude. In private, she was destitute both of its influence and its spirit. In the midst of a licentious court, she herself was the most licentious. After the death of Peter III., she would never submit to the authority of a husband, though repeatedly solicited both by Orloff and Potemkin; but chose rather to indulge herself in all the variety of unrestrained wantonness. Whenever she cast her eyes upon one of her subjects with whom she wished to exalt to the situation of favourite, she immediately created him her general aid-de-camp, that he might accompany her every where without reproach or observation; and appointed him an apartment in the palace, which apartment communicated with that of the empress by a private passage. He was then given to understand, that, if he wished to retain her favour, he must not converse familiarly with any other woman, or leave the palace without express permission. When the favourite had rendered himself obnoxious, or had lost the power of pleasing, he received orders to travel; but his dismissal was accompanied with a suitable recompence, which, in general, corresponded with the time he had served her majesty. During her reign, twelve persons had been distinguished by this high honour, upon whom she bestowed in lands, money, jewels, &c. to the value of above 88,000,000 of rubles; and the estates which were given to the family of Orloff alone contained nearly 45,000 boors.

The love of fame was another predominating feature in the character of Catharine. Whatever was likely to conduce to the advancement of her glory, was undertaken with eagerness, and prosecuted with vigour. This passion, which in her degenerated into vanity, often led her to engage in unjust wars, from which no benefit was to be reaped either to the empire or herself, but the empty satisfaction of having conquered. It however also induced her to undertake many projects, both laudable in themselves and beneficial to her subjects; but such was the restlessness of her mind, that her plans seldom received their full execution. She was continually carried away by some new passion, to which all preceding ones gave place; and this continued only until some other idea of stronger influence was started. Every thing was begun with great pomp, but was soon forgotten, so that at her death, the monuments of her reign are said to have resembled so many wrecks and dilapidations: colleges, colonies, establishments, manufactories, hospitals, canals, towns, fortresses, &c. all had been begun, but all were given up before they were finished. This weakness of Catharine's drew a most satirical remark from the emperor Joseph II. When travelling in the Crimea, he was invited by the empress to place the second stone of the town of Eckatorinolof, of which she herself, with great parade, had laid the first; and on his return he said, "I have finished in a single day a very important business with the empress of Russia, she has laid the first stone of a city, and I have laid the last." Her vanity led her even to aspire to literary fame, and to rival the reputation which Frederick of Prussia had obtained by his writings. She wrote her celebrated "Instructions for a Code of Laws," copies of which were sent to several of the sovereigns of Europe for their approbation; some dramatic pieces, which were acted and admired at the Hermitage; and several moral tales and allegories for the instruction of her children. But these were raised rather on account of the hand that wrote them, than for their merit; and the best of all her writings are her Letters to Voltaire, which are indeed much more interesting than those of the old philosophical courtier himself.

With all her failings, however, Catharine possessed many noble qualities, which shed a lustre over her reign, and which will be long remembered by her country. The murder of her husband, and the butcheries of Ismail and Warsaw, were the crimes of her station, not of her heart. The one, as she had usurped a throne, was necessary for her own safety and the continuance of her power; the others arose from the bloody dispositions of the Russian soldiery. Catharine was naturally humane and generous, of most engaging manners, and was never known to be immoderately transported with passion. Her criminal laws breathe a spirit of mildness, worthy the imitation of more civilized nations; and during her long reign a sentence of death was extremely rare. Though possessed of absolute power, yet, in her "Instructions," she acknowledges no authority but that which was founded upon justice; and her whole plan was directed to the formation of a solid legislature, and to prevent the capricious injustice of all who were intrusted with the administration of the laws. Her spirit of toleration was truly admirable. At the commencement of her reign, she laid down a resolution, which she adhered to, without any deviation, to the last day of her life, that no person should suffer in any respect on account of his religious opinions. Papist, Calvinist, Mahometan, or Heathen, could aspire to any office in the state, civil or military, without any apprehension of his being rejected for his particular creed. When once speaking of heretics, she said smiling, "Poor wretches, since we know that they are to suffer so much, and so long in the world to come, it is but reasonable that we should endeavour..."

by all means, to make their situation here as comfortable to them as we can.'

As a sovereign, Catharine ranked among the wisest and most powerful princes of her age; and it is a sufficient evidence of her fortitude, abilities, and decision, that, though a foreigner and usurper, she maintained her authority in the midst of disaffection and rebellion, extended the boundaries of her empire, and made her vices be forgotten in her greatness, and her apparent regard for the public good. "Her sex," says one of her biographers, "giving a bolder relief to the great qualities displayed by her upon the throne, will place her above all comparison in history; and we must recur to the fabulous ages of an Isis or a Semiramis, to find a woman who has excelled, or rather undertaken such daring projects."

Among these projects, however, her usurpation of Courland, and the partition of Poland, will ever stand against her as monuments of her rapacious injustice, though they have been equalled in later times, and may be attempted to be justified by the general practice of nations, who, in their rage for conquest, are seldom guided by the principles of justice and good faith. dotes sur la Revolution de Russie. (p)

CATHARINE'S, St., an island on the coast of Brazil, situated in Long. 47° 37' west, and between 27° 19' 10" and 27° 49' of south latitude. It is about six miles broad in its narrowest part, and is separated from the continent by a channel about 400 yards wide. The surface of this island is diversified with mountains, plains, and swamps. The mountains of the interior, and the conical rocks which rise abruptly from the sea, are of primitive granite. Close to the fort, on the left hand of the entrance to the harbour, is a vein of grunstein in different states of decomposition, which ultimately changes into clay of a quality superior to that which is found in the valleys. The island is covered with trees that are perpetually green, but from their being intermixed with briars and thorns, the forests are impassable, and are said to be infested with noxious serpents. The houses are erected on the margin of the sea; and the surrounding woods, abounding in orange trees and aromatic plants, yield a most delightful fragrance.

The soil in the interior of the island, though rather humid, is surprisingly fertile; it consists chiefly of a rich vegetable decomposition, and yields almost spontaneously all sorts of fruits, vegetables, and grain. The cultivated lands are under considerable improvement. They were formerly covered with large trees; but as great quantities have of late years been cut down for the purposes of ship-building, good timber is now scarce. Flax, from which the fishermen make their lines, nets, and cordage, grows here of a good quality. The produce of St. Catharine's consists in rice, maize, mandioca, coffee, oranges, lemons, ciontrons, cotton, sassafras, and guiacum. Sugar and indigo are raised in small quantities, and the potatoes are reckoned the finest in the world.

The climate is healthful and serene. The prevalent winds which are from the south-west and north-east, moderate the solstitial heats. The former prevail from September to March, and the latter from April to August. The genial nature of the climate is indicated by a profusion of the finest flowers. The rose and the jessamine are in bloom all the year round. Myrtles are very common, and a beautiful variety of the passion flower is found in equal abundance. The principal animals are opossoms, monkeys, and armadillos. The beautiful coral snake occurs among the numerous tribe of serpents; and the principal birds are, cranes, hawks, parrots, humming birds, and toucans. The sea produces a great variety of excellent fish, and so well is the market supplied, that a quantity sufficient to dine 12 persons may be had for a shilling. A large ox cost 8 piastres, (when La Perouse visited the island,) a hog of 150lbs. cost 4 piastres, and turkeys were sold for a piastre the pair. In 1804 the price of meat was about 14d. per pound, and poultry, eggs, and the finest vegetables, were both abundant and cheap.

As the inhabitants require all the produce of the island for their own consumption, their trade is of course inconsiderable. Numerous coasting vessels from Bahia, Pernambuco, &c. bound for the La Plata, touch here; and the island is amply supplied with artisans of all descriptions.

From the landing place, which is at the bottom of a verdant slope of about 500 yards, the town has a very beautiful appearance, and its fine cathedral appears in the distance. The town consists of several streets. The houses, which have two or three stories with boarded floors, are well built, and they are provided with neat gardens. The number of inhabitants is between five and six thousand. On entering the port of St. Catharine's by the north there are several islands. On one of them, to the westward of the entrance, is the fort of Santa Cruz, the most considerable in the island. Off this fort, there is a safe anchorage for a fleet of ships of war, and ships of 300 tons may enter the harbour. There are several watering places on the island. The fort of Santa Cruz is only a large enclosed battery, and is incapable of making a regular defence. The garrison in 1785 consisted of 50 men, ill paid and clothed. Here are other four forts, Porto Groed, Ratones, Estreito, and Concepção.

The island of St. Catharine's is divided into 4 parishes, 1st, Nossa Senhora de Dereito; 2d, St. Antonio; 3d, Lagunys; and 4th, Riberen. The divisions on the opposite part of the coast, called 1st, St. José; 2d, St. Miguel; Nossa Senhora de Rosario, are under the jurisdiction of the governor of St. Catharine's, who, in some instances, is subject to the government of Rio de Janeiro, and, in others, to the captaincy of St. Paul's. The inhabitants are in general hospitable and obliging to strangers. The ladies are handsome and lively, and are chiefly employed in the manufacture of lace.

The population of the island and of its dependencies on the opposite coast, amounts to about 30,000. See La Perouse's Voyage, vol. i. and ii. ; but especially Mawe's Travels in the Interior of Brazil, particularly in the Gold and Diamond Districts of that Country, by authority of the Prince Regent of Portugal. London, 1812. (π)

CATILINA, L. SERGIUS, a patrician of Rome, was descended of an old and respectable family. Neither his father nor grandfather appear to have filled any public office, but several of his ancestors were

men of talents and of consideration in the state. See Pliny, vii. 28. His great grandfather was praetor of the city in the year U. C. 553, and obtained great credit for his moderation and integrity. See Livy, l. xxxii. c. 27, 29, 31, and lib. iii. c. 21, 24. When Catiline first entered upon the stage of public life, the highest expectations were formed of his future eminence, and though his character was not free from all imputation of levity, yet his fellow citizens reposed with confidence on his patriotism, and excused his excesses as the errors of unguarded youth. But in the discharge of the office of praetor, to which he was elected at the usual age, he shewed such complete want of principle, and such unbridled profligacy, that it was easy to foresee, in the conduct of the abandoned magistrate, the depravity of the future traitor. In the year after, he was sent as the propraetor to Africa. In this situation he governed with the utmost inhumanity, and, to feed his extravagance and debauchery, exacted immense contributions from the inhabitants. The oppression of his administration was so severely felt, that a deputation was sent from Africa to impeach him of cruelty and extortion.† But it seldom happened that the unhappy provinces, which suffered all the miseries of war, aggravated by the permanent and arbitrary despotism of capricious governors, could obtain redress by an appeal to Rome: (Cicero in Verr. passim.) The Senate, conscious of their own injustice and rapacity, felt the inconsistency of punishing in others the crimes which they had themselves committed, and often made common cause with their officers against the wretched provinces. Catiline was acquitted, and no notice, in consequence of these proceedings, was taken of him, but to declare him incapable of standing candidate that year for the consulship, because he had neglected to register his name. During this prosecution, Catiline requested Cicero to be his counsel, who either was, or pretended to be, so much deceived regarding his real character, that he at first consented, but, in consequence of the disclosure of some acts of villany, afterwards refused.‡

The excesses and prodigality of Catiline after his return from Africa involved him in much embarrassment: and it was from the pressure of pecuniary distress, and the galloping load of public infamy, that he first formed the design of enriching himself in the spoils and destruction of his country. Bold as such a scheme was, and appalling one would have thought to every mind, however depraved and hardened, there were not wanting numbers in Rome, who, from their profligacy and despair, shrank from no enterprises or enormities which could promise them any relief. "Qua ob summan miseriae mutum de tenere conditio
tem pertinacites, dum turbare ac miscere omnem, in meliorum fortunas et opes impellens velati ad hosti-

† Multas graves sententias (inquit Pedianus in Cic. Orat. in tog. Candid. in eo dicta sunt.
‡ Fenestella says, that Cicero did defend him; but this is a mistake, as Torquatus was his counsel. See Cicero Orat. pro Sylla.
§ See the elegant work of Gravina De Ortu et Progressu Juris Civilis, lib. 1. sect. 12, for a most nervous and eloquent description of the blood-thirsty ferocious savageness of these hardened monsters. un prandom." While he secured a sufficient number of these needy villains, whom gold could easily tempt, "unto a close exploit of death," Catiline was not attentive to the arts by which he could gain adherents of more influence and importance. With this view, he drew around him many young men of family, by his attractive and fascinating manners, whom he led gradually on to vice, until he had ruined for ever their characters and their fortunes, and made them companions in profligacy. When, like the envenomed spider, he had entangled his victims irretrievably in his snares, and plunged them into the gulf of ruin, he proposed to them his plan of extirpating themselves by the overthrow of their country, or the dreadful alternative of dying in the haunts of misery and vice, and exposed to the execration of every good and virtuous Roman. Their hesitation was not long; and thus were the materials of a mine laid, which had nearly exploded in the centre of Rome, and covered the world with its fragments. In the mean time Catiline stood candidate for the consulship, backed with the powerful support of Crassus and Caesar. Among his competitors was M. Fulvius Cicero, whose integrity and transcendent talents rendered him equally an object of hatred to every faction, and of admiration and confidence to the good and the wise. Some suspicions of Catiline's designs having been surmised among the people, they took alarm, and chose Cicero and Antonius consuls. The fury of Catiline on being thus baffled in his attempt to retrieve his ruined fortune, broke out into the most violent turbulence, and happily discovered to the Romans the character of this candidate for power and popularity. The consuls and patricians were on their guard at the next election, and effectual measures were taken to prevent his success. Irritated by the vigour and opposition of Cicero, whose powerful mind disconcerted all his designs, and met him in every plot, he resolved to assassinate him and the other consul, on the day of election for the ensuing year. But the genius of Cicero still predominated; the plot was discovered, and Catiline rejected with disgrace. His outrageous resentment precipitated him into open rebellion, and several armies of his partizans were collected in different parts of Italy. The event of this rash conspiracy, and the circumstances connected with it, are so well known, and have been blazoned forth with such parade in every page of Cicero's writings, that any detail of them here is wholly unnecessary. It is customary to represent Catiline as a mere tool employed by Caesar and Crassus to corrupt the people, and alienate them from their attachment to the established constitution, but whose impiety and ambition carried him to lengths to which these more wary politicians were unwilling, openly at least, to proceed. But in this opinion we cannot concur. The conduct and views of Catiline betrayed none of the artifices or subversiv-eness of an instrument of faction. He had no design of advancing the interests of any party or political leader. His object was not to depress one party in order to raise another, but the destruction of all parties, and the general ruin and desolation of the state.
Of the character of Catiline in early life, and of the habits which drew him on to such a consummation of wickedness, it is much to be regretted that no full account has been transmitted to us. It would have been a most instructive moral lesson to mark the progress of such a man, and to witness the delusions and wickedness which irresistibly brought him into the rapid whirlpool of vice. Sallust mentions, in general terms, that he was a profligate almost when a boy, and was early hardened in guilt. But the authority of Cicero, who says, that originally he had a good disposition, and evinced a strong desire of honourable distinction, is on this point unanswerable. “Habuit ille perrnulta non expressa signa sed adumbrata virtutem,” &c. But of the power and vigour of his talents, of his ardent and comprehensive mind, and of the dauntless and lofty intrepidity of his character, he has left too striking proofs to allow any slur to be thrown upon his abilities. Bold and ferile in invention, and of invincible perseverance and courage in execution, he was well fitted for the head of a faction. Yet the same qualities, kept under steady control by reason and prudence, would have rendered him an ornament to his country. But he was naturally volatile; and his keenness of disposition led him to join with equal eagerness in the society of the virtuous or the profligate,—in the pursuits of virtue, or the indulgence of vice. Unaccustomed to regular restraint, his mind yielded easily to temptations; and by a lamentable perversion of talents, he became the first in the career of licentiousness, as he had once been also in more becoming and worthy occupations. It was natural that a character produced by so strange a mixture of vicious and praiseworthy principles, by a combination of passion with the talents and energy that could render it formidable, should prove dangerous to the liberty and independence of his country. But the actions of Catiline, let it be remembered, are preserved to us only in the treacherous and exaggerated statements of political adversaries; and we ought to receive, with caution, the invectives with which his memory has been loaded. At the period when his conspiracy was formed, the internal condition of Rome was such as to make almost any change preferable to her lifeless and degraded government. The people were corrupt and licentious; more interested in the triumph of the factions to which they had attached themselves, than in securing the freedom, and promoting the welfare of their country. The energy and spirit of public virtue was palsied by the deadening influence of luxury; and the public opinion, the firmest bulwark against the encroachments of tyranny, was now employed to buoy up the vices of party. The government was become a capricious oligarchy; a few ambitions and intriguing leaders, to whose power and influence the liberty of the people was sacrificed, divided the state, and embroiled it in the miseries of civil disensions. To the arrogance and struggles of these conflicting factions, the people submitted with abject acquiescence; they even encouraged and strengthened the intrigues of party; and though a determined resistance might have crushed this many-headed monster, they seemed to consider that their hopes of liberty were gone, and thoughtlessly joined in raising the power which finally reduced them to subjection. While such was the situation of Rome, we cannot

wonder that a man of ardent and enterprising talents should have seized the opportunity which her distracted state afforded of aiming at absolute power.

J. H.)

Cato of Utica, a celebrated Roman, was the great-grandson of Cato the Censor. At a very early period he was left an orphan, and, along with his brother Cassio, and his sister Porchia and Servilia, was brought up in the house of Livius Drusus, his maternal uncle, who at that time had great influence in the administration of public affairs. He soon gave marked indications of that firm, virtuous, and decided character, by which he was afterwards so much distinguished. It appeared in his look, in his manner, in his conversation, and even in his amusements. Plutarch relates various anecdotes of his childhood, which shew how much the dispositions of the boy resembled those of the man. One of these particularly deserves to be mentioned. When in his fourteenth year, he happened to be in Sylla’s house, and seeing the heads of many illustrious persons carried out, and the spectacles sighing in secret at the bloody scene, he asked his preceptor, “Why somebody did not kill that man?” “Because,” said he, “they fear him more than they hate him.” “Why then,” said Cato, “do you not give me a sword, that I may kill him, and deliver my country from slavery?” His austere manner of life led Cato to be partial to the doctrine of the Stoics, whose philosophy he studied and embraced. He also devoted considerable attention to popular eloquence, in which he became so mean proficient. In the servile war with Spartacus, he served as a volunteer, and gave such proofs of his military skill and courage, as to secure for himself the highest praises of the commander, and afterwards a tribune’s commission in the army sent into Macedonia under the Prætor Rubrius. On being appointed to the office of questor, for the duties of which he had prepared himself with great industry, he introduced a very thorough reform into that department, correcting with an unsparring hand the abuses which had crept into it, punishing those who had been guilty of introducing them, and putting the affairs of the treasury on a new and excellent footing. For his conduct in this, he received great applause from the people. The office of tribune, which he filled in the consulship of Cicero, was equally honoured by his integrity and public spirit. He obtained it in spite of very formidable opposition, by the assistance of men of honour and virtue, and he discharged its functions, in the midst of many difficulties, with credit to himself, satisfaction to the people, and advantage to the state.

Cato took an early and conspicuous part in the public transactions of that most interesting and momentous period in the history of Rome. His whole conduct seems to have been actuated by a spirit of patriotism. He respected men in proportion to their solicitude for the general welfare. To those who were hostile or indifferent to the interests of the republic, he set himself in active and undaunted opposition; and forgot personal comfort, and the partialities of friendship, and every private consideration, when the interests of his country demanded his aid. To Cicero he gave his warm support; not yielding to him implicitly in every case, but defending the great principles and features of his administration, and openly bestowing up-
on him the title of Father of his Country, an eulogium of no mean value as pronounced by the stern and patriotic Cato. He shewed great zeal and courage in attacking those who had joined in the conspiracy, of which Catiline was the head, and succeeded, by his energy and his eloquence in the senate, in procuring the capital punishment of the conspirators. On this occasion, he boldly attacked Caesar, who argued for mild measures, and who himself was not altogether free from suspicion of being a partaker in the guilt of those for whom he pleaded. Fearing every thing that was bad to the commonwealth from the vast and unprincipled ambition of this extraordinary man, Cato regarded him with jealousy and distrust, and thwarted him without ceremony and without intermission, in those projects by which he attempted to aggrandize himself at the expense of his country. After a variety of occurrences, in all of which Cato acted in the most disinterested manner, as well as with his characteristic boldness, the fate of Rome came to depend upon the issue of a contest between Pompey and Caesar. Although he had disliked and opposed many of the proceedings of Pompey; although he had on some occasions met with very injurious treatment from him; and although the prospect of that civil war, which was now inevitable, filled him with sorrow; yet, sensible that it was necessary to take a decided part, and that the only hope which remained for the liberties of Rome, was to be derived from Pompey's success, he attached himself to the cause of that general, and co-operated with him for the discomfiture and humiliation of Caesar. The prudence of some parts of Cato's conduct in this important crisis, may perhaps be disputed; and it has ever been suspected that his suspicion of Caesar was partly produced by the personal injuries which he had received. But when it is recollected that the injuries alluded to were the effects of the profligacy of Caesar, who had debauched Cato's sister; and that the difficulties which a man of real virtue had to struggle with in those corrupted times were neither few nor inconsiderable, the character of this patriot cannot suffer from such partial and feeble imputations.

After the fatal battle of Pharsalia, Cato retired into Africa with the forces under his command, expecting to meet with Pompey. Hearing of Pompey's death, he marched into Libya to join Scipio, which he accomplished after a painful and hazardous march in the midst of winter. Scipio acted rashly and foolishly: for though Cato, who remained in Utica as governor of the town, strongly advised him not to risk a general engagement, he despised the advice, and was completely overthrown. Caesar advanced to Utica: "Strange!" said Cato when he heard of his approach, "it seems he takes us for men!" Cato was determined not to fall into the conqueror's hands: and seeing no chance of escape, or of successful resistance if he should escape, he resolved to fly to the last refuge of a Roman. Having demanded a sword, and read Plato's dialogue on the immortality of the soul, he stabbed himself under the left breast. The physician attempted to sew up the wound, but Cato tore it open again, plucked out his bowels, and instantly expired. Caesar on receiving the intelligence of Cato's death, is reported to have exclaimed, "Cato, I envy thee thy death, since thou couldst envy me the glory of saving thy life." Cato was forty-eight years of age when he died. He left a son and daughter. The former was worthless: the latter married Brutus, who killed Caesar, was trusted with the secret of the conspiracy, and died as her father had done. See Plutarch, Sallust, &c. (τ) CATOPTRICS, from κατόπτρος specularum, and that from καινατην και στημιου, I see, is that branch of optics which treats of the laws and properties of light, when reflected either from plane or curved surfaces. See the article Optics. (w) CATTLE. See Agriculture, Index.

CATULLUS, Caius Valerius, a celebrated Roman poet, was born at Verona, of a respectable family, probably about the year of Rome 667. His father, Valerius, appears to have been a man of some consideration in the commonwealth: at least, it is certain that he enjoyed the friendship of Julius Cæsar, who was in the habit of lodging at his house, when he happened to pass by the way of Verona. Although by no means in very opulent circumstances, Catullus must have inherited a moderate fortune; for he not only possessed a small-villa at Tibur, whither he occasionally retired from the bustle of a city life; but in the beautiful little poem, which he addressed to the peninsula of Sirmio, he speaks of that delightful spot as his hereditary property, and his home.

He accompanied Memmius, the preitor, in his expedition to Bithynia; from which, however, he tells us, neither he nor his comrades derived much emolument or advantage:

 jLabel qaud erat, mihi nec ipsi. 
Nec prætoribus esse, nec cohorti, 
Cui quisquam caput unctius referre.—X. 9, &c.

In his progress to Bithynia, upon reaching Troas, he had the misfortune to lose his brother, whom, in several of his poems, he laments with great feeling and tenderness.

Catullus usually resided at Rome, where he devoted his time to literature, to society, and pleasure. His wit and genius recommended him to the company, and procured him the friendship of many of the most distinguished characters of his age and country, among whom were Manlius Torquatus, Cicero, Calvus, an orator and poet, Cornelius Nepos, to whom he dedicated his poems, Asinius Pollio, Lucretius the poet, and several other persons of no mean reputation. His mistress, whose real name was Clodia, was celebrated by him under the name of Lesbia, probably from Lesbos, the birth-place of Sappho. This lady, to whom he appears to have been much attached, became, as he himself informs us in one of his poems, not in the most delicate terms, a common prostitute.

Catullus was a man of learning, according to the notions of his age, having acquired a perfect knowledge of the Greek language, from which he translated two of his most beautiful poems—the one from Sappho, and the other from Callimachus. Hence, he came to be distinguished by contemporary writers by the epithet doctus. The precise date of his death is uncertain; but that event is generally believed to have taken place about the fortieth year of his age.

A considerable proportion of the poems of Catullus consists of verses written upon amatory subjects,
of which some are exquisitely beautiful, while many are rendered disgusting to every reader of chaste feelings, by the most offensive indelicacy. The grossness which pervades these productions has been ascribed, in a great measure, to the influence of the depraved taste of the times, in which compositions of this nature were not merely tolerated, but highly relished; and Catullus himself endeavours to extenuate his offences against decency, by observing, that the morals of a poet ought to be irreproachable, but that his verses need not be pure.

Nam castum esse deectum pium poetam
Ipsum, vericus nihili necesse est.—XVI. 5.

Such a distinction, which is but too often attempted to be drawn by amatory poets, we conceive to be altogether inadmissible. What a good man writes ought to flow from the same principle with what he does; and if any one countenances, or disseminates vice or indecency by his writings, it is something worse than absurd to attempt to justify himself by an appeal to the purity of his conduct. Nor can we allow the gross taste of the times in which he lives to constitute a legitimate apology for the obscenity of an individual writer. It ought to be the study of every virtuous man to preserve himself free from the contagion of licentious example; and this is a duty, if possible, still more incumbent upon an author, who labours not only for the age in which he lives, but for posterity; and whose writings, therefore, may have no trivial influence on the opinions and moral conduct of remote generations. Besides, we know that other authors, nearly of the same age with Catullus, preserved, in general, throughout their works, a purity of principle and decency of expression, which entitle them to the praise of virtue, as well as of genius.

Catullus also wrote bitter satirical invectives against those whose conduct incurred his disapprobation. In some of his pieces of this description, he severely attacked the character of Julius Caesar, under the name of Romulus. This extraordinary person, whose private life laid him sufficiently open to censure, could not fail to be incensed at seeing himself thus exposed to public view in an unfavourable light; but the poet having afterwards made an apology, Caesar generously forgave him, and lived with him on the same friendly footing as he had previously done. Most of these epigrammatic effusions are composed in iambic and Phalæcian verse of eleven syllables, called versus hendecasyllabi; and are remarkable chiefly for their poignant severity and licentious indelicacy.

The poems of Catullus were highly esteemed by the ancients, several of whom speak of the author and his works in terms of respect and admiration. Indeed, if we select from among the number of his productions, such as are free from indecinate allusions and obscene language, we shall find much that deserves to be admired. He has a sweetness and classical propriety of expression, a tenderness and playful simplicity, which must render his verses interesting to every reader of taste and feeling.

The principal editions of the poems of Catullus, according to Bayle, are those of Scaliger and of Passerat. The oldest edition is probably that of Venice, 1488, with the comments of Anthony Parthenius. There are also the edition of Grævius, Utrecht, 1680, in 8vo. with the entire notes of a great number of commentators; that of Isaac Vossius, Lond. 1684, in 4to, with a very learned commentary; the Variorum edition of Frankfort, 1621, by John Gebhard, with the very ample index of Tuscanilla; the edition of Vulpius, 1710, 4to.; of Mattaire, 1715, 12mo. and in the Corpus Poëtarum; of Silvius, in toto Delphini, Paris, 1685, 2 vols. 4to.; the Cambridge edition, 1702, 4to.; and Baskerville's, Birmingham, 1772, 4to. An English translation in verse, with the Latin text and notes, was published in 1795.——

CATURUS, a genus of plants of the class Dioscia, and order Triandria. See Botany, p. 334.

CAVAN, an inland county in the province of Ulster, Ireland, situated midway between the Atlantic Ocean and the Irish Sea, from the shores of which its eastern and western extremities are each distant about 14 miles. It is bounded by the county of Fermanagh on the north; by Monaghan on the north-east and east; by Meath, West Meath, and Longford on the south; and by Leitrim on the west. Its greatest length, from east to west, is about 51 English miles; and its greatest breadth, from north to south, 28 miles. Its area contains 758 square miles. The whole county is covered with hills, of which none rise to any remarkable height, though Sliabh-Rusell, and the mountains of Ballynageeragh, strongly mark its northern and western boundaries; and Bruce Hill is a striking object in its southern extremity. The waters which issue from the lakes in West Meath flow through this county; and, expanding in some places into small lakes, retaining in others the appearance of rivers, form many picturesque and beautiful scenes. Cavan can scarcely be regarded, however, as a desirable place of residence. Its climate, though salubrious, is boisterous, cold, and uncomfortable; except on a few gentlemen's seats, it is sheltered by no forests or plantations; and though its interior is adorned by lakes of great extent and beauty, in many places, particularly to the north and west, it is bleak, dreary, and exposed. The soil is in general poor, and though almost the whole of it is under tillage, yet the wretched system of agriculture which prevails here contributes but little to its improvement. It is chiefly occupied by manufacturers, who rent small farms, seldom exceeding 20 acres; and whose principal object is to raise a sufficient quantity of oats and potatoes for the support of their families, with small crops of flax, to give employment to their women. The average value of land is from 26s. to 30s. the acre.

The manufactures of Cavan make it a populous and flourishing county, and will in time contribute materially to the improvement of its agriculture. The fabric for which it is most celebrated is a thin linen, for the most part 7 ths wide. The average sale of linen, manufactured in this county, is estimated at about L. 100,000 per annum. Of late, however, the superior demand for cotton goods has induced the manufacturers of Cavan to direct much of their attention to the weaving of muslins.

This county is stated by Mr. Wakefield to contain at least 6000 freeholders, one-half of whom neglect to enrol their names. It sends two members to par-
CAVAN.

Caucasus, one of the 41 governments into which the Russian empire is divided. This government is subdivided into two provinces; Astrakan, and another known by the same name as that of the government. Within the latter of these provinces is comprised the Cuban, and all the districts to the east and south, now in the possession of Russia, between the rivers Don and the Cuban, and between the Black Sea and the Caspian, extending as far as the confines of Georgia, and which is constantly receiving new accessions, in consequence of the reduction and submission of the wandering hordes. The same name of Caucasus is the common appellation by which the whole of the great ridge of mountains is distinguished that stretches between the Caspian and the Black Seas; and it is also the name of the very high mountain which constitutes the principal summit in this great and extensive ridge.

The Caucasian mountains are the most distinguishing feature in the region in which they are situated. They stretch from the mouth of the river Cuban in the north-west, to the outlet of the river Kur, into the Caspian Sea, in the south-east. There seems reason to believe, that a connected chain extends also from this ridge of mountains in a south-western direction, to the vicinity of the bay of Scanderoo, as at the other extremity of it other chains branch out into Persia, which theyervade from north-west to south-east. These latter ridges terminate in the deserts of the south eastern part of that country, or at least are so imperfectly connected with the mountains of Hindoo-Koh, that it would be difficult to trace their junction. Much less can they be considered as an extension of Mount Taurus, which terminates the county may afford for the education of its youth, we have not been able to ascertain.

This county contains 50 parishes, of which 26, with 24 churches, are in the diocese of Kilmore; three in the diocese of Ardagh, and one in that of Meath. It was formerly called East Brefynn, and sometimes O'Reilly's county, from the Irish family which possessed it. It was forfeited at the beginning of the reign of James I.; and a great proportion of it is still in possession of the descendants of those settlers to whom he allotted it. See Wakefield's Account of Ireland, Statistical and Political, 1812; Sir Charles Coote's Statistical Account of Cavan; and Beaufort's Memoir of a Map of Ireland. (μ)

CAVAN, the assize town of the above county, is a post and market town, but is in no other respect of any importance. Previous to the act of Union, it sent two members to parliament, but now has not the privilege of returning one. N. Lat. 54°, W. Long. 7° 16'. (μ)

CAVANILLA, a genus of plants of the class Dicicia; and order Tetrandria. See BOTANY, p. 335.
Of the whole range of the Caucasian mountains, extending in the manner that has been already delineated, from west to east, or rather in a direction between north-west and south-east from the Euxine to the Caspian, the length is stated to be about 350 or 400 English miles. As they approach the seas on each side, these hills decline very much in height. Throughout the range, where the elevation is greatest, there is a tract of about five miles in breadth, which is covered with eternal ice. The breadth of the whole chain on the northern declivity, extends at most to 50 miles, and runs along on the prodigious northern plain which, taken in the quadrature, measures 1000 English miles, being bounded on the east by the Siberian, and on the west by the Valakhian mountains. To the northward and southward of this tract of mountainous ground, the country, in all directions, is generally flat and level. The Marshal Von Bieberstein, who remained in these regions a considerable time, and was at the greatest pains to ascertain precisely every circumstance of consequence concerning them, states the extent of the Caucasus in length, from its western extremity at Gbakh to Tarhug, to be 95 German miles; its breadth, on the side adjoining the Caspian Sea, to be 53; in the middle, where the river Terek to the north, and Arakui to the south, form a division between its eastern and western parts, 96; and on the western side, along the Porta Cumana, a celebrated pass, 150 miles. The icy ridges of this mountainous tract, and indeed its ridges in general at their highest points, consist usually of granite. Immediately adjoining to these, both on the northern and southern sides, are mountains of slate. Farther on are hills of limestone or chalk, which terminate in sandhills. The main mountain, or rather the high ridge of the main mountain, from which the whole declines and sinks towards the two seas, seemed to Guldenstadt to be not more than from five to seven versts in breadth. This he describes as a granitic stratum, consisting mostly of a line of mounts, of a truly Alpine height, which, by reason of their local elevation, particularly in some open fissures, contain everlasting snow and ice, generally exhibit bald rock, without any covering of earth or plants and trees, and in some parts pierce into the clouds. The extension of this principal ridge towards the two sides, measured from north to south, or right across, he reckons, on an average, to be 70 versts; and the north side, he observes, is visibly steeper or higher than the southern, as it declines in a far narrower or smaller breadth, or rather only sinks down towards one part. The limestone mountains mentioned, run in a flat clayey field, of 20 miles in breadth, gradually declining till they end in a promontory 10 miles broad, which consist almost wholly of sandstone, and that again runs out again in a clayey plain about eight miles broad, in which there occur numerous sandstone hills. In this plain there abound common salt and natron, and in the promontory, and its continuations, there are found sulphur, sulphur-pyrites, warm sulphureous springs, iron-stone, vitriol, petroleum, rock-salt sources, nitrous salts, bitter salts, magnesia, vitriolata, alun, selenite, &c.; also some petrifications, chiefly in flint. Specimens of lead and copper are rarely seen in the promontory, but often in the higher mountains. The slate of this district contains alun. There appears in it also aerie of lead, in which there occurs silver and copper pyrites, in courses of quartz and spar. Courses of blyeplantz are seen in particular situations, likewise other lead ores, and various ores of other kinds. In the upper regions, it is remarked that the river Hippus, in Iberia, yields gold; that the mountains in these parts are very rich in minerals, and that the gold mines at Cumana were wrought by the Romans. The mountains on the Kura, especially in the district of Azghur, likewise contain very rich ores, and in the plains adjacent to that river, there are found fine marble, coal, and warm springs. In the mountains bordering on the Terek, as far as the village Stephantzinda, there occur lead, silver, and iron ore. In the Georgian province Somghetia, rich silver and iron ore, marble, and Jasper, are met with; in the circle of Quoetsh, copper ore; in the principality of Tamblut, rich lead, silver, and gold mines; in the principality of Lori, considerable copper-mines and good mill-stones; in the principality of Unslar, rich copper-mines; in the parts about Akdale, gold, silver, and copper; and in the province of Albania, marble and alabaster, iron, warm baths, petroleum, and rock salt. Thus it appears that, in the highest points, the Caucasian chain of mountains is covered with snow and ice; and that this chain having its highest, middle, and fore-mountains or promontories, the sides of it generally are very rich in minerals; and, probably, in those parts which are now added to the Russian empire, contain a treasure of the precious metals. The elevation of this ridge is, on the whole, very considerable, and many of the rocky parts are extremely steep and prominent.

Professor Pallas, in his observations during a journey along these mountains, takes notice somewhat particularly of three of them that occur, two in the immediate vicinity of each other, and the third at a greater distance, and which rising one above another in height and importance, may be considered to exhibit specimens of the principal altitudes that occur in this tract, as the account of them may be of use towards giving a more accurate idea of the conformation and aspect of the range of country.

The lowest of those heights to which he has had occasion to advert, is the Metshuka, situated, he remarks, on the common and extensive basis of the
Beشtau and its adjacent hills. This mountain borders on the Podkuma, about 5 verst north-west below Constantinogorsk. It is a calcareous mass of considerable extent, and in a conical form. It is richly covered with wood, and apparently more than one-third part the height of the lofty Beshtau. It consists of a greyish, firm, calcareous mineral, without petrifications, not unlike the hornstone, and which is disposed in tolerably thick horizontal beds. It has an appendage on the anterior side, consisting of a species of tophus, and in the centre of its summit there is a deep cleft like a valley, overgrown with wood. From the foot of the mountain a steep and narrow ridge, consisting of an uncommonly beautiful white tophus, extends along the low country of the Podkuma to the west, and in a curved direction towards the north-west, not unlike a promontory. This ridge divides itself at the western extremity into two branches, one of which extends directly to the west, runs nearer to the river, is upwards of 200 paces longer than the other, and appears to be a more ancient production of the sulphurous waters. The direction of the shorter branch is, so far as it extends, more north-western. They are both plentifully covered over, and ornamented with various kinds of rock and other plants. On the southern side of the whole ridge, there were observed here and there some as it were rounded projections of tophus, disposed in successive laminated strata, which appeared to owe their origin to small springs, or channels of lime-water impregnated with sulphur, and some of which still continued to run while others were then in a dry state. These strata, as well as the whole mountain, decline abruptly towards the low country.

The Beshtau, the next mountain, and next in elevation to the one now described, is remarked, by the same writer, to be frequently enveloped in clouds to its very base, while the summit even appears to project over them. This mountain is situated on a level and very extensive eminence, rising much above the current of the rivers Kuma and Podkuma, together with several adjacent mountains, among which the Metshuka just noticed, is one of the nearest and most considerable. That eminence presents no species of rock, except the very ancient limestone which forms the whole of this mountainous tract, and has scarcely any petrifications. It occupies the whole space between the two rivers, and produces no trees but those growing on the four contiguous mountains. In the background these are connected by what is called the Asses Ridge, and form between them a large glen or valley; from the midst of which, and the loftiest of the whole species, rises a fifth mountain, reaching the clouds with its summit. This is of a conical or rather angular form, and so narrow on its top, that scarcely ten persons have room to stand by each other. From that point, several narrow ridges extend towards the four adjacent mountains; to which circumstance the name is apparently owing, by which this mighty mass is designated of Beshtau, or the five mountains. Towards the top of the mountain the wood, which abounds on all or most of the adjacent hills, begins to decrease, and to degenerate into dwarf trees. Mingling with, or rising above, these in respect of their position, there occur numerous shrubs chiefly of the beautiful kind; the azalea pontia, which last are finally succeeded by the barren summit of the eminence. From the top of the Metshuka, it is perceived that the mountainous tract which connects the Beshtau with the principal adjacent heights, appears to run chiefly in a direction with the stream of the river Kuma already mentioned, the eminences rising progressively as they extend towards the south-west, till they unite with the Elburus, situated near to the sources of the river Cuban.

The Elburus is the most distinguished of the eminences that seems to have attracted the attention of Professor Pallas in this quarter. The account which he gives of it and of the adjoining elevated ridges is as follows. "From Madshary," says he, "we first descried the snowy mountains of the Caucasus. During the whole of this day's journey, they appeared particularly distinct to us on account of the serenity of the air, and exhibited in their train a most magnificent spectacle. Besides the lofty and colossal Elburus, which towered above all the others, and as it were guarded the whole chain on its western extremity, there were four principal groups crowned with snow, which were particularly conspicuous by their irregular summits. The black mountains, as they are usually called here Tahunye Gory, appeared at this distance like a regular wall which connected the snowy mountains that rose above it, while it formed their basis. The height of these black mountains is apparently equal to that of the Beshtau, though the latter is 150 verst distant from the former; and that part of the Elburus which is covered with snow appears to be above double the height of the Beshtau, which, however, is much nearer the place whence we viewed those vast piles. The other groups of these snowy mountains appear to the eye one-third lower than the Elburus: the most conspicuous are the broken mounts near the rise of the Aredon, and the summits of Kasibek beyond the source of the Terek." In a note it is remarked, that the Elburus is not inferior, perhaps, to Mont Blanc. The different surrounding tribes, it seems, distinguish it by different names. From what particular nation it has received the name of Elburus has not been ascertained. But in those parts it appears to have been pitched upon as a fit object with which to connect some of the notions of the prevailing superstition. It is considered as the residence of the king of the hobboblins, distinguished by the appellation Dshim Padishah; and in the vicissitudes of an unfortunate war, it serves as an asylum to the discomfited nations. The most considerable of the mountains, it is observed, which form a chain with the Elburus, are Ketshergan, Barma-cut, and Auar-setsh, which lie near the sources of the Kuma and Podkuma: between these and the Baksaun there are, towards the east, Mount Urdel, and the mountains of Kandshall, as well as several others. Towards the north and east of the Beshtau, an extensive plain presents itself to the eye, over which there is, in clear weather, a prospect even as far as Kislar and the Caspian Sea.

It has already been remarked, that the Caucasian mountains contain abundant stores of various valuable minerals. There is diffused in the same quarter a copious supply of other kinds of natural wealth, equally deserving of attention. Many of the valleys in this district are extremely fertile; and an abundance is everywhere within reach of some of the substances from which the most effectual aid may be
obtained towards exciting the principles of fertility inherent naturally in a soil, or adding to those which thus even in their original state they possess. There are found here, in different quarters, arable land of an excellent quality, meadows, pastures, and extensive and valuable tracts of woodland; which last produce the finest forest-trees of various kinds, furnish an inexhaustible supply of fire-wood, and by affording places of refuge for a profusion of useful game, make amends for the inconvenience with which, indeed, al- so they are in some degree attended, of offering haunts to animals of prey.

In the same tract of territory, several important rivers run in different directions; such as, on the Russian side of the mountains, the Terek, the Cuban, and Kumna; on their southern quarter, by which they are connected with the Persian dominions, as well as more immediately with several other less considerable states, the Rian, the Kur, and the Aras. The whole region, too, is intersected in all its parts with a vast profusion of minor streams tributary to these or other considerable rivers.

Amongst the other divisions of their natural productions deserving of consideration, may be reckoned the mineral waters that have been discovered in some of the Caucasian mountains. These occur chiefly upon or in the neighbourhood of the Meshbuka, already mentioned, and the immediately connected hills. The first of them that may be noticed, is a cold spring, situated in the vicinity alluded to, and at the distance of 55 versts from the fortress of Constantinohor, towards the N. W. It has its origin in a kind of pit, between two rivers of fresh water, issuing from several crevices in the rocks. Thence the limpid mineral water rushes forth with a violent motion, continually ejecting large bubbles, together with a ferruginous brown and sleek sand, thus perfectly resembling coffee in a state of ebullition. The violence with which this sand is forced to the surface is more or less consider- able at different times, and frequently on immersing a glass a little way downwards, it may be taken out more than half full of it, but as it is immediately precipitated, the effervescent water then appears as clear as crystal; and even in the spring itself, the sand by its own weight falls to the bottom, so as not to be carried into the channel of the bason. The great mass of water that is sent forth from the extensive cavity through which immediately the fluid is brought into contact with the external air, having foamed about for some time, and thrown up its sprays in various directions, is finally discharged, by the hollow channel mentioned, into one of the rivers by which it is surrounded in the form of a semicircle. Its junction with this, and through it with the other body of water, though each of these be more considerable than itself, is yet attended with the remarkable effect, that the barbel and trout, which are very numerous in the upper parts of these streams, cannot exist in the places where they receive this mixture; an effect to be attributed, no doubt, to the remains of carbonic acid in this mineral water, and of which, in the upper parts of the spring where its force is more enti- re, the influence is such, that fish taken and plunged into it immediately float motionless on the surface, and recover but slowly when replaced in the water of the rivulets.

The stream proceeding from the mineral source is distinguished, in the language of some of the adjacent tribes, by the name of Nartzan, or Nar Tsana, which name, after its junction with the contiguous rivulets, it communicates also to them, so that for some length in its course, the same continues to be the appellation of the whole body of these united waters. The spot whence primarily the Nartzan derives its origin is contained in a valley situated at the foot of lofty mountains of limestone, by two high ridges of which description the valley is nearly enclosed, while it is fronted by a third of greater elevation than either of the others. The source of the spring may perhaps be found to be in a horizontal line of sandstone below the calcareous strata of these surrounding moun- tains, and from which bed it is that it appears to convey with it the brown sand. The traces of the actual existence in this quarter of such sandstone may be conceived in various places in the vicinity, as well as the fact legitimately inferred, from different consider- ations that will suggest themselves to the attention of the careful observer.

In addition to the principal source, the mineral wa- ter in question is transmitted also through several inferior veins of different sizes, some of which occur here and there in the shallow parts of the basin itself. On plunging the hand into this water, no remark- able sensation of cold is felt; on the contrary, it seems in some veins to be like warm, particularly during the cold air of the morning. It appears cold, however, when drunk, especially when the heat of the sun promotes its evaporation, and thus imparts to it a degree of freshness. If it be drunk while the body is heated, it has an effect on the stomach similar to ice. The thermometer of Reaumur indicates in it a temperature of about 10 degrees when the atmosphere is at 16. It stimulates the tongue with an agreeable acid taste resembling that of Seltzer water, a quantity of the carbonic acid equal to that contained in the strongest of which waters it still continues to hold, notwithstanding its disposition to part with a great proportion of that with which it is originally impregnated, and is in fact super- saturated. When recently and properly drawn, it has a briskness equal to that of the best Champa- gne wine; and if put up with due care for keeping, it will remain for any length of time fresh and clear, notwithstanding the magnesia contained in it. It effervesces with all kinds of wine, and in general may be drunk in any quantity at pleasure without danger. It has been examined by different persons capable of judging of its merits, and some of whom were sent purposely by government to ascertain its nature; when the result, it is said, proved it to be in reality possessed of medicinal virtu- tue. It is reported evidently to refresh and invigo- rate the body insomuch as to have produced wonder- ful effects on several sick and debilitated persons. It is stated to be of the greatest efficacy in hemor- rhoidal obstructions, after invertebrate fevers, and the subsequent chronic complaints thence originating, as also in cases of the suppression of the menses, and similar indispositions which are frequently the forerunners of disease. There seems, moreover, reason to be- lieve, that if brought into more general use, so that its properties might become better known, it would be found serviceable also in various other maladies.

For its remarkable briskness, the water of this mi-
no spring seems to be indebted chiefly to the carbonic acid, saturated with lime and magnesia, as well as to the salts which it holds in solution. When placed on a very gentle fire, it speedily boils with great agitation, immediately begins to grow turbid, and deposits a white sediment. From 16 pounds of water, the dry sediment obtained by evaporation weighed 8 drachms and 20 grains. This sediment loses, in the process of drying, about 7 grains. The result of the chemical analysis of it by M. Lovitz the academicians, gave from 133 grains the following ingredients: Of muriate of magnesia, 1 grain; Glauber’s salt in a dry state, 46; vitriolated magnesia in ditto, 25; muriate of soda, 10; carbonate of lime, 26; carbonate of magnesia, 10; carbonate of iron, 2; sulphate of lime 13. From 20 pounds (apothecary’s weight) of the water, subjected to a similar analysis, the following were the ingredients obtained: Of carbonic acid 580 cubic inches; of carbonate of lime, 87 grains; of carbonate of magnesia, 12$\frac{1}{2}$ grains; of carbonate of iron, 2$\frac{1}{2}$; of sulphate of soda, 53$\frac{1}{2}$; of sulphate of lime, 4$\frac{1}{2}$; of sulphate of magnesia, 27$\frac{3}{4}$; of muriate of soda, 27$\frac{3}{4}$; of muriate of magnesia, 2$\frac{1}{2}$; of resinous extract, 5.

In the vicinity of the spring of Nartzan, and at different elevations in the mountain Metshuka before described, there occur several important springs of hot sulphureous water. The first of these rises from the round extremity of the principal but shorter ridge already mentioned, as constituting one part of a sort of continuation connected with that mountain. Near the source of the veins, by the contributions from which this spring is formed, a bath has been hewn in the tophus stone, and contiguous to it a small chamber has been built of wood for the use of bathers. At a quarter height in the mountain, in an open cleft upwards of a fathom broad and deep, by ten arshines in length, there is found another natural hot-bath of a temperature rather higher than that of the former spring; this extends into the rock of sandstone towards the east, is six feet wide, nearly ten fathoms long, and has a smooth vault not unlike an artificial grotto. This is the place resorted to by the Turcoman women for bathing, while their husbands make use of the lower bath. At still greater heights than these, and rising progressively one above another, there occurred three other springs of a similar description and character with those just mentioned. With regard to the water of them all, the smell of the sulphur, perceptible at a considerable distance, the snow-white tophus stone, of a crystalline nature, which is here very frequent, and the flowers of sulphur precipitated in the channels of the descending water, are sufficient indications of its principal constituents. Even after it has run probably over the whole length of the tophus ridge, this water is yet in the most distant springs hotter than the hand can bear, and causes the mercury to rise in the thermometer of Reaumur 57$\frac{3}{4}$ degrees, or 162 degrees of Fahrenheit. The abundant calcareous sediment which it deposits, is at first, and continues for some time afterwards, as soft as pap, in which state it is used by the Circassians and other tribes, for whitening their houses. In a bed of this substance, which is four or five inches thick, needles of the spath kind are gradually produced; and this crystallization becomes more and more frequent, as well as compact, till at length the whole bed is converted into a heavy snow-white tophus, that exhibits pores and almost perpendicular needles in its fracture. This species of tophus is acted upon by the nitric acid, which causes a violent effervescence, so that the stone is completely and speedily dissolved: if exposed to fire, it discovers no perceptible trace of sulphur. Every pound of the sulphureous water last mentioned, contains upwards of 16 grains of a white earthy sediment. The water itself has a slightly styptic, sweetish taste, and evidently contains a portion of alum, which renders it serviceable in diarrhoea and dysenteries, particularly when the first passages have previously been evacuated. In rheumatic pains, cutaneous eruptions, and invertebrate ulcers, it is of essential service, if used as a warm bath. Gouty and paralytic patients have recovered by its use. But in intermittent fevers this bath ought not to be resorted to, as it is apt to occasion dangerous obstructions.

In 1801 an account was given by Mr Simpson, a chemist, of a warm spring discovered in the chain of the Caucasian mountains, five versts north-east from the fortress of Constantinohor, and forty from the first mentioned cold spring. It runs straight towards the west, down the steep declivity of a chalky, shelly, and curiously coloured mountain, falls from the height of forty-four yards, divides itself into small rivulets, and entirely disappears at the foot of the mountain. Another report was made during the same year, concerning the Caucasian mineral waters, by the general Obriekzow, in consequence of which Drs Hordinsky and Krushevitich, and Mr Skwentzon, a chemist, were sent thither for the purpose of procuring such precise and satisfactory information respecting them as might serve to determine government whether any, and what steps ought to be adopted with a view to turning them to useful account. At the same time, accordingly, Mr Skwentzon was employed in ascertaining the nature and the composition of the two springs just alluded to, the medical gentlemen applied themselves to discover their proper use and application, and in making practical experiments on different individuals of both sexes. The substance of their accounts, in some of the particulars of which, it will be perceived, that they have been anticipated in the observations already introduced, is as follows:

The temperature of the hot spring, during the warmest parts of summer, is, in the evening, from $35$ to $37$ degrees in Reaumur’s thermometer. The quantity of water discharged in three minutes and 15 seconds, is 3,580 lb., and its weight is equal to that of distilled water brought to the strength of a mineral water. It has a smell of sulphur, and contains sulphuric and carbonic acid; after the evaporation of 300 pounds, till the vessel was quite dry, there remained 12 oz. 7 dr. and 35 grs. of solid matter. The water of this spring is good for curing eruptions of the skin, intermittent agues, scrobutic, chronic and venereal diseases, dropsy, and long standing rheumatism. The cold spring, according also to Reaumur’s thermometer, has at all times 10 degrees of temperature. The weight of its water to that of distilled water, is in the proportion of 50 to 30. It is very transparent, has a sharp acid taste, and a smell of carbonic acid, which substance enters into its composition; after the evaporation of 400 pounds of it by boiling, there remained 9 oz. and 1$\frac{1}{2}$ dr. of solid matter. The ef-
The effect of this water, whether drunk, or only applied externally, is very beneficial in chronic rheumatisms, in cases of general debility occasioned by venereal excesses, in luxorrhoids, king's evil, ring-worms, palsy, internal obstructions, and in all diseases where it is necessary to stimulate and strengthen the action of the vitals.

The composition of this latter, or the cold spring of Constantinohor, as found by Mr. Skwentzon, is that which has been already given. In 20 lb. of the water of the warm spring, the ingredients, according to the result of his analyses, are these; of carbonic acid, 106 1/2 cubic inches; of sulphurised hydrogen gas, 80 gr.; of carbonate of lime, 99 1/2 gr.; of carbonate of magnesia, 17 do.; of sulphat of soda, 101 1/2 gr.; of sulphate of lime 31 1/2; of sulphat of magnesia, 66 1/2; of muriate of soda, 158 1/2; of muriate of magnesia, 14; of resinous extract, 3.

Mr. Skwentzon having ascertained the principal component parts of the two springs in the Caucasian mountains, which chiefly engaged his attention, drew up and produced, upon his return home, a comparative table of their ingredients with those of other celebrated mineral waters; and government have spared no expense in rendering them convenient places of resort.

The mountainous regions of Caucasus have been, from time immemorial, and still are the habitation of bold and valiant warriors, who have, with determined resolution, resisted the reiterated attacks of the Mongols, Arabs, Persians, Tartars, and Russians, and maintained, in a considerable degree, their freedom and independence. On the most elevated parts at the same time even of these vast ridges, and in vallies almost inaccessible, there is found, along with these, a singular mixture of small people of various denominations, differing from one another, most probably in origin as well as in language, but with respect to whom many of the circumstances that appear most curious and out of the common track, do not easily admit of any tolerable explication. The distinct and appropriate languages spoken in this quarter, are said to be numerous, and to branch out into an incredible diversity of dialects, some of which deviate so entirely from the known languages of Asia and Europe, as to admit, in no degree even of comparison with them; some are known languages, without any foreign admixture, and there are others which seem to consist of a mixture of several known ancient languages, such, for example, as the old Georgian, the Mongolian, the Persian, the Arabic, and the Tartarian.

It will be understood, from the circumstance of the languages just named having been introduced, more or less, among the inhabitants of the Caucasian mountains, that, though not subdued, the original inhabitants of those parts have not escaped all commixture with different foreign tribes. In fact the population of these regions, generally considered, may be held to consist chiefly of mingled races, made up partly of the primitive settlers, partly of colonies of those nations by whom, at different times, they have been more or less brought under subjection. From the difficulty, however, of ascertaining precisely the primitive stocks from which all the descriptions of persons that occur here, or rather the tribes or branches of tribes that constitute the population of those mountains, have been derived, it has been usual to comprise them all, with the exception of the Georgians, under the general denomination of the Mountain-Tartars. This subject has been involved in obscurity, in consequence of some writers having admitted almost as many different races of people, as there are principal names of tribes and families. Guldendenst is the first who had the merit of endeavouring to reduce the small scattered tribes which occur in these parts to certain classes, and of combining the names belonging to a particular tongue by collecting accurate vocabularies. Professor Pallat, proceeding upon his plan, has given a pretty distinct and satisfactory account of the nations inhabiting the northern parts of the Caucasus, to which nations, it is to be observed, he has chiefly confined his attention, as being those most intimately connected with Russia, and which, at different periods, had in a great measure acknowledged its sovereignty.

The following are the tribes comprehended in his enumeration:

1. The small Abasa, or Altikesek. Under this general designation are reckoned six subordinate divisions, viz. the Shantemir, the Klitch, the Kesha, the Lou, the Bibert, the Duderuk. The people of this tribe inhabit the country between the rivulet Maraukh and the river Podkuma, consequently occupying a part of the Turkish and part of the Russian frontiers. They do not submit to the government of princes, but are ruled severally by the elders of their subdivisions. At a former period they were Christians, but their nobles now profess the Mahometan religion. Agriculture is not unknown amongst them, but they maintain themselves chiefly by the rearing of cattle, and they possess a beautiful breed of horses.

2. The great Abasa, who occupy a considerable tract of territory stretching generally to northward and westward of that just mentioned. The subdivisions comprehended under this appellation are the Beshibai, the Barakai, the Tubi and Ubukh, the Shaptopsk, the Natukash or Natkhu-Kaitshians. Agriculture and the rearing of cattle are a little attended to by some of those belonging to this tribe, but generally they are much neglected. The Beshibai keep a few goats and sheep, and pay great attention to the cultivation of bees. The Natukhians cultivate a small quantity of rye, and occasionally keep hogs, animals rarely met with among the other nations inhabiting this country. The several divisions of them are given to dissensions amongst themselves, and many of them devoting themselves to a predatory life, obtain by this means a hard-earned and precarious subsistence.

3. The warlike nation of the Circassians inhabit principally the promontory of the Caucasus, extending themselves also to the adjacent beautiful plain, from which they have expelled the ancient inhabitants, and subjected the greater part of them to their dominion. From the superior importance of this tribe, it has been usual, though improperly, to comprise under the same appellation, several of the contiguous and less important tribes. But the people, in strictness, thus designed, are those who inhabit the part of Caucasus, called the Great and the Little Kabardia, the islands of the lower Cuban, and the southern bank of that river. They denominate themselves Adege; i. e. islanders; by the Russians they are called Tchekersssi, and by the rest of Europe by the name here given to them of Circassians. See Circassia.
4. The Nagais, or the Tartars of the Cuban, who dwell among the Circassians, as well as in their vicinity, and generally lead a pastoral life; they are the remainder of the Mongolian Tartars, formerly a powerful people who, after the reign of Zengis-Khan, invaded and governed part of Asia as well as Europe, but have, during the last century, been so much reduced by the vicissitudes of war and their own turbulent conduct, that at present they scarcely deserve the name of a nation. They occur, however, in small numbers, in different parts of the region under consideration, and are subdivided into the following principal branches: the Naurus, the Kassai, the Kaspolat, the Kantschak, the Mangut, or Mamsugut, the Gedissau, the Dshambolnik, and the Gishtikul; they are a restless unsettled people, whose disposition to robbery has been little reduced, notwithstanding the severity of the punishments to which they have been subjected. Their principal means of support are their flocks, though a little attention is also paid to agriculture, particularly to the cultivation of millet.

5. Several separated branches of the Nagais and Tartars, are scattered on the mountains of the Caucasus, viz. the Kumyks, the Terekmes, the Karata-shais, and the Tshegems. These people are nearly in the same state of society with those previously mentioned. Christianity seems at one period to have made some progress amongst them. Their attention is chiefly directed to some branches of agriculture, to the rearing of their herds and flocks, or to the produce of honey. They turn also to some account others of their natural productions, such as iron, lead, nitre, and the skins of wild animals. One of the divisions of this people, the Tshegems, have received from some writers the name of Zekhi, from the analogy of which name it has been conjectured that they were originally Bohemian fugitives.

6. The Ossetes, or Ir, and according to their own denomination Rones, are a very peculiar people, who, having been compelled to retire to the interior parts of the high-mountainous, have, for their boundary towards the north, the Caucasus, towards the west the river Urup, to the east the Terek, to the south west the river Rion, or Phasis of the ancients, and to the south east Aragva. The whole tribe is divided into districts, or Kom, and villages or Kou. It is observed that the tongue peculiar to these people has many words in common with the Persian, German, and Slavonic languages, as well as expressions analogous to the dialect of these nations. The Ossetes are a barbarous, predatory, and miserable race of men, who have alwaysinfested the public road leading to Georgia through the mountains which they inhabit. The two most populous and powerful of their districts are those of Dugor and of Durdugor.

7. The Lamurs, Galgaits or Ingushians, differ entirely from all other inhabitants of the Caucasus, in language, as well as in stature and in features. Their manner of pronouncing is as if their mouths were full of stones; they are said to be an honest and brave set of people, who maintain their independence, and are subject only to their elders or priests, by whom their religious sacrifices are performed. They are almost the only nation inhabiting the Caucasus among whom the shield has been preserved as a part of their accoutrements. They are excellent marksmen, but giving little attention either to agriculture or the rearing of cattle, they are constantly in a state of poverty; they live in the vicinity of the sources of the rivers Kumbelu and Sunsha, and extend their habitations along the high mountains to the eastern bank of the Terek, where they border on the Ossetines. The Karubulakes likewise border on the Ingushians towards the west, and on the Tshetschentzes towards the east. These three last communities speak nearly the same language, which is not known to have the least analogy to any other dialect except that spoken at Tushet; in respect of this similarity, the judicious Guldenstadt has thought fit to class them altogether under the common denomination of Mitzdshegis or Kesti, who appear to be the remainder of the true Alamins. They are by no means, however, of the same national character—the Tshetschentzes, indeed, differing so radically from the Ingushians, as to be justly considered the most turbulent, hostile, and predatory inhabitants of the mountains.

8. Of the Suani, like the last mentioned people, a race of mountaineers, the habitations on the southern basis of the Elburus, extend to the west as far as the source of the Engur; towards the south they border on the principality of Dadian, and the Imeretian province of Odishi; towards the east, on the source of the Tzenis tzkale or horse river, the Hippus, undoubtedly, of the ancients. They live dispersed in particular families, are great depredators, yet call themselves Christians; they pay some attention to agriculture and the rearing of cattle. Their principal intercourse is with the provinces of Imeretia and Mingrelia. The amount of their population is not exactly known, but it appears not to be considerable.

In the Caucasian mountains, besides the tribes which have thus been enumerated, there occur several others: the Lessgians, who inhabit the province of Lessgistan, in the eastern Caucasus, between Kakhetty and Daghistan; they are divided into 27 stems, and are totally independent. The Taulintzians, who occupy the summits of the mountains, are also divided into several petty tribes, and acknowledge the protection of Persia. The Amberlina, who dwell in the valleys formed by the mountains of Ghilan, and, though they often change their patron-sovereign, have recently owned a submission to the Persian monarch. Among the modern inhabitants of the environs of the Caucasus, may be also included those Kozaks of Russia, or other colonists, who have been recently settled along the banks of some of the principal rivers, chiefly those in the north, and who serve as a cordon to check the incursions of the native predatory tribes. For an account of the Georgians or Grussians, the most numerous and powerful body of the inhabitants of these mountains, see the article Georgia.

The appellation by which the whole of this mountain range is meant, the highest and most extensive in the northern part of Asia, is distinguished, that of Caucasus is supposed to have been transmitted to the Greeks, in consequence of their intercourse with the Persians. In the language of this people, cau or cah signifies a mountain, whence, it is said, was formed caub cau, or the mountain of the Chassas, an ancient formidable tribe who inhabited the immense tract
extending from the eastern limits of India to the confines of Persia, and probably as far as the Euxine and Mediterranean Seas. Captain Wilford informs us, *(Asiatic Researches*, vol. vi. p. 455.) that the Chasas are often mentioned in the sacred books of the Hindoos. Their descendants still inhabit the same regions, and continue to be called by the same name. They belonged to the class of warriors, but they have been degraded, agreeably to the institutes of Menu, in consequence of their omission of the holy rites, and of seeing no Bramins. Isidorus *(Orig. l. 14. c. 28.)* says, that Cauactus, in the eastern languages, signifies white; and that a mountain close to it is called Casis by the Scythians, in whose language it signifies snow and whiteness. See Pallas's *Travels through the Southern Provinces of the Russian Empire in the years 1799-4*, vol. i. Tooke's *View of the Russian Empire*, vol. i. *Campionhausen's Travels through several Provinces of the Russian Empire,* &c.; and *De Bieberstein's Tableau des provinces occident. de la Mer Caspienne*, Petersburg, 1798. *(k)*

CAYENNE, or FRENCH GUIANA, a province of South America, situated between 1° and 5° N. Lat. and 51° and 54° W. Long. It is bounded on the west by Surinam, on the north and east by the Atlantic Ocean, and to the southward by the Portuguese territories, whence, as far as its boundaries have been defined, it is separated by the course of the Oyapoco. The extent of this province is computed to be 3½ British miles in length, by 240 in breadth. Its immediate limit towards the west is the small river Amano, and on the east that called Aracara.

The project of forming a settlement here was first entertained in the year 1655. A report had prevailed for some time before, that, in the interior parts of Guiana, there was a country known by the name of El Dorado, which contained immense riches in gold and precious stones, more than had been found even in Mexico and Peru. This fable having fired the imaginations of every nation in Europe, it is supposed that it was in quest of the ideal country which it brought into view that Sir Walter Raleigh proceeded on his last voyage. The French were not behind their neighbours, in their endeavours to find out so desirable a country; and in the progress, or in the result of the attempts set on foot for this pur-
this enterprise; and that prejudice which ought to have attached to the manner of conducting the affair having been transferred to the country, government was prevented for a time from paying the least attention to it, and a number of Europeans and inhabitants of the West Indian islands, who might otherwise have thought of doing so, were deterred from settling in Guiana. The force of the mischievous prejudice alluded to, has however subsided by degrees; and, from the peace of 1783 to the Revolution, the French government was meritoriously attentive, by the introduction of new articles of cultivation, and by other means, to the improvement of this valuable district.

The coast of Cayenne is generally low and marshy, and subject to inundations, from the number of rivers which rush down the mountains with great impetuosity. The soil is in many parts uncommonly fertile, though in others it is dry, sandy, and soon exhausted. The productions are on the whole of an excellent quality; and it is easy here to gain a subsistence. The Cayenne pepper is a noted article of the produce. This is the fruit of the capsicum baccatum, gathered when ripe, dried in the sun, then pounded and mixed with salt. It is sometimes baked with a small addition of flour; and the biscuit rushed into powder, is sent to Europe. Owing, at the same time, to the disposition of the inhabitants to indulge to excess in the use of this article, a considerable quantity of it is even always imported from Peru. The subject to which the colonists first directed their attention in this quarter, with a view to profit, was the arnatto. Thence, they proceeded to the culture of cotton, indigo, and sugar. The coffee tree was brought from Surinam in 1721, by some deserters, who thus purchased their pardon. Cocoa was planted ten or twelve years after. Maize, cassia, and vanilla, have also succeeded, though not very conspicuously, at Cayenne. Several kinds of grapes have been lately introduced; and a wine is made there, said to be peculiarly medicinal in fevers.

The state of the population, and production of this colony, stood thus in 1763: The number of whites were 500, who employed 1500 negroes and 2500 native Indians, and raised about 260,000 lbs. of arnatto, 80,000 lbs. of sugar, 18,000 lbs. of cotton, 27,000 lbs. of coffee, 92,000 lbs. of cocoa. They exported also upwards of 600 trees for timber, and 104 planks. The same was still nearly the state of things in 1763. The cultivation of indigo, which at one time was carried on very successfully here, afterwards sustained a considerable diminution.

The island of Cayenne, or Cayanno, which, as it forms but an inconsiderable part of the whole province, though it has been frequently, yet has erroneously and improperly been confounded with it, is separated from the continent only by two arms of a river of the same name. Northwards it is formed by the sea, in other directions by the river mentioned, together with the Oywa and the Orayu. It is about 18 miles long, and eight or ten broad. The situation of this island makes it a most unfit place for a settlement; and it would probably have fared much better with the colonists, had they, instead of taking up their residence in it, in the first instance, commenced their operations on the mainland. The part of the land here adjacent to the sea is hilly and mountainous, in which respect it is distinguished from the generality of the coast of Guiana, that is for the most part, low, and covered with swamp-pines, a species of large trees which grow even in the sea, and form forests at a considerable distance from the shore. The central parts are low and swampy, subject to continual inundations; the necessary means for the prevention of which, it is much doubted whether the soil be good enough to justify putting in practice. All the productions of the neighbouring continent are supplied also by the island; but with this difference, that the latter is as it were exhausted, and does not equally indemnify the planter for his trouble and expence. The number of the inhabitants, exclusively of the garrison, amounts to about 1000 or 1200 whites, persons commonly of the lowest class, who are chained down as it were to the glebe of the colony, because their means will not allow them to emigrate to other parts. They cultivate merely as much land as is requisite for their subsistence, obtaining from Europe in return for the part of their scanty produce which they can spare, wine, flour, clothing, and some other things of which chiefly they stand in need. The remoter continental lands are often fruitful in a very astonishing degree; yet as the produce of the soil, which is a kind of black sand, covering a loamy clay, and fit for making bricks, is not to be obtained without labour and expence, the culture of it has been much neglected. Several of the settlers, thinly scattered over vast deserts, and separated by impervious brakes and brambles, and, at the same time, surrounded by negroes, who threatened to endanger their safety and peace, have relinquished cultivation altogether, confining themselves to the rearing of cattle, which could be kept without care or trouble, in the immense savannas or natural meadows of the country. In these interior parts, little as the improvement of them has been attended to, and though, consequently, they remain obstructed by thick forests and underwood, and almost in all respects quite in a state of nature, there is fed a great number of horses, sheep, goats, and cattle, which roam in them at pleasure; and the beef and mutton obtained in this mode of rearing and pasturing the animals are reckoned excellent.

The climate of Cayenne is much more salubrious than that of any of the Antilles. There are here properly only two different seasons, the dry and the rainy seasons. The former generally continues from the beginning of June until the end of September, during which time the heat is commonly very oppressive, the air is almost always serene, and scarcely a few drops of rain descend to purify and cool the atmosphere. The heavy falls of rain begin in the month of October, and are very frequent in December, January, February, and March, at which time they begin gradually to decrease, until the dry season again sets in. During the rainy season, that is for 7 or 8 months, the heat is very moderate for a place so near to the equator. Nay, the negroes sometimes complain of cold; and, upon the whole, the state of health is as good there as in Europe. However, at the time when stagnant waters are dried up and corrupted by the heat, fevers prevail for about two months, which, though not contagious, prove very destructive. This town, the capital not only of the island of the
CAY

Cayenne.

same name but of the colony at large, the seat of government, and of the courts of justice and of the military, is situated close to the sea on the right bank, and near to the mouth of a river also of the same name, which is there about a league in width. It is of small dimensions, the houses are badly constructed of wood, and it is surrounded by a swampy moat and wretched walls, which form a sort of irregular hexagon. The fort that commands the town is built of earth, and is tolerably strong towards the sea, especially for this reason, that, from the want of depth of water, ships of a large size cannot approach it within gun-shot. The navigation moreover on this coast is generally dangerous, being impeded by banks of sand and mud-flats of considerable extent; which frequently shift. There is besides not even any harbour of consequence in these parts, except that which the island affords, nor scarcely a place indeed where a boat may land with safety, particularly during the prevalence of the heavy rollers and breakers in the times of the spring tides. The palace of the government, and the ancient mansion of the Jesuits, are the only buildings in this city deserving of particular notice. They form two large façades fronting the place of parade, which presents a pleasing prospect, being bounded with two rows of orange trees of the largest size, that exhale an exquisite fragrance, and are crowded with colibris skipping from branch to branch. The population of this town having of late years increased, and its circuit not admitting of a proportionate enlargement, a new town has been built on the neighbouring savanna, separated from the ancient one merely by a ditch. This, which is already the more considerable of the two, and is daily increasing, is constructed on a regular plan; the streets are wide, admitting the free access and circulation of air, and contain some elegant houses, the beautiful appearance of which becomes more striking, from the obvious marks of poverty and wretchedness exhibited by every thing about them.

The inhabitants of French Guiana have within their reach an abundant supply of all the requisites for a good table, but they generally prefer salt meat and fish to fresh provisions. From their relish also for high-seasoned foods, they cultivate for culinary purposes, besides the pepper called by the name of the province, several other sorts, the sharpest and most pungent they can procure. The Creoles prefer the cassava, which is a large round cake, about three lines thick, made of course flour of manioc and slightly baked on a tin-plate, to the best and finest sorts of bread. Besides the other articles of subsistence common to Guiana and other colonies, there is in frequent use here a dish called caloril, which is prepared of the fruit of a plant known by the name of conuba. At every meal a negro, when the first course is removed, presents the guests with a glass of ratina. This liquor is as transparent at Cayenne as the purest spring-water; it is very wholesome, and acquires a more pleasant flavour the older it grows, especially since the practice has been introduced of distilling it over newly gathered cinnamon. The same liquor, which is prepared here, and indeed forms a considerable article of the commerce of the province, is in great request on the tables of the luxurious at Paramaribo, and throughout these colonies.

The dress of the male sex in Cayenne consists in white pantaloons, and a linen jacket. The women spend most of their time in hammocks, a piece of furniture which is much valued in Guiana, and which serves at once for ornament and convenience. These hammocks are made of cotton. They are in general from six to seven feet in length and nearly of the same breadth, and are fastened on both ends by a number of small cotton strings, which join to large ropes of the same stuff. By these ropes, which are attached to the walls of the room with large hooks, the whole burden of the hammocks is supported. It is in the corners of the room commonly that these hammocks are thus suspended, where they hang like swings, and in a garland-like form. Very fine specimens of such hammocks are made at Cayenne, but the most beautiful are imported from Peru in Brazil on the right bank of the river Amazon. Those latter hammocks are made of variegated cotton after various designs, and ornamented with borders, tassels, and fringes. They cost about 50 dollars. See Bingham's Voyage to the Demerary, &c. (k)

Cecil, William, Lord Burleigh, the famous minister of Queen Elizabeth, was born at Bourn in Lincolnshire, in 1520, of an ancient and respectable family, his father, Richard Cecil, being master of the robes to Henry VIII. After receiving the rudiments of education at the schools of Grantham and Stamford, he was sent, in his fifteenth year, to St John's college, Cambridge, where he distinguished himself by the regularity of his habits, and unwaried assiduity. It is recorded, that he made an agreement with the bell ringer, to be called every morning so early as four o'clock. Logic and Greek were his chief, but not his only studies, for he soon discovered a wish to take in a comprehensive range of information. In 1541 he was removed to Gray's Inn to study law, where he displayed the same indefatigable application, making it a rule to commit to writing every thing worth notice in the course of his reading, and taking the pains to arrange his information in the clearest order. Many of his manuscripts are still preserved, in private and public libraries. The intimacy of his father at court, having procured his introduction at an early age to Henry, who piqued himself both on his learning and his discernment of learned men, Cecil was soon induced to prefer a political to a legal career. In this determination he was confirmed by matrimonial connections; the friends of his first wife, whom he married when he was only twenty-one, having introduced him to the protector Somerset. This introduction was afterwards strengthened by the king's preceptor, Sir Anthony Cook, whose daughter Cecil married some time after he had had the misfortune of being deprived of his first wife. Zealous like Somerset in promoting the Reformation, Cecil received from that nobleman the respectable appointment of master of the requests, and continued to discover so much assiduity and ability, as to be thought worthy of the state of secretary of state at the early age of twenty-eight. The protector being soon after overpowered by the intrigues of the Earl of Warwick and his party, Cecil fled with his patron; but, after a confinement of three months in the Tower, the joint effect of the young king's favour, and of his own aptitude for business, was his.

Cecil, William.

réinstatement in his office of secretary under the new
leaders. On this occasion he was knighted, and
when he entered on office, he afforded, amid all the ca-
bals of the time, the example of a minister occupying
himself exclusively with the concerns of his depart-
ment. By these means he avoided all concern in the
intrigues by which Warwick, now duke of Northum-
berland, sought to secure his own ascendency for life,
by getting the succession to the crown vested in
Lady Jane Grey. Cecil performed his duty in co-
operating to place the crown on the head of the law-
ful heiress, Mary; but aware at the same time of her
bigotted attachment to popery, he made no other
use of his influence than to obtain a pardon for any
thing that might have offended her in his past trans-
actions. The new court would gladly have had the
benefit of his abilities in office, but an abjuration of
the Protestant religion was, with Cecil, an inadmissibe
condition, and he retired for a time from all inter-
ference with politics. He was soon, however, returned
to parliament for Lincolnshire, and though this took
place without his solicitation, he acted his part in the
House with great firmness, and incurred some dan-
ger by advocating the popular cause. That danger
would have been increased, had it been discovered
that he was in the habit of corresponding with Eliza-
beth before the death of her suspicious sister.

On Elizabeth's accession (1558,) Cecil was the
first privy counsellor sworn in, and in the capacity of
Secretary of State, entered on that career of public
service, which was destined to last during the long
period of forty years, and to terminate only with his
life. He lost no time in directing his sovereign's at-
tention to the establishment of the Protestant reli-
gion, according to the present form of worship of the
church of England. In advocating the cause of
simplicity in the reformed ritual, he experienced con-
siderable difficulty from Elizabeth's predilection,
(though a Protestant,) to the imposing splendour of
Roman ceremonies, a predilection in which the queen
received the support of many dignitaries of the
church. In civil affairs, the ascendency of Cecil was
far more conspicuous. His thoughtful habits, and a
facility in composition early acquired, led him to fol-
low the rule of recording on paper his opinions on
subjects of importance, and writing answers to all
publications hostile to the queen's government. That
economy of the public money, which is in the mouth
of every minister, was perhaps never so judiciously
and effectually practised as by him. The rule of
this reign was not to withdraw from the burden of
continental wars, but to avoid taking a leading part,
and to confine the exercise of interference to those
circumstances in which it had become indispensably
necessary. Teaching her allies to rely on their own
resources, Elizabeth was accustomed to bring home
her troops, and redeem her loans as soon as the
state of military operations permitted it. Her cautious
minister persuaded her to despise all dreams of con-
tinental acquisition, and to decline even the proffered
sovereignty of Holland. Cecil was, in consequence,
often censured as the adviser of a narrow-minded po-

cy, but he was indifferent to such accusations, and
placed his reliance on the evidence of facts. He re-
sisted also, as much as in his power, the importuni-
ties of idle and rapacious courtiers. While thus hos-
tile to irregular grants, he was punctual and even li-

eral in the reward of real services. He is consider-
ed the author of a very material reform in the mode
of paying the army, by which the money of the sol-
diers, instead of going through the medium of the
officers, a practice liable to great abuse, was trans-
mittetl directly from government to the privates.
From this, and other circumstances, arose the saying,
that "the queen paid liberally though she rewarded
sparingly."

The gradation of Cecil's honour was as follows: In
1761 he was promoted to the office of master of the
wards, or, in other words, president of the court of
wards. In 1571, after he had been the chief in-
strument of extinguishing a dangerous rebellion in
the north, he was made Baron Burleigh; and in 1572,
after escaping from a conspiracy against his life, in
which the Spanish ambassador was implicated, he
was made a knight of the garter. In the same year,
on the death of the lord high treasurer, he was raised
to that exalted and laborious station. In the exer-
cise of its functions, Cecil was equally vigilant in re-
gard to the collection and distribution of the public
money; permitting no undue partiality in the former,
and, in the latter, making it an express rule to issue
nothing without a direct order from the queen. He
never imitated the usual practice of treasurers in oc-
casionally borrowing from the treasury for private
purposes; and he was almost the only minister of
that age, who, at his death, owed nothing to the
public. Though frequently the admirer of vigorous
measures, the general character of his policy was
peace. "War," he used to say, "is soon kindled,
but peace is very hardly procured." "A realm
wins more by one year's peace than by ten years
war." The reader who will take the pains to com-
pare the ambition of Europe in these days and in our
own, will find, that, while the inducements to war
were equally great, the course of policy pursued in
the two cases, forms a remarkable contrast. Scotland
and France were at that time torn by intestine con-
vulsions, and the low countries involved in a tedious
war with Philip II. All presented tempting op-
portunities of conquest to an English army; but
conquest, Cecil well knew, is not the true foundation
of national strength. He was the first to discover
the hostile intentions of Philip towards England, but
delayed, as long as possible, the resort to actual
warfare. When the defeat of the armada put a finish to
Philip's hopes, and disposed him to reasonable terms
of peace, Cecil, who had hitherto been most vigilant
in opposing him, now became the advocate of a ces-
ation of military operations, unsuccessfully indeed,
for the passions which prompted a continuance of the
war were too violent to yield to reason and argument.
Zcel for religion, revenge for meditated subjugation,
and the hope of rich captures, all contributed to sti-
mulate the nation to a prosecution of hostility against
Philip. In regard to France, the public mind being
less strongly agitated, Cecil's prudent counsels were
adopted by his sovereign, and, agreeably to them,
such assistance only afforded as was requisite to pre-
serve the Hugonots from falling under subjection to
their Catholic adversaries. Succour to that extent
was called for by the cause of religion, but to go far-
ther would, in Cecil's opinion, have answered no use-

The policy of Elizabeth, in regard to Scotland, was more delicate and complicated than towards either France or Spain. Mary had committed the imprudence, never to be forgiven, of assuming her title, and disputing her legitimacy. She eclipsed Elizabeth, likewise, in those personal charms, of which the queen of England was as jealous as the less enlightened part of her sex. On the other hand, the free tenets of the Scottish Protestants were as much the aversion of Elizabeth as those of her own Puritans. When they proceeded to bring their sovereign to trial, and to deprive her of her liberty and her power, the high prerogative feelings of Elizabeth were alarmed, and she could with difficulty be restrained from sending an army against them. The long confinement to which Mary was afterwards subjected in England, resulted from the concurrent advice of Cecil and of all Elizabeth's ministers, who regarded her as an implacable enemy, both to their mistress and their religion. They represented, likewise, that the possession of the person of the Scottish sovereign gave Elizabeth a powerful hold over the Protestants in Scotland, who dreaded nothing so much as the return of an offended sovereign. In the trial of the unfortunate Mary, Cecil was one of the leading commissioners. He was privy, also, to the transmission of the warrant for her execution, though by no means the principal cause of that unjustifiable act, as his artful sovereign affected to declare. No princess ever understood better than Elizabeth, the art of shifting odium from herself; the blame of the Duke of Norfolk's death having, in like manner, been charged by her on Cecil.

To perform the various duties of the situations occupied by this statesman, required an extraordinary share of application. Yet, by adhering strictly to method, and to his favourite maxim, that the "shortest way to do many things is to do one thing at once," he contrived to fulfil his task without either hurry or confusion. In his court, he expedited more causes in one term than his predecessors had been accustomed to get through in a twelvemonth. Even when labouring under severe pain from gout, he frequently made himself be carried to his office for the dispatch of business; and one of his contemporaries has declared, that, during a period of twenty-four years, he never saw him idle for half an hour together. He was remarked for preserving an unaltered countenance in the most embarrassing situations, and for allowing no one among his friends to acquire an ascendancy over him, so as to influence his public conduct. He behaved with great command of temper towards his enemies; and as he favoured his familiar acquaintances no more than strangers, in regard to government promotions, it became a common saying, that he was a "better enemy than friend." Merit in their respective departments was with him the only title to preferment; and never were the agents of the English government better chosen than under his direction. He was remarkable for obtaining early intelligence of the secret plans of the queen's enemies, both at home and abroad; and if the methods to which he resorted for this purpose were exceptionable, we should recollect, that he lived in an age when the public doctrine of his antagonists was, to "keep no faith with heretics." No man could be more delicate or impartial in the administration of justice,—a virtue by no means common in those days, when the favour of the great was the road to wealth and preferment. It was common for him to receive every day, during term time, a number of petitions, which he took home with him, read during the evening, and was ready with his answers to the whole body of applicants the next morning.

His style of living was more costly than might have been expected in a man so completely absorbed in business. He had four places of residence,—his lodgings at court, his house in the Strand, his seat at Theobald's, which was his favourite resort, and Burleigh-house, the family residence. It was computed, that his domestic expenses at his house in London amounted to L. 30 a week in his absence, and L. 40 or L. 50 when he was present. This style of expence, and the open hospitality connected with it, have been ascribed to the view of cultivating popularity. It was at Theobald's that he was accustomed to receive his share of those frequent visits with which his royal mistress was accustomed to compliment her principal ministers. In regard to the queen's temper, though his gravity and respectability of character exempted him from frequent returns of those sallies of passion which she was accustomed to vent on her courtiers, he was subjected, notwithstanding, to serious mortification. At several periods of his long career, we find him desirous of retiring from office; but Elizabeth would never listen to it, and used to rally him on it in letters which are still preserved, and form a curious commentary to the stately gravity of official communications in the present day. While she would not hesitate, when contradicted, to call him a "froward old fool," she was studious, at other times, to make up, by a return of attention, for such occasional rudeness. When, in his latter years, his gout had become very troublesome, she used to make him sit down in her presence, saying, "My lord, we make use of you, not for your bad legs, but for your good head." The attacks of this complaint concurred, with his habit of business, in rendering him very temperate. His rule was, to partake of few dishes, to drink only thrice at a meal, and very seldom of wine. Though noon was, in these days, the hour of dinner, it was not usual with him to refrain from supper.

Burleigh was remarkable for his piety, and, in regard to his tenets, was strictly attached to the established church. He was regarded, in fact, as its official protector at court; a circumstance which is thought to have induced his rival Leicester to place himself at the head of the Puritans. In addition to his other good qualities, he was eminently charitable, it being computed that he and Lady Burleigh distributed annually L. 500 to the poor. His death took place in 1598, in his 78th year. In summing up the leading features of his character, we find no pretensions to the possession of oratory, or of engaging...
address; unwearyed application; and cool consideration constitute the basis of his fame. Neither his speeches nor writings indicate any attempt to display imagination,—all appears the rigid and deliberate exercise of intellect. It is needless to say, how much more of the statesman is discovered by these qualities, than by that which so often constitutes a passport to power,—a fluency in public speaking. And when we look back to the judgment with which Burleigh steered the vessel of the state, in times no less perilous than the present, we may be induced to wish that the habits of our ministers were more akin to those of this cautious and successful statesman; in particular, that it were in their power to retain the share of his time appropriated to parliamentary debate. A larger proportion would thus be left for the exercise of that reflection in the closet, which so eminently characterised the cabinet of Queen Elizabeth, and was the source of that renown with which his name has been handed down to posterity. (\x)

CECIL, ROBERT; Earl of Salisbury, son of the preceding, though less eminent than his father, was sufficiently distinguished to merit a place in British biography. He appears, for the date is by no means free of doubt, to have been born in 1503; and, after serving in the English fleet against the armadas, and being returned member for Hertfordshire, he was appointed, in 1596, second secretary of state under Sir Francis Walsingham. Having the advantage of his father's admirable example and instruction, he was thought worthy to succeed him in the high station of lord treasurer, and continued to fill it during the remaining years of Elizabeth's life. Though frequently at variance with the Earl of Essex, he did not yield to that impetuous nobleman in rooted antipathy to the Spaniards. Attached as he was to the queen, and zealous in pleading in parliament in defence of her obnoxious measures, he was too knowing a courtier to neglect the rising sun, and ventured on a correspondence with King James, which had at one time been well nigh discovered by his suspicious mistress. Being still a commoner, (for he was a younger son of Lord Burleigh,) King James, on his accession, bestowed on him the honour of a peerage, and soon after made him one of the knights of the garter. Though not continued in the post of treasurer, he was confidentially employed, and was almost the only minister who resisted the growing influence of the Spaniards at court. On the death of the Earl of Dorset in 1608, he was appointed to succeed him as treasurer,—a place of great difficulty, in consequence of the king's thoughtless profusion. To this unfortunate disposition he made so much opposition as prudence allowed, and was, on the other hand, indefatigable in drawing the utmost from the royal demesnes. At the same time, he was by no means unmindful of his own interest, and, though he surrendered the patent for the mastership of the court of wards, he found means to amass a very considerable fortune. He approved himself in parliament an equally zealous advocate for the prerogative under James as under Elizabeth. His constitution, always delicate, was impaired by application to business, and began to give way in 1609. The decay was progressive till 1612, in which year his death took place.

Compared with his father, the Earl of Salisbury will be found a minister of perhaps equal ability, but inferior in conduct and probity. His particular talent was in diplomacy, for no man could more dexterously penetrate, in a conference, the views of foreign ministers, or conceal his own. Notwithstanding his love of money, he was completely above the reach of corruption from abroad. His exceptionable acts in raising public supplies, by the sales of titles, and otherwise, are to be attributed chiefly to the factious and corrupt character of the court. The great imputations on his memory, are his hostile measures against two eminent but unfortunate men, the Earl of Essex and Sir Walter Raleigh. In regard to the former, it is pretty clear, that the part he took was dictated by his duty to his sovereign and his country; and as to the latter, it is possible, that when, by the publication of farther documents, we become fully acquainted with the history of the transaction, we shall find reason to acquit him of vindictive persecution. Those who dislike his memory, in consequence of his subserviency to the crown, may have some satisfaction in learning, that his life at court was by no means a happy one. In 1603, after James's accession, he wrote to his friend, Sir John Harrington: 'Good knight, I am pushed from the throne of comfort, and know not where the winds and waves of a court will bear me. 'Tis a great task to prove one's honesty, and yet not spoil one's fortune. I wish I waited now in your presence-chamber, with ease at my food, and rest in my bed.' And, in his last illness, he addressed to his friend, Sir Walter Cope, the following remarkable expression: "Ease and pleasure quake to hear of death; but my life, full of cares and miseries, desir'd to be dissolved."

In his person the Earl of Salisbury was little indebted to nature, being very crooked; but his countenance was not unbecoming; and he was remarked for the fierceness of his eye. He was allowed by his enemies to be an excellent speaker, though an indifferent writer. Several of his speeches were printed, as well as a book against the Papists, and Notes on a Discourse (by Dr John Dee) on the Reformation of the Calendar. His official letters to our foreign ambassadors are very full and explicit. Many of them are to be found in Sawyer's Memorials of State, a work of 3 vols, folio, published in 1725. (\x)

CECROPIA, a genus of plants of the class Dicoc, and order Diandra. See Botany, p. 153.

CEDREA, a genus of plants of the class Pentandra, and order Monogynia. See Botany, p. 153.

CEDROTA, a genus of plants of the class Ocatandra, and order Monogynia. See Botany, p. 204.

CELANO, the name of a town and lake of Naples, in the province of Abruzzo Ultra. It is about 47 miles in circumference, 10 miles wide at its greatest breadth, four at its least breadth, and its average depth 12 feet. This lake is embosomed in an amphitheatre of lofty mountains crowned with snow, and its margin is covered with numerous villages, and well cultivated farms. The ground is well inclosed, and the sides of the mountains are covered with thick woods. The lake abounds with a variety of fish, and wild fowl in great quantities repair to it at stated seasons. The cress, of Claudia, for draining the lake, is about a mile and a half from the
CELASTRUS, a genus of plants of the class Pentandria, and order Monogyina. See Botany, p. 172.

CELEBES, a large and populous island in the Indian seas. Neither the exact site nor dimensions of this island are known to be yet ascertained. Captain Forrest, a judicious navigator, affirms that it stretches from about 2° north latitude to 6° 10' south, and lies between 116° 40' and 121° 40' east longitude. Von Wurmb lays it down from the third degree of north to the fifth degree of south latitude, and fixes its longitude under 160°. Some navigators and geographers maintain, that its breadth is 500 miles, others restrict it to 70, or even 45. Probably it does not exceed 100 in the broadest parts, and diminishes considerably in the narrowest. We may remark, in general, that though valuable European settlements have long been established here, there is scarcely an island in the same situation, in the history and description of which greater confusion prevails.

By the natives, and also the neighbouring people, this island is called, Negreli Oran Buggess, or Tanana Macasar. Though lying directly under the line, the climate of Celebes is temperate, from the heat being moderated by the sea breeze circulating among the mountains and valleys. Slight shocks of earthquakes are sometimes felt, and violent storms occasionally visit the country.

Gold is obtained in several districts of Celebes, particularly towards the east, from the beds of rivers or torrents issuing from the mountains, and also from pits purposely dug for it. On discovering a gold mine, the workmen first conduct water to its immediate vicinity, and then dig down until finding a kind of black sand among which it is lodged. Quantities of this are taken up by the miners, who place themselves amidst a pond, pool, or stream of water, and putting the sand into a flat wooden dish, wash the whole gradually away, until the heavy particles of gold falling to the bottom, alone remain in a cavity in the centre. The gold thus collected is dried in a cocoa nut shell near the fire, and cleansed as well as possible from any remaining grains of sand. Before digging a mine, the workmen turn aside the nearest river, or drain off part of it; then they search a foot deep in the sand for pieces of native gold. Their expectations of success are regulated by the appearance of the neighbouring stones and rocks: Where rich ore is found, blue and yellow are predominant; where the ore is of less value, the stones are grey. Gold is obtained from the crevices of the rocks in pieces of considerable size; one was lately seen weighing nine pennyweights, and others are got equal to two or three rials. The water, issuing from the mountains, brings down earth along with it, which being received in vessels, deposits the gold in the bottom after the water has filtered through. For the most part, the gold of Celebes is pure and of the richest quality, but generally more valuable at the first opening of a mine. No accurate calculation can be formed of the quantities obtained throughout the island, but the Dutch were formerly enabled to procure to the value of 124,000l. annually. Iron and copper are likewise found in considerable abundance.

The hills of Celebes are covered with woods, among which are fruit trees and bushes known only by description to Europeans. Lemons and oranges are in great profusion; and also the more necessary plants of sugar cane, Indian corn, rice, and cotton.

Of quadrupeds, there are horses, cows, buffaloes, wild hogs, goats, and sheep of large size. The horses are of a small black breed, and are greatly esteemed by the natives. The flesh of cows and goats is ate, but no use whatever is made of the milk.

This island is plentifully stocked with wild fowl and poultry, and a great quantity of turtle abounds on the coast. The latter is a principal object of pursuit among the natives, not as an article of food, but for the sake of the shell. This they are said to possess the singular art of taking off without injury to the animal, which, after the operation, is allowed to escape.

The inhabitants of Celebes are supposed to be two or three millions in number. Yet, though it be certain that the island is extremely fertile and populous, we conceive that the calculation is exaggerated. They are of a copper colour, or reddish yellow, rather of a squat figure, and ungraceful demeanour. Nevertheless some of the women have regular features and pleasing countenances, and are nearly as fair as Europeans. In general, the natives are suspicious, cruel, and ferocious, the common character of mankind in the same latitudes; but they are ingenuous, high-spirited, and brave. The men are capable of great fatigue, and can patiently endure protracted abstinence; they are temperate in living, and hence longevity is frequently met with. The women are greatly addicted to sensuality, susceptible of warm attachments, and their jealousy is unbounded.

The heat of the climate is so favourable to vegetation, that agricultural operations are attended with little care or anxiety. Rice, cotton, and the sugar cane, are its chief objects. The fields for cultivating the first of these vegetables are divided by fences, which shews that the natives have an accurate notion of the distinction of property, and the disposition of the surface is accommodated to essential circumstances. Some of the grounds for producing rice are on declivities, where little canals about twenty yards asunder are formed for the irrigation of the land. The fields are overflowed to the depth of six or eight inches during sixteen days, and being then in a very humid state, about 20 bullocks trained to the work are inclosed, and driven round and round until the ground is completely poached. Water is again admitted to overflow the surface, and the land is afterwards considered in a fit state to produce the crop. Rice plants are next stuck into the mud eight inches asunder, and, until half grown, the ground is constantly watered; but at that period the shade of the plants keeps it moist, which obviates the necessity of continuing to overflow it. Being cut and put up in
CELEBES.

small bunches when ripe, the rice is built into stacks, and after remaining thus about fourteen days is carried home. To preserve it from the weevil, it is not cleaned from the stalk, and, by occasional airing, it may be kept fit for use during two years. With similar precautions, Indian corn may be preserved six months. Abundance of sago is obtained, and may be sold at a substitute for bread among the numerous inhabitants of Celebes. It is a preparation from the soft pith of a tree, which is described as resembling the cocoa tree, but with a larger leaf, and about two feet in diameter. Being felled, the trunk is divided into pieces of about ten feet long, which are split up by means of wedges. The pith is taken out, pounded with a mallet, and washed in a river, after which the sago is separated from the bran, and carried home in utensils made of leaves. It is dressed or boiled without water; if put aside in a pot, the sago soon becomes moist and forms into a cake, in which state it will keep several days; if not required for immediate consumption, it is laid in a stream, where it may be preserved six or eight months. The sugar cane is cut into joints, from which the outer skin is peeled, and the joints pounded to softness in large mortars. In the next place the substance is pressed, and the liquor boiled until it attains a certain consistence, when it is taken off the fire and cooked. This is kept for making sweetmeats, the only use to which it is applied.

Thus the natives of Celebes appear imperfectly skilled in agriculture; but profiting by the soil and climate, they obtain abundant crops, part of which are exported.

Great confusion prevails in any accounts that can be procured of the civil divisions of territory in this island. It is evident, however, that they are numerous, and that the inhabitants of each have a certain peculiarity of manners, which distinguishes them from those of the rest. Six or seven principal divisions have been named, which seem independent of each other. Goa or Goach, Bony or Pong, Wajoo or Tuadjoo, Sopin, Selindrim, and Mandilar. Besides these, are Tello, Sandrabony, and various territories, which may partly be synonymous with the former. Dispersed throughout these divisions are different tribes, called by some Barreo, Tobogees, Tremany, and Uncuila, who inhabit towns and villages chiefly towards the coast. The British are best acquainted with the town of Macassar, from a Dutch settlement being established there. It was lately calculated to have contained about 10,000 native inhabitants, of whom 2000 were capable of bearing arms. Two towns, Parlow and Dungally, are situated in Parlow Bay. The former is of considerable size, consisting of about 500 houses, and is the capital of a fertile district called Kyly, or Uncuila. It is a place of considerable trade, and the residence of many wealthy native merchants. The latter is towards twelve miles distant, and independent of its government. It stands on a point of land, and is defended by a fort or block-house situated on a hill, in which are about 15 swivels, 30 blunderbusses, and 200 small arms. Considerable trade is carried on from both these towns, and numerous artificers inhabit both. The town of Tomboo stands at a little distance from the sea, on the banks of a river flowing into a fine bay of the same name. It is less compact than the others, and contains about 700 inhabitants, who have only a few small arms for their defence. They are a war-like race, but seem possessed of very little prudence; for though abundantly stored with provisions, they dispose of them so regardlessly, that they are not only often obliged to purchase a supply from other places, but sometimes reduced to want. Besides these towns, there are many more along the western coast, and towards the south parts of the island, which have been more frequented by Europeans than the others.

With respect to the trade and manufactures of the natives of Celebes, as their wants are few, their commerce is limited; neither do they carry on any regular trade with more distant countries, especially from having scarcely any manufactures that would be an object of acquisition, though valuable to themselves. However, they weave a quantity of very fine cotton cloth, chequered red and blue, which is greatly esteemed in India, and is imitated on the coast of Coromandel. They also weave strong white cotton cloths, from the abundance of cotton on their island, which they are very expert at cleaning. Beautiful silk belts, wherein they fix their creeses or daggers, likewise are manufactured; and they make a kind of paper from the inner bark of a small tree. They understand the art of working in gold and silver; and can cast brass guns six feet long, which will carry a half pound ball. A number of slaves are annually sold to traders from Batavia or elsewhere. These unfortunate beings are generally kidnapped, and being secretly sold to Europeans, are carried away in their vessels. A Chinese junk or vessel of large size annually arrives at Macassar, and the goods being exposed to sale in a large building specially adapted for the purpose, are very soon disposed of among the natives, the Dutch, and other settlers. Arms and ammunition, iron and steel, blue and white cloths, and opium, are imported. Gold, rice, sago, tortoise shell, and cotton cloths, are, besides the articles already named, among the exports.

Several remarkable peculiarities are seen in the government of the petty states of Celebes: each is ruled by a rajah or chief, some of whom succeed by inheritance, and others are elected to the dignity. The female sex is not excluded from the highest degrees of sovereignty. Something resembling parts of the feudal system, as recognised in Europe, is also seen in the island. Formerly the rajah, or king of Goach, as he is denominated by the Dutch, was the most powerful in Celebes, although the territory of Bony it is said could send 70,000 fighting men into the field. But the policy of that nation having been to maintain one tribe against another, his power has declined. Bony is governed by a rajah called Pajong, who is elected by seven chiefs, enjoying this privilege by hereditary right, and which may rest in women by descent. The Pajong is under control of 400 representatives of the people of three different degrees, who have a voice in the government of the country. Wajoo or Tuadjoo is governed by a rajah, elected from the chiefs of the highest rank, who are chosen from forty others of lower rank, but who nevertheless are said to be the actual rulers of the state. Besides these there is still another order, who, as before, have some control in state affairs. The council of forty, of which women may be members equal-
An oath of fealty, somewhat similar to that which of old was known in countries acknowledging the feudal system, and also investitures of land, prevail in Celebes. At least we know, that such is the case with regard to foreigners. The person is introduced to the presence of the rajah, when he takes up a shield and dagger, and goes through all the warlike manoeuvres of the people with great violence and agitation, at the same time vowing vengeance against the various tribes at war with the rajah. This being done, the dagger and shield are laid down, and if the person be a man of consideration he seats himself by the rajah, while the others are to be sworn in, perform a similar ceremony. When one obtains a grant of land he takes possession of it in form, by kindling a fire upon it, and piling up a heap of stones, a ceremony resembling the same used in this kingdom.

It is said that some of the laws of the natives of Celebes are written, and that others are administered according to the custom of their predecessors, as preserved in the remembrance of aged persons. Crimes are not punished arbitrarily at the will of the chief, but according to established laws. The accusation, however, is brought before him, and he orders an investigation of the fact. When a report is made, if it be of a crime deserving capital punishment, the chief gives a sign with his eyes, and the culprit is carried forth and poniarded. Should aggravated circumstances have attended it, the chief ordains a more severe punishment: the criminal is bound to a tree, and his skin picked with daggers in innumerable places, which are rubbed over with sugar and molasses. His whole body is soon covered by swarms of ants, and he is literally devoured alive. This horrible punishment is never inflicted on persons of high rank, who are simply poniarded to death. Nevertheless some of the rajahs rule with arbitrary sway, and little account is made of life by the natives.

The different tribes are frequently involved in mutual wars, originating from very slight occasions, and they even venture attacks on Europeans, which are generally irregular. All are noted pirates, and commit many depredations on the vessels of every nation which they meet at sea. There they are held in greater dread than by land; their vessels being often mistaken for those of more powerful people, and because much stratagem is employed to decoy the wary. Long voyages are made by them to Prince of Wales Island, Batavia, and so far as the coast of New Holland. In engagements by land the victors decipitate the slain, and prisoners are sold for slaves at between £5 and £10 each. The arms are spear, dagger, and shield; but many have muskets likewise. In the words of an intelligent voyager, one of these natives altogether very much resembles a Scottish highlander when the ends of his plaid are sewed together.

His arms are a sword, lance, dagger, and target; sometimes a musket and bayonet or blunderbuss instead of the lance; but then he is attended by a lad, who, himself armed, carries several lances." In particular districts the natives fight with barbed arrows poisoned, blown out of black ebony blow guns about four or five feet long. In the use of them they are very expert, and can kill at the distance of twenty yards. The effect of these arrows is most destructive, and the object speedily expires in excruciating agonies.

The Mahometan religion was established in Celebes in the end of the sixteenth or beginning of the seventeenth century, and the inhabitants thence entertain a great abhorrence against Christians. There is a high priest, who in one district was, of late years, a foreigner from a distant island, to whom much deference was shown. A rajah desirous of making war, previously consults the priest on its probable success, who, after a pretended reference to a book, declares his opinion; if unfavourable, the rajah prefers submitting to an indignity; if the reverse, he prepares for it by providing himself with a charm from the priest, which he believes renders him invulnerable. But the charm, which is only a square piece of paper inscribed with certain characters, remains no more than six months in force.

The inhabitants of Celebes do not adhere strictly to the Mahometan law in their matrimonial alliances. If a man can afford to maintain four wives, he may marry that number, but not otherwise. The marriages of the higher ranks are attended with many ceremonies, and are always preceded by presents. Three swivels and twenty pieces of white cloth were considered a liberal donation when, on a recent occasion, the children of two chiefs were united. Here the man had accidentally visited Celebes in a piratical vessel from another island; and on the day appointed, his father, the commander, together with his crew, came on shore, armed as if for battle. The high-priest then attired him in a pair of long silk trowsers, and also in five or six silk gowns of different colours, with a wrapper over the whole: he put a cap on his head, which was surmounted by a turban. A procession towards the town, which was the residence of the woman's father, ensued; the bridegroom being guarded by twenty of his own men armed with spears and shields, on whose approach a number of men armed in the same manner issued from the town, when a sham fight well supported began. The towns- men, however, gradually retreated until they reached the gate, when a piece of chintz stretched across prevented their entrance. It was withdrawn on the defender's receiving a present of a little betel-nut, but replaced elsewhere, while the sham-fight continued with much apparent vehemence, until the donation was repeated. This ceremony was successively renewed, the towns- men always retreating until the man reached the house of the bride's residence. Immediately upon his entrance, he seated himself beside her, and the high-priest performed the marriage ceremony, enjoining mutual regard, and telling the bride she must forsake all other men for her husband's sake, be attentive to him and acknowledge his superiority. The priest then began to sing a lively tune, at the close of which all the guests joined in chorus.

Youths are circumcised at about the age of fifteen.
and a year after undergo the ceremony of having their teeth blackened, which last operation is performed on girls also, and is considered an ornament. Different festivals are celebrated on the island, which vary according to the period, and the parties that participate in them. One is held at the close of harvest, when a large tree is cut off, the branches being cut off, are replaced by the extremities of sago or cocoa-nut branches, so disposed that the leaves hang down, and baskets containing boiled rice or Indian corn are suspended from them. When the tree is thus completely decorated, every person in the town contributes a dish of something, such as fish or fowl, for a feast at sun-set, and collect to dance about it. An exterior circle is formed by the old people, an interior one by the war-men and their wives, and within that is another of youths and girls. Dancing is protracted until midnight, when they partake of the feast, beside a large fire, and by the light of lamps. The dance is then resumed; and the tree afterwards, with great tumult, in which all engage, is despoiled of the baskets of rice. This done, the actors again return to the feast, which is now finished.

The principal diversion of the people is cock-fighting, which is practised every afternoon, and is very well understood among them. The whole men in a town collect to participate of the sport, and spend half the night in gambling with cards and dice when it is over.

The natives of Celebes entertain an idea, that if a sick person can eat he will recover; and employ incantations in endeavouring to operate many of their cures. Their principal specific is betel-nut, and the rajah is a chief operator. His taking a piece into his mouth, and blowing on the part affected, is considered a sovereign remedy. If the complaint be a fever, a drum is beaten by two men, one at each end, without intermission, until the patient either dies or recovers.

On the death of a rajah, his body is immediately conveyed to a building where all public business is transacted, the people singing and throwing stones before it on the way, and at the same time bearing their warlike implements. Eight girls sit with the body, four on each side, two days and a night, fanning it, while two lamps are kept constantly burning. The rajah generally provides himself with a coffin during his life, and he is carried to the grave by all the warriors of the place, who exhibit a sham fight. A fire is kindled at the grave after the earth is returned, and watch kept there during the night: next morning a house is erected, where the widow of the deceased, attended by her female kindred, reside during a month. But when about to leave it, a remarkable ceremony, which we believe is elsewhere unexampled, takes place. A woman or girl is barbarously murdered by the natives, as a sacrifice to the manes of the deceased. Two young chiefs commence the cruel ceremony, by plunging their spears into the body of the innocent victim, who meets her fate with fortitude; and she soon falls under the weapons of others. Her head is then severed and presented to the successor of the deceased, who is no longer recognised by his former name.

Very little of the history of this large island is known to Europeans. The natives of some of the states claim high antiquity, founding their origin in fabulous traditions transmitted from their ancestors. In the year 1603, Gough had its thirteenth chief or king, and in about the middle of last century its twenty-second. The territory of Boni had its sixteenth sovereign in 1713, and its twenty-second in 1775. It then appears how rapidly succession takes place, and instead of between three or four generations occupying a century as in Europe, the number is infinitely greater. Probably the frequent wars of petty states contribute much more than the effect of climate to shorten the natural term of life; for it appears that very aged persons are occasionally found in the warmer regions.

In the year 1512, the Portuguese established themselves in Celebes, and are said to have assisted the natives to build the fort of Macassar, which is rather more than a furlong from the beach, and is now the principal residence of the Europeans. The Dutch, esteeming a settlement on the island of great consequence to their trade, made themselves masters of the fort in 1667; and from thence gradually extended their encroachments on the natives. Some years ago they had no less than 570 towns or villages under their control. But the natives did not view their growing influence without jealousy, and resorting to arms, endeavoured to repel their successive aggressions. Some of the more warlike tribes laid waste their possessions, and threatened to attack the fort, which they summoned to surrender. The Dutch found means to retain other tribes in their service, by whose assistance they made a sally when in the greatest danger, and obtained a signal victory. A more artful policy than force of arms was adopted, in exciting distrust among the respective tribes, so that by alternately aiding one, they could repress the power of another. Thus they lived in a state of security amidst the uninterrupted wars which have prevailed during the preceding century.

Settlements on the island of Celebes were of very great importance to the Dutch, from its vicinity to their most productive spice islands, on which account, though a yearly loss resulted from the expense of keeping up this government, they anxiously repaired them. (c)

CELLINI, Benvenuto, a Florentine artist, equally celebrated for the diversity of his adventures, and for his talents in sculpture, statuary, medallling, and jewellery.

Benvenuto was the son of John Cellini, the descendant of a respectable family in the family of Ambra, and was born in the year 1500. At an early age he began to shew a decided prepossession for the arts, which was probably promoted by witnessing his father's works in ivory. But here he received no encouragement, for John Cellini was bent on making his son a musician only, and used every persuasion to induce him to become a skilful performer. Though obedient to paternal command, Benvenuto's natural genius broke through all restraint, and while still a very young man, his works in gold and silver after the manner of the antique, were exhibited as admirable productions. Michael Angelo Buonarotti had then completed some of his cartoons, which inspired Cellini with an ardent desire to improve from his style. Cellini next directed his attention to seal-engra-
Cellini himself invariably testified a preference for the manner of the ancients; and some of his minor works having excited disputes among the connoisseurs, whether or not they were real antiques, the fact was frequently referred to himself.

During the course of a war wherein the pope was involved, the successes of the French emboldened them to march towards Rome. All the inhabitants immediately took up arms; and Cellini, having raised a company of men, led them to repulse the Duke of Bourbon, who was scaling the walls of the city. The duke fell on a discharge directed by Cellini; and notwithstanding the confusion occasioned by this event, the enemy entered Rome, and in the general retreat which commenced towards the castle of St. Angelo, Pope Clement VII. had scarcely time to leave the Vatican. Cellini now distinguished himself as an engineer; and he himself having pointed the gun, killed the Prince of Orange while riding along the trenches. In presence of the pope, also, he killed a Spanish colonel, who had once been in the service of his holiness, on which occasion he received absolution from homicide. The pope being alarmed for falling into the power of the besiegers, laid all his regalia, and an immense quantity of jewels belonging to the apostolical chamber, before Cellini, and commanded him to take out the latter, and melt the gold. Accordingly, each precious stone was wrapped in paper, and sewed in the pope's clothes; and a furnace being erected, 100 pounds of gold were obtained from the regalia. An accommodation took place without farther extremities; and Cellini, having returned to Florence, had an opportunity of exercising all his genius on a gold medal of Hercules tearing asunder the jaws of the Nemean lion. Michael Angelo, beholding it, declared his manner was altogether new, and recommended him for the execution of another medal, in which he was equally successful. This is described to have been a figure of Atlas supporting the heavens, which were represented by a ball of crystal, while the zodiac was imitated on a field of lapis lazuli.

Soon afterwards Cellini returned to the service of the pope, and was entrusted with the most valuable works for which he had occasion: he was appointed stamp-master to the mint, and also mace-bearer to his holiness. Not satisfied with the extent of these favours, he ventured to solicit another situation, which the pope refused, saying, if he obtained what was so considerable, he would think of nothing and neglect his art. In this the pope was probably right, for Cellini was presumptuous and confident in his talents, which were exercised only when he judged it expedient. His temper was inflexible and capricious, and led him into constant broils, fatal to others, and nearly so to himself. He disregarded the punctuality of his engagements with the pope, and, refusing to deliver up the costly materials on which he was employed, he was deprived of his office in the mint before he had long enjoyed it. Cellini had already killed more than one person in sudden affrays, and the death of another being apprehended, he fled for safety. The pope issued his commands to seize and hang him wherever he could be found. The wounded man however recovered, and the artist, having contrived to make his peace with the pontiff, continued executing medals, which gained his highest favour and approbation. At this time Pope Clement died; and Cellini now killed another man in an affray, yet the new pope, Paul III., not only espoused his cause, but promised to reanimate him in the mint. On intelligence being received that Charles V. had made a successful expedition against Tunis, he was ordered, among other things, to make a crown for a prayer book, valued at 6000 gold crowns. This he was entrusted with delivering in the pope's name to the emperor. Though gradually rising in confidence, and employed in the most costly works, he lost the pope's favour, and withdrew to France.

Probably Cellini did not receive the patronage, on this occasion, that he expected; for after travelling some time in the retinue of Francis I., he returned to Rome.

He had now to undergo a severe trial, and became exposed to a situation of the most imminent danger. He was suddenly seized in the streets, and carried prisoner to the castle of St. Angelo. The nature of his offence was not concealed, and he was accused of being possessed of great wealth, partly arising from some of the jewels which, during the sack of Rome, were removed from the papal regalia. Cellini treated the accusation with the utmost contempt; he recapitulated the circumstances which had occurred on that occasion, and maintained that there was a list of the whole jewels taken 500 years preceding, which was recorded in the apostolical chamber, where they would still be found. He said that when Cesar Iscatinaro came from the enemy to treat concerning an accommodation with the pope, his holiness, to propitiate the negotiation, dropped a ring, worth 4000 crowns, from his finger, and on Iscatinaro stopping to lift it, requested him to wear it for his sake, which was a fact that would also probably be found recorded. Although it does not appear that there was any truth in the accusation, Cellini was detained in confinement, and the pope, in answer to the king of France's intercession for his extradition, called him a turbulent and troublesome man, whom he had imprisoned for murder, and other atrocious crimes.

Cellini finding no prospect of liberation, determined to make his escape from the top of the lofty tower in which he was kept. He effected his purpose with much ingenuity and success, in descending from the height; but in making farther progress, he unfortunately fell from a second rampart and broke his leg, a dagger which had been concealed in one of his
CELLINI.

boots penetrating deep into the flesh. Having crawled to the mansion of the Duke Ottavio Farnese, he was humbly received and protected, while crowds repaired to behold the inaccessible of the place which he had left.

When Cellini had recovered from the effects of the accident, he was again carried to the castle of St. Angelo, where the confinement he underwent was infinitely more rigorous than before. He was imprisoned in a dark and loathsome dungeon, infested by noxious reptiles, and scarcely supplied with subsistence for the preservation of life. The treatment he suffered was such as frequently to prompt him to lay violent hands on himself, and reduced him to the utmost despair.

By the earnest intercession of the Cardinal of Ferrara, in name of Francis I., he was enlarged after the lapse of several years.

Cellini now repaired to France, as the king was desirous that he should enter his service, and it was fortunate that he did so, for the pope soon repented that he had granted his release. He was engaged at a liberal salary, and presented with 500 crowns to defray the expense of his journey from Italy, in the course of which he unluckily killed a man at Viterbo.

The first work in which Cellini was employed was twelve silver statues of gods and goddesses, exactly the height of the king, three of which he probably completed. He made uncommon exertions with that of Jupiter, for which he cast a magnificent bronze pedestal, bearing the rape of Ganymede, Leda and the swan, and other fabulous histories in relief. The statue weighed 300 pounds; in its right hand it held a thunderbolt, which it was just in the attitude of throwing; and in the left was a globe of the earth. The whole rested on its gilt pedestal, on four balls, so that a child could turn it. This production raised Cellini high in the royal favour: he obtained a grant of the castle of Nello, in which his works were carried on, and also letters of naturalization. The king promised him 2000 crowns for it, and proposed to assign him the like sum yearly, from the revenues of a vacant abbey.

Cellini began to exhibit his talents in casting bronze heads and busts, and modelled a gate for the palace of Fontainebleau, which was executed with various embellishments after the antique. He also designed a colossus, 54 feet in height, which it is probable was commenced, but not completed; for an anecdote is related of one of his assistants concealing a favourite female, from her mother, in the head of it. In the mean time, his silver statues of Mars and Vulcan were making rapid progress, and he seemed to have attained the summit of his wishes, so far as respected success and reputation. He enjoyed a pension of 1000 crowns yearly, and had 40 men in his employment.

Cellini, however, neglecting to court the good offices of Madame d'Estampes, the French king's mistress, the favour of the king, if not withdrawn, was diminished; he was accused, and apparently tried for certain obnoxious crimes; his allowances run into arrear; the combination of all these circumstances led to his sudden retreat from the kingdom, where, for several years, he had been gradually rising in celebrity. The king, having afterwards testified his displeasure, and demanded an account of the works he had executed, Cellini expressed his readiness to return to his service, that he might defeat the malice of his enemies, and assured him, that, so far from deriving profit, a considerable portion of his salary was still due.

Cellini had formerly been employed by Cosmo di Medici, Grand Duke of Tuscany, a liberal patron of the arts, to strike several fine medals, and was appointed engraver to the mint. Immediately on regaining Italy he was taken into his service, and, at the duke's desire, undertook to cast a superb statue of Perseus, in bronze, to ornament the grand square of Florence. In a few weeks he, with great pains, finished a model in yellow wax, about a cubit long, with which the Duke, who was an eminent judge of everything relative to the arts, declared his satisfaction, saying to Cellini, that the statue, if cast with equal success, would exceed all others in his possession. The artist readily pledging himself for the performance of it, commenced his operations. He formed a model in plaster, the full size of the statue, from which the cast should be made, beginning with Medusa lying at the feet of Perseus. But judging the clay of Florence unfit for his purpose, he tried its quality by previously casting a fine head of the duke. Next he cast the figure of Medusa, wherein he had used particular caution, and formed his moulds of a compound devised by himself. The statue came out so clean and perfect, that, in the opinion of other artists, to retouch it was unnecessary. Cellini was deeply interested in the completion of his work; it excited more anxiety than all the others in which he had been engaged; for he trusted that it would remain to perpetuate his renown in statuary, and a lively dispute commenced between him and his patron, whether he should be able to fulfil his undertaking.

The cast being completed, Cellini began to uncover it, when all the parts appeared in uncommon, and in what he had not anticipated, in equal perfection. Proceeding to the right foot, he was induced to conclude that the conjectures advanced by his patron, that it would be defective, had been erroneous, when uncovering it still more, he found that not only the toes, but part of the foot itself, were wanting, as he had predicted.

Some interval elapsed before the work was adapted to public inspection, which Cellini partly occupied in the necessary improvements, partly in travelling and in casting other figures. At last being exhibited in Florence, it was viewed with universal admiration, the whole city flocking to behold it, and crowds gathered round the artist, as if to gaze on one who was capable of producing so beautiful a piece of workmanship. Sonnets and epigrams addressed to Cellini, bestowing the highest praises upon him, were posted up in different parts of the city, and the grand duke, his patron, declared, that he should receive a liberal reward. Among the spectators were two Sicilian gentlemen on a mission from their own to the Tuscan government, who immediately invited the artist to Sicily.

At a late period of his life, Cellini testified a desire to be employed on a huge block of fine marble which had been purposely quarried for a statue of Neptune. He had previously shewn himself to be an able sculptor, and in particular had restored a mu-
tiated Gaumede of Grecian workmanship, with surprising art. Being disappointed of this, he engaged in a crucifix with much anxiety, with which there seems to have been mingled a great degree of devotion. He was the more stimulated to exertion, from believing himself the first who sculptured crucifixes in this substance. This work, which Cellini presented to his patron, the grand duke, received the same applause with his other performances, and gave birth to several sonnets from admirers of the arts.

Cellini was now advanced in life, and it does not appear that he produced anything more of great celebrity, though his presence was courted by crowned heads in other kingdoms. He died 15th February, 1570, and was interred with great ceremony in the church of the Nunziata in Florence, the whole members of the Florentine academy being present.

Cellini, as an artist, rivalled, if he did not surpass, all his contemporaries, the celebrated Michael Angelo being scarcely excepted. His jewellery, medals, vases, casts, and sculptures, have been alike prized, and are still the objects of anxious search. He enjoyed the good fortune of living at a time when eminent abilities, and not constrained or artful commendation, could bring their possessor into notice, and when genuine taste for elegant design and sculpture prevailed. Neither did he languish in obscurity; for he perhaps experienced more distinguished patronage than any other artist can boast. But all his successes were interrupted by a violent and irascible temper, which constantly involved him in difficulties, which prompted him to commit more than one assassination, and which would scarcely permit him to treat his superiors with deference. He was jealous of those talents which he was too conscious he possessed, and though he respected those of Michael Angelo, Donato, and a few of his contemporaries, he was accustomed to undervalue the qualifications of many artists whom the public admired.

Besides the productions of art which came from Cellini's hand, he wrote his own memoirs in the Italian language, a narrative replete with entertainment. But he wisely abstained from publishing it, which was done long after his decease. He also composed a skilful work on the arts that he chiefly practised, which was published towards the close of his life. This is highly celebrated by Vasari, and it certainly bears incontestable evidence of comprehensive genius and originality; unlike his memoirs, it exhibits temperate reasoning. It is divided into two parts, in the first of which he treats of jewellery, enamelling, coining, the art of making gold and silver vessels, and of silver statues larger than life. The second is dedicated to details on the mode of casting statues in bronze, on the quality of marble for statuary, the fabrication of colossal figures, and a discourse on the art of design. The originals of these works is extremely rare in Britain. See Life of Cellini; Vasari Vite de Pitori Museum Florentinum, tom. v.; Cellini due trattati dell' Orficeria. (c)

CELLULAR Substance. See Anatomy, p. 746.

CELOSIA, a genus of plants of the class Pentandria, and order Monogynia. See Botany, p. 156.

CELSTA, a genus of plants of the class Didynamia, and order Angiospernia. See Botany, p. 250.

CELSUS, an Epicurean philosopher, who flourished in the second century, and is chiefly distinguished as one of the early and most violent opposers of Christianity. Of his life nothing is now known; but it was probable that he was a person of some celebrity, as Lucian has dedicated to him his Pseudo-
manifest. His principal work, which he wrote against the Christians, and which he entitled Ἐπιστολὴν ἀληθείας, The True Word, is now lost; but its arguments and objections are preserved in the excellent answer of Origen, which Dr Pin characterises as the completest and best written apology for the Christian religion which the ancients have left us. In this treatise, Origen has not merely given us the substance of Cel-

 Celus's objections, but has fairly stated them in the very words, and in the order in which they were set forth by their author; so that from these extracts we are enabled to form a tolerably correct estimate of Celus's reasoning and abilities. Though it must be admitted that many of his objections are frivo-

lous, scarcely deserving a serious refutation, and betray rather a spiteful desire of throwing obloquy upon the Christians, than an honest wish of meeting their opinions and morals with logical reasoning, and a candid statement of facts, yet we cannot join entirely with those who represent him as a trifling caviller, or a futile calumniator. His arguments display considerable ingenuity and learning, and prove him to be perfectly versed in all the arts of controversy. It is indeed no small praise, that his book was considered worthy of an answer from the pen of Origen; and, to its credit, we may also observe, that it may be considered as the great armoury from which almost every weapon has been drawn which has been pointed against our religion since the days of Celsius. Modern cavillers have gone over the same ground, and insisted upon the same objections, as their great predecessor; and their answer, as well as his, is to be found in the Apology of Origen. But however the opponents of Christianity may have been indebted to him for their principal arguments, its advocates have also profited by his admissions; and, consequently, we are disposed to be equally grateful with them for the advantages that may be derived from his writings. His testimony to the books of the New Testa-

ment is particularly valuable; for, while he misrep-

resents and perverts the facts which they contain, he bears evidence of their truth; and this evidence is the more considerable, as it is altogether beside the in-

tention of the author. Of the fragments of Celsius's work, which are preserved by Origen, there are three summaries in the English language, viz. one by Dr Dodridge, one by Dr John Leland of Dublin, and another by Dr Sherlock. Besides his λόγος αληθείας, a piece against magic is ascribed to him both by Ori-

Celus, and Lucian; and he is also said to have promised another work, in which he undertook to shew, how men should live who would follow the rules of philo-

CELSUS, A. CORNELIUS, an eminent physician and philosopher, who is supposed to have written towards the end of the reign of Augustus, or, at latest, in the beginning of that of Tiberius. All that is known of his history, is merely that he was a Ro-
man; but what was his situation in life, and whether he practised any branch of medicine, or was only an amateur in the art, has not been completely ascertained. In many parts of his work De Medicina, however, he appears to speak frequently from experience; and it can scarcely be conceived, that such a perfect knowledge of the art as he has displayed, both concerning the most difficult operations of surgery, as well as the nature and treatment of diseases, could have been acquired without long practice and application. After describing a particular method of cure used by Heracleides in the admission of the eye-lids, he adds, "Ego sic restitutionem neminem memini, (De Medicina, lib. viii. c. 7.) "I remember of no person being cured in this way." which expression evidently implies, that he himself had exercised the profession, or otherwise he would not have ventured to place his own experience against the success of any cure recommended by others. Numerous similar expressions may be adduced, equally strong, in favour of the supposition that he practised the medical art; but Dr. Grievé concludes, from a severe censure (De Medicina, lib. iii. c. 4.) which Celsus has passed upon those physicians who often neglect their patients by engaging in too extensive a practice, that his practice was confined to his acquaintance and friends, and that his fortune and generosity rendered him superior to the view of living by the profession. But, whatever was his station in society, his writings have recommended him to the admiration of posterity. His treatise on medicine is often quoted with approbation by our best writers on physic, and contains all that is most valuable in the works of Hippocrates. According to Boerhaave, indeed, it is to Celsus that we are indebted for the opinions and true meaning of many parts in the writings of that father of physic, which would otherwise have been unintelligible or misunderstood. But, in addition to the extent and correctness of his medical knowledge, he is distinguished for the purity and elegance of his Latin, which entitle him to be ranked among the first writers of the Augustan age. Celsus is said to have written treatises upon several other subjects, particularly upon rhetoric and agriculture, but none of them have been handed down to our times. The former is frequently quoted by Quintilian, and, though he often differs from him in opinion, yet he bears honourable testimony to his learning and acquirements. When recommending to orators to make themselves masters of all the sciences, after mentioning Homer, Plato, Aristotle, Cato, Varro, and Cicero, some of the greatest geniuses that ever appeared, he adds, "Why should I name any more instances? when even Cornelius Celsus, a man of a moderate genius, has not only composed treatises upon all these arts, but has also left precepts of the military art, agriculture, and medicine. The bare attempt requires us to believe, that he understood all these subjects; but to give perfection to so great a work is a difficult task, to which no man has ever been found equal," (Inst. Orat. lib. xii. c. 11.) Columella, also, in his work De Rer Rustica, lib. ii. c. 2, frequently mentions him with great respect, comparing him with the best writers on husbandry, and represents him as one who was, "not only skilled in agriculture, but who took in the whole compass of natural knowledge." His merit as an author is sufficiently indicated by the numerous editions through which his work De Medicina has passed, and by the high esteem in which it is still held. The best edition is supposed to be that of Almeloven, which was edited at Padua in 1722, by Vulpius; and there is a good English translation by Dr. Grieve, published in 1756. See Le Clerc Hist. de Med.; and Friends' Hist. of Physic. (p)

**CELTIS**, a genus of plants of the class Polygama, and order Monacia. See BOTANY, p. 249.

**CELTS**, an ancient people inhabiting, according to the earliest historical notices, the western parts of Europe.

It appears now to be generally admitted, that the Celts were a peculiar people, distinguished by many remarkable particulars from the Scythians or Goths, with whom they have been often confounded. The distinction, however, between the nations alluded to, has not been admitted without a full and elaborate discussion of the subject. Many learned authors have contended for their identity; all antiquity has been explored by the writers on opposite sides; and, upon a question which surely might have been discussed with a due attention to good manners, much bitterness and insolence have been shewn. Among those who have contended for the identity of the Celts and Goths, a principal place must be assigned to Cluverius and Pelloutier; and likewise, though he contends for nothing more than an identity of origin, to the late Sir William Jones: while, of all the champions for their diversity, Mr. Pinkerton, aided by a profound and acute writer in the second volume of the *Edinburgh Review*, is by far the most formidable. The points supposed to be established by Mr. Pinkerton and the learned critic, are the following:

1. At a period, probably as early as the year 1400 A. C. the Scythians had pushed themselves from the vicinity of the river Araxis, westwards and northwards, over a considerable part of Europe. 2. The Scythians were afterwards mentioned in history under the names of Getæ, Gothi, and Germani; but whether distinguished by these names, or by the more comprehensive appellation of Scyths, the people thus distinguished were one and the same.

3. With regard to the Celts, the earliest notices would lead us to place them about the year 500 A. C. in the neighbourhood of the Pyrenees, whence they were driven by the Germans or Goths on the east, and the Aquitanis, probably an Iberian race, on the south, into that part of Gaul where they were found in the time of Cæsar. 4. That the inhabitants of the Highlands of Scotland, and the Welsh, together with some of the Irish tribes, are the remains now existing of the ancient Celts. 5. That when the Greek and Roman authors use the words *Getæ* and *Gallae*, Celte and Galli, they often refer exclusively to the Belgic Gauls, (see the mass of authorities quoted in the *Edinburgh Review*, vol. ii. p. 365, art. Vindication of the Celts.) 6. That though this is frequently the case, the distinction is sometimes accurately made between the Belgic Gauls and the Celtic; as in the introduction to the first book of Cæsar's *Commentaries*, where the Belgæ are represented as inhabiting one part of Gaul, the Aquitanis another, and the Celte a third; and in the language with which the account of the Druids, given by the same author, commences, *In omni
Gallia, corum hominum, qui aliquo sunt numero atque honore, genera sunt dico.—In omni Gallia, that is, as the passage is commonly understood, in all the Celtic part of Gaul.

We may consider the distinction between the Celts and the Goths as established, first, By the difference of their persons; 2dly, By the difference of their religious belief, and sacred observances; 3dly, By the difference of their political institutions; and, lastly, By the difference of their language. In pointing out these differences, almost every thing interesting in the history of the Celts may be conveniently brought into view.

1. The Celts were distinguished from the Scythians, Goths, or Germani, by their external appearance. They had not the light hair and blue eyes, which were regarded in ancient times as an indication of a German origin; nor had they the lofty stature and large limbs, which are still considered as characteristic of the German tribes. It was to their extraordinary appearance and ferocious aspect, as well as to their barbarous valour, that, the Gauls (of Scythian or Gothic extraction) were indebted for their victories over the Romans; and, before the strength and discipline of Rome could match the prowess of these fierce invaders, it was necessary to familiarize the legions with the tremendous looks and savage howling of the Gaulish warriors. On the other hand, the Celts were a people of an inferior stature, swarthly in their complexion, with dark eyes, and hair short, coarse, and black. In their external appearance, they seem to have resembled the Finns and Laplanders of modern times. History records but little of their victories and conquests; and Mr Pinkerton, in frantic declamation, pronounces them to be radical savages, incapable of instruction or progress in society.

2. But if the Celts were distinguished from the Goths by their external appearance, they were distinguished from them, in a still greater degree, by their religious belief and their sacred observances. Among the Celts there existed a hierarchy, regularly constituted and established; a class of men exercising the functions of the priesthood, and extending their authority over every department of civil life; clearly marked out, and separated from the rest of the community, and enjoying many and exclusive privileges. Our readers will perceive, that we allude to the Druids. It is universally acknowledged, that Druidism was peculiar to the Celts, and that nothing resembling that extraordinary system was to be found among the Gothic or Teutonic tribes. This difference is striking and fundamental: And the fact, that the Germans had no Druids, is mentioned by Cæsar as a circumstance completely discriminative of the Celtic and Gothic nations. It has been affirmed, that the Druids were not acquainted with the great and primary truth of the unity of the divine nature. But if this was the case, and if the notion alluded to formed a part of their secret creed, or what the Greeks would have called their isoterio doctrine, we have sufficient authority for maintaining, that they countenanced, at the same time, the belief and the worship of many gods, as Jupiter, Mars, Apollo, Mercury, and Minerva, or beings of heavenly origin and power, whose attributes and office corresponded with those of the principal divinities of Rome. They held likewise the doctrine of Metempsychosis, or the transmigration of souls. Of a general receptacle of spirits, enjoying various degrees of happiness, or doomed to various measures of suffering, they appear to have had no idea. Their notion seems to have been, that the soul of man is destined to occupy various bodies in succession; and that the alternate transference and residence of the thinking part were to be continued for an indefinite length of time, beyond which the enquiry was not pushed. In addition to all this, it must be stated, that the Druids were philosophers. They had raised their understandings above the first wants and enjoyments of our species. They had attempted to pierce into the recesses of nature. Their investigations related to the constitution of the physical world, the motion of the heavenly bodies, the size and figure of the earth, and the power and purposes of the immortal gods. Schools of philosophy were established among them. What they knew they taught the youth committed to their care. These were generally the sons of nobles, and persons of distinction. Some of the pupils spent no fewer than twenty years under the tuition of the Druidical college. It was a principal part of their education, to treasure up in the memory a very great number of verses, in which the mysteries of science and of religion were unfolded; for these ancient masters of Celtic wisdom, though acquainted with alphabetical characters, made no use of them in the schools over which they presided. Into the schools alluded to, the vulgar were not permitted to enter. It seems to be an acknowledged principle of the Druidical system, to keep the people in perpetual ignorance; and we shall immediately see, that it was a part likewise of their system, to keep them in a debasing and pitiable state of political subjection. See DRUID.

In almost every particular mentioned above, the German nations appear to have differed from the Celtic. They had no separate class of men exercising the functions of the priesthood, and enjoying the privileges of exemption from taxes and from military service. Their ecclesiastical officers (for they deserve no better name) were nearly as ignorant as themselves. The notion of a direct immortality, in contradistinction to that of a Metempsychosis, was prevalent among them. And the chief pleasure of the Gothic paradise,—a pleasure in which none but the brave and victorious soldier was allowed to participate,—consisted in drinking ale out of the skulls of his enemies whom he had slain in battle. They had no institutions corresponding to the Druidical schools; no philosophy; no doctrine, either secret or divulged; nothing kept hid from the people, because there was nothing to be concealed.

3. In their political institutions likewise, a considerable difference appears to have existed between the Gothic and Celtic tribes. Among these tribes, the state of the people, regarded as distinct from that of the privileged orders, seems to have varied in a most extraordinary degree. In the one great class of human beings, the people were free, and valued themselves upon their liberty; in the other, they were doomed to obey, and satisfied with subjection. Among the Goths and Germans, every man was a soldier, consulted on occasions of the highest political importance, and listened to with that attention to
which a free man is entitled. Among the Celts, every man who could not establish his claim to be
ranked with the Druids or the knights, was a slave;
his comfort or misery, his life or his death, depended
almost exclusively upon the will of his master. In
order to shew that the difference now alluded to really
existed, we shall just set down, in opposition to one
another, two short sentences extracted from Cæsar's
Commentaries, the one referring to the state of the
people among the Celts, and the other referring to
the state of the people among the Scythians, Ger-
mans, or Goths. The passage relating to the Celts
is the following: "Nam plebs, patriae servorum habe-
tur loco, quae per se nihil autel, et nulli adhibetur
concilio." (De Bello Gallico, lib. vi. c. 12.) They
were, in point of fact, only the instruments of their
superiors. The passage which relates to the Ger-
mans or Goths, is in these remarkable words: "Atque
ubi quis ex principibus, in concilio se dixit decem foro,
ut qui sequi velint profiteantur, consurgunt ii qui cau-
sam et hominem probant, sumnque auxilium pollicen-
tur, atque a multitudine collaudantur." (De Bello
Gal. lib. vi. c. 22.) When any one of the chiefs, (so
the words may be rendered,) proposes himself as
a leader in any expedition, they (not the chiefs, but
the people,) who approve of the undertaking, and of him
who engages to execute it, signify their approbation,
promise their support amidst the applause of
the whole assembly. That this is the true meaning of
the passage last quoted, we learn, beyond the possi-
Bility of doubt or difficulty, from the declaration of
Tacitus with regard to the same people; "De mino-
ribus rebus, principes consultant, de majoribus, om-
nes." De Mor. Germ.

Among the Gothic nations, the commencement of
what has been called the feudal system, may easily
be traced. The chief men were possessed of authority
and influence; but their authority was exercised
within considerable limits, and their influence subject-
ed to considerable restraint. In matters of inferior
concern, the decision of the chief was final, but all
affairs of high interest were discussed and determined
by the people at large. It is to the power of the
chiefs thus restrained, and to the mode of civil govern-
ment connected with it, that Mr Pinkerton has given
the name of the feudal system in its purity. And
according to the opinion of that learned gentleman,
this feudal system in its purity is carefully to be dis-
tinguished from the latter feudal system, or that sys-
tem in its corrupted state. Among the Celts, on
the other hand, while the chiefs commanded the ar-
 mies, and were in other respects not destitute of
power, the supreme judicial and even legislative au-
thority appears to have engaged, almost entirely, by
the other privileged order, that of the Druids. The
Druids judged in all controversies whether public or
private, whether of a civil or of a religious nature.
They ordained and inflicted punishments. If any
one refused to abide by their decision, he was instant-
ly excluded from the sacred observances; he became
the subject of a most severe excommunication; he
was held as accused; he was avoided as a person on
whom the mark of the divine displeasure had been
set; he lost all claim to justice, and all title to pro-
tection. In one respect, however, the two cases,
that of the Goths and the Celts, considered in a po-
litical point of view, may justly be said to agree. In
both, the power of the chief was limited; but among
the Gothic tribes, the check proceeded from the peo-
ple, the voice of freemen was raised aloud against
oppression; while among the Celts the power of the
chiefs seems to have been nearly absorbed in that of
the Druids, and the voice of the people, if heard at
all, was noticed, only as a symptom of rebellious in-
solence, and marked only to be punished.

4. The last point of difference between the Celts
and the Goths, is their language. It is not to be de-
nied, however, that in ascertaining this point of dif-
ference, considerable obstacles present themselves.
It is not easy to procure correct specimens of any
ancient language, and even when correct specimens
have been obtained, it is not easy to determine whe-
ther the language be pure. With the exception of
tribes debased by physical circumstances, there is,
perhaps, no instance upon record, of a people living
for a very great length of time in utter seclusion from
the rest of the world, retaining their original language
in all its purity, and their manners in all their charac-
teristic features. Intercourse must always take place,
in a greater or less degree, among contiguous tribes.
Their very hostilities lead to intercourse; and where-
ever intercourse is supposed, characteristic features,
either of language or of manners, will gradually pass
away. Besides, if there be any truth in the opinion
of Sir William Jones, that the Celts and Goths,
thoug differing exceedingly from one another at the
periods to which the Greek and Roman historians re-
fer, were nevertheless, originally, or with regard to
their present stocks, the same people, we must expect
to find the same elementary words in the speech of
both nations. However diversified in its general ap-
pearance, the substratum of their language will be the
same; traces of the native tongue will be discoverable
in both; just as in the various languages of Europe
which have been derived from the Latin, sufficient in-
dications of a common origin may still be perceived.

In their state of comparative advancement, howev-
er, the language of the Celts appears to differ very
obviously from that of the Goths. We have speci-
mens of both tongues, as well as of their kindred dia-
lects, given by Dr Percy in his Preface to the works
of M. Mallet, a work which, together with the Press
face now mentioned, has so often been quoted and
referred to by authors on this subject. Indeed the
means of deciding the question of the identity or di-
versity of the languages alluded to, do not appear to
be very remote or inaccessible. There is a Gothic
Version of the Evangelists, which has frequently been
published (by Junius, 4to, 1665, and by Lyte at Ox-
ford, 1750.) And since the year 1750, a fragment
of the Epistle to the Romans, likewise in the Gothic
tongue, has been discovered at Wolfenbuttel, and
published by the Rev. F. A. Knittel, archdeacon of
that place. The versions of the New Testament
into the Gaelic or Erse language are sufficiently nu-
merous. See Cluverii, Germania Antiqua; Pellon-
tier, Histoire des Celtes; Edinburgh Review, vol. ii.;
Mallet's Introduction to the History of Denmark,
translated by Bishop Percy, and published under the
title of Northern Antiquities; Pinkerton's Enquiry
into the History of Scotland, and Dissertation annex-
ed. (h)
CEMENTS. This term is of very extensive significance, comprehending every substance employed for the purpose of connecting together other substances. It, therefore, comprises the whole of those substances used by chemists to close the joints of chemical vessels; to repair flaws, or to coat the exterior parts of those vessels which are subjected to the action of heat.

Occasionally cements are employed for coating vessels that are to be exposed to a very considerable heat; and the process is called loration, or coating. Iron furnaces are generally coated in the inside, to prevent the destruction consequent on continued exposure to the action of the fire.

For the common purposes, such as to prevent the escape of steam, the vapours of alcohol, or of any other liquid which is not corrosive, slips of bladder which have been soaked in warm water until they become adhesive, answer extremely well for glass; and pap, with paste, for metallic tubes. A solution of gum arabic, or the white of an egg, increases the adhesiveness.

Linsted meal, or almond paste, well beaten up with water, so as to form a pretty dense paste, form a very firm lute for common purposes. But it is unfit for a higher temperature than that of boiling water, or for the continued action of acrid gases. It will, however, confine ammoniacal and the acid gases sufficiently long for the usual experiments. Milk, lime water, or a weak solution of glue or size, improves it considerably.

Many very impervious lutés are made with quick-lime as a basis. This quicklime is reduced into a ductile mass by an admixture of some mucilaginous matters. As combinations of this sort are obviously very numerous, we shall give only a very few of them.

Take some lime that has been perfectly burnt, dip it into water, and allow it to fall into a very fine powder, which it will readily do if the calcination has been complete, and then beat this powder very carefully with equal parts of the white of eggs and of water, to the consistence of thin paste. The lute thus formed should be laid on thin slips of cloth, and applied to the junction of the vessels to be luted. If a small quantity of the powdered lime be sprinkled upon the slips of cloth, the junction will be rendered more complete. The same lute may be made in a simpler way; take thin slips of cloth, moistened with the white of eggs, and sprinkle them over with the powdered lime. This last mode has the advantage of drying with great rapidity.

Lime mixed with dissolved glue also forms a very excellent cement; and, when the white of eggs are added, the lut d'ame is then formed. The above lutés, however, do not resist the action of water, though they are quite impervious to vapours.

Very poor skimmed milk cheese, rubbed down to the consistence of thick soup, with the addition of lime, makes a good lute.

Paris plaster, mixed with any mucilaginous matters, is useful as a cement. Sometimes other substances are added, as clay, flour, red oxide of iron, &c.

The calcareous lutés become extremely hard, and it is difficult to free vessels from them. They are therefore not proper where delicate vessels which are to be preserved are employed. In large works, or in experiments where large vessels are used, it is well to have a quantity of them at hand, as they are very convenient for stopping up any accidental crack, either of the lute originally applied, or of the vessel itself. It may be also observed, that these lutés will not confine acid vapours for any length of time; but for every other purpose they are admirably adapted, particularly where heat is necessary.

The fat lute, as it is commonly called, is of very general use, but peculiarly so when exposed to acid vapours. It also possesses another advantage, that of being never hardened to an inconvenient degree. Any good clay, such as pipe clay, or potter's clay, perfectly dry, must be reduced to a very fine powder, and then gradually beaten up into thick paste with drying linseed oil. The beating must be continued until the mass ceases to adhere to the pestle. It improves from being kept in a covered vessel, in a cool situation. It becomes quite fit for use by being beaten up again for a few minutes with a few drops of linseed oil.

The above may be considered as constituting by far the most generally useful lutés for connecting chemical apparatus together; there are, besides these, another class of lutés, which is of high value to the practical chemist, and of some of them we shall now give a short account. As glass vessels, when subjected to a considerable temperature, are liable to melt, they are frequently coated with lutés, which protect them, and obviate the inconveniences which would result from complete exposure. Earthen vessels being naturally porous, are apt to allow any volatile matters contained in them to escape; this is also remedied by similar means. To secure glass vessels, sand is mixed with as much clay as binds the whole mass together, and is beaten up with any fibrous matter, which gives an additional degree of mechanical security. Windsor loam answers well; but an equally useful cement may be formed from an admixture of sand and coarsely ground potter's ware; to which horse dung, chopped straw, chaff, horse or cow's hair, or tow, may be added, in such proportions as will render the whole mass perfectly ductile. An ounce of hair is said to be sufficient for five pounds of the earthy mixture. The mass should be beaten together with great care, so as to diffuse the hair throughout the whole of it. It may be then applied to the surface, to be coated, either in the dry state, or by repeated dippings into a thick mixture of the mass with water. If the coating be smeared with linseed oil after it is thoroughly dry, it will be less liable to crack.

As a coating for earthenware vessels, various compounds may be formed of a variety of fluxes, mixed into a thin paste with clay and lime. One ounce of borax dissolved in a pint of boiling water, added to as much lime as will form a thin paste, will be an excellent coating of this kind. After this has been applied to the earthen vessel, and has become properly dry, a lute of lime and linseed oil should be laid over the whole. When it is completely dry, the vessel is fit for use. By renewing the last lute, the vessel may be used several times with safety. This preparation has been chiefly recommended as a coating for vessels in which phosphorus is prepared.

It is frequently necessary to lute the covers of crucibles, so as to exclude any communication with the external air; and it is an object of importance, to have a lute that can bear a high temperature. An excellent compound of that kind is formed by boras
first calcined and then fused, brick dust and clay finely powdered, and moistened with a little water. About a tenth of the whole may be borax. Litharge may be used, though it is inferior to the borax.

Clay, iron filings, and water, make a durable cement for iron vessels exposed to a high temperature.

Very useful lutes are made of oily substances united to resinous matters. They answer extremely well at a moderate temperature, and with those vapours that do not dissolve their component parts. They will adhere to glass, which enhances their value. Bees' wax, softened with one-eighth of the spirits of turpentine, forms a cement of this kind.

One part of bees' wax, four of rosin, melted and mixed up with one part of brickdust finely powdered, forms the cement used by turners, with which the handles of knives are cemented to their blades.

Equal parts of pitch, turpentine, and wax, boiled till the essential oil is dissipated, makes a coating to a wooden chamber, which is perfectly impervious to the vapours of sulphurous acid. It is therefore useful in the manufacture of alum. Suet and wood ashes make a simple cement, which is well adapted to stop leaks in casks.

Gum arabic, dissolved in water, is a cement well known for applying paper to glass, &c. Isinglass, dissolved in vinegar, is still better.

The following formula has been given for a cement to unite glass or steel:

"Take of mastich five or six bits as big as peas, dissolve in as much alcohol as will render them liquid. In another vessel, dissolve as much isinglass (previously soaked in water) in brandy or rum as will make two ounces, by measure, of a strong glue, warm it, and incorporate with it, by rubbing, two or three small bits of galbanum or ammoniacum, and then add the mastich solution; keep the cement in a bottle well stopped, and gently warm it before use."

Of late, the use of cements in chemical experiments has been nearly superseded by the introduction of accurately ground glasses, which, without the introduction of other substances, may be made perfectly air tight. Much inconvenience certainly arises from the use of them, which is thus obviated. They still, however, are necessary in many large manufactories, and are retained by the practical chemist. See Bridge, p. 522; Appendix to Chemistry; and Civil Architecture. (C. M.)

Cemetery, a place appropriated for the reception of the dead.

In order to free the living of the dangerous and offensive miasmas arising from the presence of bodies, or bodies lying in the same place, by fire. Thus the untutored native of the Australasian regions, as we have seen, raised a bier for his departed wife, and, unassisted, consigned her ashes to the dust. The remote inhabitants of the north, precluded by perpetual frosts from penetrating the ground, cover their deceased with the branches of trees, to prevent them from being devoured by beasts of prey. Though the ties of con-sanguinity be recognised by mankind farther advanced in civilization, it does not appear that they are careful to deposit the bodies of relatives in the immediate vicinity of each other. Hence particular cemeteries, or those for common use, are unknown.

Yet it has anxiously been desired by men in general, that their bones should rest in the soil of their nativity. When the Nomadic tribes of South America, wandering many hundred miles from their proper boundaries, lose one of their number, they make a skeleton of his bones, and carry it on his favourite horse to the cemetery of his family, however distant. Certain tribes make skeletons of all their deceased, which are placed in a sitting posture, clothed in robes and feathers, in the cemetery. Every year the cemetery is opened, and the skeletons are cleansed and clothed anew. In another portion of that vast continent a pious festival is celebrated, wherein each person carries the patrid and decaying carcass of his father on his shoulders in solemn procession, and again returns it to the earth.

The cemeteries of the Jews, were caves and grounds apart from their cities. Abraham, we are told, purchased the field of Machpelah, and there buried Sarah his wife in a cave, wherein he himself was afterwards deposited. The Israelites buried the bones of Joseph which they had brought out of Egypt, "in a parcel of ground which Jacob bought of the sons of Hamon;" and the Jewish laws particularly ordained the interment of criminals who died by the cord.

Other ancient nations, such as the Greeks and Romans, though they burned their dead, had cemeteries without the cities for depositing the urns containing the fragments of bones and ashes. Cremation did not invariably prevail, and it was not unusual even to make the house or garden of the deceased his cemetery. But among the Romans, the emperor Adrian prohibited sepulture within the city, and there was a cemetery beyond its walls appropriated for the poor; the other cemeteries for persons of rank or fortune were generally near a high way. The Campus Martius was the cemetery of distinguished characters.

The modern Turks and Chinese imitate the Greeks and Romans in placing their cemeteries without their cities. They are generally situated on eminences, and abound with cypress trees. The Chinese never inter in a grave previously occupied, at least before all the remnants of the former body have disappeared, and therefore their cemeteries occupy a large surface of ground. If unfortunate in life, the son sometimes digs up his father from the grave to propitiate his destiny.

The ancient cemeteries in Great Britain were of various descriptions. Barrows or cairns denote the sepulture of celebrated persons, commonly, it is conjectured, those who fell in battle. The author of this article some years ago opened a cemetery in Scotland, which probably ascends to a period of remote antiquity. Numerous coffins, for the most part of small size, were formed of rude slates, built mound for mound; they were almost level with the surface of the earth and the edges of some of the slates were visible above it. Their site was on a thin soil covering rock, though deep earth was in the immediate vicinity. These coffins did not lie east and west, but some almost due north and south, from which it may be inferred they had been used anterior to the intro-
Cemetery. Many contained fragments of bones, and some teeth very entire.

The cemeteries in this kingdom are either public or private, and frequently in the centre of crowded cities. Formerly it appears, that fairs and markets were held in public cemeteries. A Scottish law of 1594 ordains, that each is to be surrounded by a wall two ells in height. Within the precincts portions generally belong to individuals, which are private property. This was very recently decided by the supreme court of justice in Scotland, in the case of an officer who had been accidentally killed, being, without authority, interred in a private burying place. The owner having complained of this invasion of his rights, the body was ordered to be dug up and interred elsewhere.

Long ago, the superstitions of mankind converted churches to cemeteries, a practice which is yet perpetuated. But this indefensible custom was not introduced without resistance; and about the year 381, there is one rescript in the Theodosian Code, which may be interpreted: "Let none suppose, that the churches of the apostles or martyrs are to be rendered ordinary places of sepulture;" and another explicit prohibition, that "no one shall bury in a church." Constantine, the first Christian emperor, had previously been interred in the porch of a church which he had erected to the apostles A. D. 337, on which St Chrysostom observes, that "The emperor was greatly honoured in the interment of his body being permitted at the door of the temple, and that he should be porter to fishermen." Various ecclesiastical canons contain decrees on the subject. The Spanish Council of Bracara, in 583, ordained, that every cemetery should be without the church. Theodos, patriarch of Antioch, in 1180, decreed, that it should never be lawful to bury in churches, according to the civil law of the Grecian empire. The Council of Nantes permitted the porch of the church to be converted to a cemetery, but prevented interment in the interior; and an ecclesiastical council held at Tribur in Germany, prohibited the laity only from finding a cemetery within its walls.

But interment in churches gradually came into universal use in Roman Catholic countries, first, from the anxiety of devotees to have their remains deposited near the relics of some favourite saint; and, secondly, from the benefit which thence resulted to the ecclesiastics who officiated there. All sacred things were rendered the subject of traffic; sepulture in a consecrated place, the remission of past sins, and indemnity for those to be committed, had their fixed and appointed prices. Certain perquisites were due to ecclesiastics for interment in the cemetery within their boundaries, which were rigorously exacted, and which it was dangerous to refuse. The heir of the deceased declining compliance, was in hazard of excommunication. Such perquisites were called mortuaries, a remnant of which may still be recognised in the hire of the pall or mortcloth at funerals.

The danger of burying in churches, and of having cemeteries in large towns, has sometimes been fatally exemplified. Some years ago, on preparing a grave for a person of rank in a church near Nantes, the body of a near relation, who had died nine months preceding, was displaced. The coffin was accidentally shattered, and an infectious principle instantly diffused itself around, with such virulence, that no less than fifteen persons of those attending the funeral died within eight days.

Cemeteries, in Christian countries, are consecrated ground: and as such, infants dying before baptism are with us denied sepulture in it, along with others. Roman Catholics, however, do not esteem the cemeteries of Protestants sufficiently sacred to receive their ashes. The origin or cause of consecration is extremely obscure: in the fifth century, it is said to have been unknown, and, according to Gregory of Tours, was introduced about the year 590. Perhaps it has been preserved, to demonstrate the right of ecclesiastics to the mortuaries of the deceased persons deposited there; and though these are abrogated, the clergyman of the parish in this kingdom is entitled to the grass that grows in the church-yard, though it has been decided by courts of law, that he cannot pasture his cattle there.

In most nations a custom has prevailed, of planting public cemeteries with trees, though one of the continental councils pronounced a decree against it in 1565. Ex cimiteriis, arborum frugiferar. et alien etiam infrugiferar cjuujusvis generis, aut arbusta stirpese omnino convulentur atque occidentur. The cypress was an emblem of mourning among the Romans: it was seen at the pile of the deceased, and in the cemeteries; and to warn priests who were defiled by the sight of a corpse against entering for the celebration of religious rites, it appeared on the outside of the door of a house, whenever a dead body was within. The cemeteries of the Turks and Chinese are planted with cypress trees: in Britain, for centuries past, the yew has been chosen. An opinion has been entertained, though with little reason, that an evergreen has thus been selected as an emblem of the immortality of the soul; and hence the practice of decking the coffin with bays, and carrying branches before the bier. Perhaps it may have been designed as a more permanent mode of testifying that attention to the deceased, which was practised by the ancients. They scattered flowers on the pile, on the urn, and in the cemeteries of their departed friends. Thus Virgil, in describing funeral ceremonies, says,

Purpurcos jaov flores, ac talia futur: Eneid, lib. v.

Manibus dante lilia plenis:

Purpurcos spargam flores Eneid, lib. vi.

The same ceremony was known to the ancient Christians; whence, St Ambrose, in his eulogy on Valentinian, says, Nec ego floribus tumulum ejus aspergam sed spiritum ejus Christi odore perfundam: spargant alii plenis lilia calathis. "I will not strew his grave with flowers, but pour on his spirit the odour of Christ: let others scatter baskets of lilies." St Jerome, in a consolatory epistle to a surviving husband, observes, that while "other husbands strewed the graves of their wives with violets, roses, lilies, and purple flowers, Papamchius bedewed the ashes of his with the balsam of alms."

Those pious customs are not altogether obliterated among ourselves. In some parts of Wales, the graves are adorned with certain flowers, denoting the age of the deceased: the violet, the rose, or plants of rue, being appropriated to the three different stages of life. Fences or borders are made of them, which are carefully preserved from decay, and cleared of obtrusive weeds by the nearest surviving relatives. Each Saturday afternoon is devoted to this.
Cenarrhenses, office. In other parts of the world, the women come frequently to pray or lament in the cemeteries, and scatter herbs above the graves.

CENTAUREA, a genus of plants of the class Syngenesia, and order Polygama Frustanea. See Botany, p. 306.

CENTAURUM, a genus of plants of the class Tetrandria, and order Monogynia. See Botany, p. 132.

CENTAURUS. See Astronomy, p. 760.

CENTURIA, See Bridge, p. 531; 342; Car-
pentry, p. 540; and Framing.

CENTORBI, the Centuripus of the ancient, is a town of Sicily, situated on five points of rocks. It was formerly a populous and splendid town, but now exhibits only a mass of ruins. The large convent of the Augustins, the ruins of banks to the west of the town, and the remains of the castle of Condrin to the east, are the only objects of note. Numerous remains of antiquity have been found in this place, and are deposited in the museum of the Prince of Biscari, already mentioned in the article CATA
nia. According to De Non, the soil in one part of the
town consists of marine concretions, intermixed with
shells. These concretions, along with tufa and a
gritty stone, lie beneath the vegetable earth; and at
a greater depth are found scoriae and lava, beneath
which is a fresh bed of grit. De Non supposes, that
the lava forms the basis of the mountain; and that,
from its being covered with marine concretions to the
depth of 600 feet, the volcano from which it flowed
must have been very ancient. Population about 3000.

namics.

CENTRANTHERA, a genus of plants of the
class Tetrandria, and order Monogynia. See Bot-
any, p. 131; and Brown's Prodrumus, &c. p. 438.

CENTROLEPIS. See Devausia, Botany Index.

CENTUNCULUS, a genus of plants of the
class Tetrandria, and order Monogynia. See Bo-
tany, p. 119.

CÉOS. See ZIA.

CEPHELIS, a genus of plants of the class Pen-
tandria, and order Monogynia. See Botany, p.
150.

CEPHALANTHUS, a genus of plants of the
class Tetrandria, and order Monogynia. See Bo-
tany, p. 119.

CEPHALONIA, an island in the Ionian sea,
nearly of a circular figure, and about 120 or 130
miles in circumference, lying in 39 degrees of north
Cephalonia latitude.

The climate of Cephalonia is temperate and agree-
able, but subject to sudden changes, which are per-
nicious to the people. Copious rains commence in
November, when thunder becomes frequent; but dur-
ing the whole winter season, roses are in blow.
Earthquakes are common, from which dreadful ef-
fects have ensued, particularly in 1736, 1742, 1753,
and 1765, when entire towns were almost laid in ruins.
Strong sulphureous exhalations rise from several places
of the soil, which in some districts is rich and fertile,
while others consist only of dry and barren rocks.

Large caverns are seen on the coast of singular ap-
pearance, the roofs being decorated by innumerable
 stalactites of fantastic shapes and various colours, and
the bottom covered with petrifications of shells.
Mount Enos, now called the Black Mountain, con-
sists solely of vertical strata, rising about 3000 feet
above the level of the sea. Ancielyt it was covered
with wood, but it is now entirely bare.

Among the different vegetables produced in Ce-
phalonla, cotton and vines are the most valuable, as
affording an essential supply for the uses of mankind.
There is a kind of winter melon, which may be pre-
served a long time, if hung up, of an oval shape,
and a beautiful yellow colour externally, with a white
pulp. Medicinal plants are likewise found, which
are said to have a wonderful effect in curing the
gout; and various testimonies are produced in their
favour. They were discovered by a physician named
Zulatti, when resident in the island; and although
few would at first acknowledge the virtue of his
preparations, many in a short time afterwards gladly re-
sorted to them. As the soil seemed peculiarly adap-
ted to indigo, a plan respecting its culture was sub-
mited to the Venetian government, by Signor Car-
bur, himself a native of Cephalonia, but who had
emigrated from the island. The senate granted a
large tract of land for the experiment, and created
him a count, engaging to countenance the under-
taking with peculiar favour. He speedily took pos-
session, and having founded a small settlement, pro-
cceeded to form extensive plantations. Neither his skill
nor conduct, however, seemed to promise that success
which might have been reasonably expected; and,
indeed, before the result of his different expeditions
could be known, he was cruelly assassinated. Olives
are produced in great abundance, from which a quan-
tity of oil is extracted sufficient to be an article of
export; and much fine manna is produced in one of
the forests, which might also prove valuable, but
the collection of it has hitherto been neglected.

There are few quadrupeds or birds in Cephalonia,
nor do many fishes frequent the shores. The prin-
cipal indigenous quadrupeds are goats, whose milk is
chiefly made into cheese, and a kind of carpets are
manufactured of their hair; but the cattle and sheep
consumed by the islanders, are brought from the
Mores, 2000 head of the former being annually im-
ported.

Though many portions of the soil are well adapt-
ed for agriculture, it is not assiduously followed, con-
sequently the products of the island in grain are in-
considerable, not exceeding five months consump-
tion. About 7,000,000 pounds of raisins are export-
ed after home consumpt, and a small quantity of raw
cotton. The wines made on the island are of agree-
Cephlonia.

Cephalonia is the largest of the Ionian islands, yet the whole population does not exceed 70,000 souls, dispersed in three small towns, and about 130 villages or hamlets; nor does it appear to be receiving any accessions. Emigrations, on the contrary, are constantly taking place, though the Venetian government made great opposition to it.

Argostoli, the chief town of this island, stands at the foot of a hill, close to a bay of the same name, in an insalubrious and disagreeable situation. Its whole appearance exhibits incontestable evidence of the effect of earthquakes; and in addition to the ruins diffusely scattered, many buildings are advancing to rapid decay. Though the residence of the executive government, it is an insconsiderable place, containing a lazaretto and several convents. On the 11th of July, in the three successive years 1765, 1766, and 1767, an earthquake is said to have been felt almost exactly at the same hour, the last of which was particularly fatal to Argostoli.

Lixuri, the second town, also stands close to the sea, but in a more favourable situation, both for health and commerce. The same earthquake, however, so destructive to Argostoli, also ravaged Lixuri. It now presents a heap of ruins, and the streets are so much obstructed by them, that it requires some address in the passenger to find his way.

The fortress of Axo, which includes an inconsiderable town, was built by the Venetians in 1595, on a hill two leagues from Argostoli. The hill being lofty and precipitous, and accessible only by intricate paths, there is an irregularity in the fortifications, which, though it might serve as a retreat to the inhabitants, would preclude it from supporting a siege. Below there is a small harbour, which the earth and stones brought down from the hill by heavy rains are gradually choking up. The cathedral, which is small, and moderately decorated, stands here, and also a public building for the accommodation of the governor of the island.

When Cephalonia came under the dominion of the Venetians, it was erected into an archbishopric; but some of the prelates claiming undue prerogatives over the clergy of Zante, excited great dissensions in the church. These were terminated by a decree of the senate, ordaining the election of an ecclesiastic of the latter island, after two Cephalonians had successively occupied the archiepiscopal see. The election is conducted with great ceremony and formality, and formerly could not take place unless in presence of the governor-general of the islands, and different members of the state.

There are no less than twenty-five monasteries and nunneries on the island, one of which, a convent of Greek nuns, is situated on a hill near the fortress of Axo. Their church, in which they piously preserve the remains of St Erasmus, is the best endowed in Cephalonia. These relics, which they view with particular veneration, are contained in a large silver shrine, and exposed at festivals, or in times of public calamity.

Amidst such a redundancy of religious houses, the education of youth seems to be cultivated in no public seminary. The natives, however, are not void of a desire to promote some points of knowledge, and in 1790 they founded an agricultural academy.

The only considerable manufactures in the island are of cotton cloths, (there called dimito,) and Rossoli. Being dyed blue, the former serve for apparel to the Greeks, and from 160,000 to 170,000 yards are exported to the Venetian islands, the Morea, and Romelia. The latter is a strong liquor of agreeable flavour, prepared from odoriferous herbs abounding on the hills, but especially on Mount Enos. Somewhat more than half the value of the former is exported.

The Cephalonians are an active and intelligent race of people, temperate, and industrious; so that while the neighbouring islanders are either overwhelmed with indolence, or dissipating their wealth in luxurious or frivolous pursuits, they are providing stores for future necessities. A project once formed, is steadily maintained, in opposition to every resistance experienced, and the projector knows to adapt himself to all the circumstances which are likely to promise success. Emigrating from their native soil, the Cephalonians are frequently occupied during 20 or 50 years in seeking the means of independence, which they return to their island to enjoy. There hospitality is a leading characteristic; strangers are well received and entertained, and their presence is courted. The people, in general, are fond of society, and the women of the island enjoy unrestrained liberty. Nevertheless, to counterbalance the qualities thus ascribed to them, it is said that the men are intriguing and vindictive, that they are slow to pardon an aggressor, and the harmony of social intercourse is interrupted by the virulence of party dissensions in the towns.

Several celebrated persons owe their birth to Cephalonia. From modern history we learn, that in the latter part of the seventeenth century, a Cephalonian named Phaulkon was viceroy of the kingdom of Siam, and formed an intercourse between that country and Europe. Phaulkon, who was sprung from noble parentage, after first emigrating to England, repaired to India, and was at length employed as a factor at See-y-thaa, the capital of Siam. There he realized a considerable fortune, which he vested in commercial speculation, and embarked along with it on a voyage for another country. He was shipwrecked, however, along with a Siamese of rank, who saved nothing but his life, and who, in gratitude for Phaulkon carrying him home in a bark which he had purchased, affording him distinguished patronage, he soon rose to the highest offices in the state, protected the Jesuits who came from France, and sent a magnificent embassy to Louis XIV. During some years he enjoyed great prosperity, and always promoted a connection with Europeans; but endeavouring to persuade the king of Siam, who was childless, to adopt the son of a nobleman educated in the Christian religion, and being suspected of endeavouring to bring the whole kingdom eventually under French domination, a conspiracy was formed against him. He was seized by a powerful minister of state, and put to death with lingering torments in 1680. Cephalonia has likewise, more recently produced able generals and mechanics. Of the latter, Count Carbrui may be named, who accomplished the transportation of the rock to Petersburgh, which has received the statue of the emperor Peter, and by whom a detail of the whole procedure has been published.
While this island was under the power of the Venetian republic, it was governed by a nobleman sent from Venice, who, along with two councillors, resided at Argostoli. The governor of the fortress of Axo was also a nobleman of the same city, but dependent on the former. The military commander was stationed at Lixuri, and the whole troops on the island did not exceed 300 men. The higher ranks of the inhabitants held a kind of senate, in which the nobles of Corfu were entitled to vote, as a reciprocal privilege was enjoyed by the Cephalonians at Corfu.

Cephalonia has now declined from that importance which many concurring circumstances prove it held in antiquity. Its cities, temples, fleets, and the enterprizes of its inhabitants, were all celebrated of old; and the contests for dominion over it, shew its consequence to neighbouring kingdoms. The ruins still existing on the surface, and the remains occasionally dug from the earth, testify that it was once more splendid and populous, and also that considerable progress had been attained in the arts. Four principal cities are mentioned by the ancients, all of which have long gone to decay, and the site of some can scarcely be recognised, though still known by analogous appellations. These were, Palis, Samos, Croni, and Pronus. The first stood about a mile from the port of Argostoli, in the most fertile part of the island, which is still called Palichi, and appears from the ruins to have been of considerable extent. Notwithstanding the ravages of time, the fragments occasionally discovered bear evidence of having been employed in elegant structures; thus corroborating the testimony of the ancient authors by whom they are described. About 50 years ago was found a tablet of Parian marble, bearing the following inscription in Greek: "By a decree, the senate and people of Palis have erected a statue in honour of the high priestess Flaviana Eutiches, the daughter of Pithodorus Glauces, and spouse of Bion Aristomantides. It was merited by her chaste and exemplary life." The theatre at Elia, for the celebration of the Olympic games, was erected by the inhabitants of Palis.

Samos was in ruins in the time of Strabo, nearly 2000 years ago. Perhaps it was more extensive than the other towns, as the island, according to a passage in the Eneid, was called by that name. Gold and silver coins, sculptured fragments, and vases of bronze and marble, are yet recovered from among the ruins, which mark the site of the city as having been on the declivity of a hill. It has been affirmed, that an odour still sensibly issued from the latter when first opened, resembling the perfumes which were used by the ancients in their funereal rites.

The position of the other two towns can scarcely be recognised; but from the ruins dispersed through the island, it is not improbable that there were several besides. The uncle of Mark Antony, according to Strabo, being exiled here after his consulate with Cicero, founded a city, called Petulia, the progress of which was interrupted by his recall to Rome. Near Lixuri, a marble urn with a pedestal was lately found in a pit, which, from an inscription, seemed to contain the ashes of one of his friends who had perished by a violent death. Coins, portions of bronze tablets, and marble statues, were at the same time discovered. A temple on Mount Enos, consecrated to Jupiter, is mentioned in history as one of the most celebrated throughout Greece. (c)

**CEPHALOPHORA**, a genus of plants of the class Syngenesia, and order Polygamia Equalis. See Botany, p. 296.

**CERCIS**, a genus of plants of the class Decandria, and order Monogynia. See Botany, p. 208.

**CERESIA**, a genus of plants of the class Triandria, and order Digynia. See Botany, p. 115.

**CERIGO**, an island in the Mediterranean, celebrated in ancient history, from its capital Cythera, dedicated to Venus.

This island, which is begirt with rocks and shoals, sometimes proving fatal to mariners, lies at the mouth of the Archipelago: it is of an oval figure, and about 50 or 60 miles in circumference. Near the coast are capacious grottos, the roofs of which are supported by pillars of stalactite, so regularly disposed, as at first sight to appear the work of art.

The climate, though temperate, is subject to sudden vicissitudes: shocks of earthquakes, generally slight and of short duration, are felt; and sometimes violent hurricanes, accompanied by scorching heat, waste the vegetation, and root up the trees.

The soil being rocky, the crops are not abundant; but a greater quantity of grain than is requisite for home consumption is obtained by the industry of the inhabitants, and its quality renders it an object of research by the neighbouring islands. A certain kind of small onions, and olives also very small, produced here, are greatly esteemed, and reserved solely for presents. Such is likewise the case with two kinds of wine, one called liatico, which are too inconsiderable for exportation.

The only indigenous quadrupeds of Cerigo are hares and rabbits: but the inhabitants possess goats, and import a few cattle from the Morea. Many migratory birds, particularly quails, frequent the island; and fish are abundant on the coast, affording a constant and copious resource. But the Neapolitans, in prosecuting the coral fishery, avail themselves more of the latter; and the hazard of falling into the hands of pirates is besides a great restraint on the islanders. Scorpions of a large size are found here.

From the uncertainty of protection, the limited productions of the island, and the want of opportunities to ameliorate the condition of the inhabitants, the population is at present inconsiderable. It scarcely exceeds 8000 souls, dispersed in a town containing 1300, and in about thirty or forty villages and ham-

removing the records of a cause from an inferior to a superior court, into which the writ is returnable, in order that the party complaining may have the more speedy and effectual justice.

This writ is usually had, after indictment found, and before trial, to remove the indictment, with all the proceedings thereupon, from any inferior court of criminal jurisdiction, into the Court of King's Bench, which is the sovereign ordinary court in criminal causes. A certiorari is frequently issued for one or other of the following purposes: 1. To consider and determine the validity of appeals or indictments, and the proceedings thereupon; and to quash or confirm them accordingly. 2. The indictment is removed into the Court of King's Bench, or before the justices of nisi prius, when it is suspected that a partial or insufficient trial will be had in the court below. 3. In order to plead the king's pardon in the superior court. 4. To issue process of outlawry against the offender in those places where the process of the inferior judges will not reach him.

A certiorari lies in all judicial proceedings in which a writ of error does not lie; and the proceedings of all inferior jurisdictions, erected by act of parliament, are returnable in the King's Bench. When a writ of certiorari has been issued and delivered to the inferior court, it supersedes the jurisdiction of that court, and renders all subsequent proceedings therein erroneous and illegal, unless the record be remanded to the court below by the King's Bench. The writ may be granted at the instance either of the prosecutor or the defendant; the former as a matter of right, the latter as a matter of discretion. Indictments found by the grand jury against a peer are transmitted by certiorari into the Court of Parliament, or into that of the Lord High Steward of Great Britain. See Blackstone's Comment. b. iv. ch. 24.; and Jacob's Law Dict. (z)

CERVANTES, MIGUEL DE SAavedra, an eminent Spanish writer, author of Don Quixote, and one of the most distinguished satirists which modern times have produced.

It appears now to be ascertained, that he was born at Alcalá in New Castile; though the place of his nativity has long been a matter of dispute, Madrid, Seville, and other cities, as well as Alcalá, contending for that honour. The date of his birth is October 9th 1547. His parents were Rodrigo de Cervantes and Leonor de Cortinas, poor, but of honourable extraction. Whether he was related to Francisco Cervantes, author of a book, entitled, Apologo de Ocio y Diversidad, and published at Alcalá in the year 1546, is, we believe, at present unknown.

According to the latest and best accounts, Cervantes received his education under an eminent teacher at Madrid. He was destined either for the church or the profession of medicine, but not relishing the methodical application which was required of him; he appears very speedily to have relinquished all severer studies, and betaken himself to the composition of verses. An elegy on the death of Queen Isabella, a poem, entitled, Æneas, and some sonnets, were his earliest productions. But they seem to have been published only to be neglected. Though rated high in the estimation of the author, they attracted little notice from the friends and patrons of literature. The great and the wise were too indolent or too busy, to attend, while he offered them consolation or amusement. This treatment appeared to Cervantes in the light of the most flagrant and criminal injustice. He considered himself as a young man cruelly dealt with, and resolved, in a paroxysm of resentment natural to a mind conscious of high powers, to bestow his labours no more on a public so ungrateful. Accordingly he quitted Spain, and withdrew himself to Rome. But his fortune was by no means ameliorated by the change; for he was reduced to such extreme distress, that he was constrained to enter into the service of the Cardinal Aquaviva, in the capacity of valet de chambre.

Such was the early condition of this man, for whose birth imperial cities have contended, and whom the world of letters now unites to honour. His miseries, however, did not stop here. He was quickly disgusted with the employment of the cardinal, and as he was wholly without friends, and seems to have had little concern or care of life, he enlisted as a soldier. In the latter capacity he served many years under Mark Antony Colonna; he was present at the battle of Lepanto gained by Don John of Austria A. D. 1571; and history may record him as one instance at least, of a poet who fought valiantly in actual combat, and who, if compelled to retreat, did not expedite his flight by throwing away his shield. In the battle of Lepanto, he had his left hand struck off by the discharge of an arquebus. The loss of his limb on this occasion he ever afterwards considered as highly honourable; regarding it, no doubt, as some proof of valour which had been subjected to trial, and found equal to its severity, or perhaps, as some evidence, that when his left hand was carried away, his right, which grasped his sword, was more actively employed.

In the year 1574, we find Cervantes a slave in Algiers. Here too his fortune was not a little diversified. His first master was Arnaute Marmi, the most ferocious as well as the most formidable of all the corsairs. From the rigorous bondage which he endured in the service of this barbarian, he often times attempted to escape. He joined three Spanish ships, whom he persuaded to leave the houses of their respective masters, and concealed himself, along with his companions, in a subterraneous abode not far from the shore. In the mean time, having procured the ransom of a prisoner, a native of Majorca, on whose fidelity he could depend, he dispatched this person to represent the case of the sufferers, and to implore that a small vessel might be sent, in order to convey them to their native country. The viceroy of Majorca was not attentive to the request; a brigantine was immediately dispatched; but the coast of Algiers was so closely watched, that the vessel could not approach. And to complete the misfortunes of the captives, they were betrayed by one of their associates, seized in their retreat, and carried before the Dey, a ruler, seldom known, even to his Mussulman subjects, by the exercise of mercy. From him therefore, Christians, and Christians who had endeavoured to escape from bondage, could not expect forgiveness. The prisoners approached the residence of the tyrant, anticipating death in its severest form. Fortunately, however, the event did not accord with their expectations. A pardon was offered them; but it was offered them on this singular condition, that they should instantly declare which of their number was the author and conductor of the
enterprise. Here his companions hesitated, but Cervantes resolutely stepping forward, pronounced with a firm and audible voice, that the fatal but honourable distinction belonged to him, and added, in a tone equally firm and audible, that, in order to save his countrymen, he was ready to die. The barbarian ruler, struck with his intrepidity, refused to punish him; and even the savage Arnaut Marmi, whose property, according to the laws and customs of Algiers, Cervantes possessed, appeared unwilling that so brave a man should be put to an ignominious death. In four successive attempts to regain his liberty, the unhappy Spaniard completely failed. Still, however, after each attempt, his life was granted him; a fact the more difficult of explanation, as such mercy is rarely shown within the dominions of Algiers. At length Cervantes was purchased from Arnaut Marmi by the Dey himself, and shut up in close confinement as his slave. But amidst all his misfortunes, the spirit of this extraordinary man continued unbroken and active. Under the eye of the court, and in the condition of a bondsman, he formed a project worthy of his enterprising character,—a project no less hazardous than that of stirring up an insurrection among the subjects of Algiers, putting himself at their head, and dispossessing, by force of arms, the ruler of the country. This plot, likewise, was discovered before it was ripe for execution; but Cervantes, by what management or dexterity we know not, still escaped the punishment of unsuccessful rebellion. Whether the tyrant respected his bravery, and spared him on that account; whether he had the art to withdraw himself at a convenient season, foreseeing the failure of his scheme; or whether his condition was too humble to provoke the royal wrath, it is useless to enquire, because we have not the means of ascertaining the fact. If we may believe Cervantes himself, it was to the first or to the second of the causes just mentioned, that he was indebted for the forbearance which he experienced. In the novel of the Captive, the most interesting perhaps of any in Don Quixote, he refers to his own case when he says, "Only one Spanish soldier knew how to deal with him, (the sovereign of Algiers,) his name was Saavedra; who, though he had done many things which will not easily be forgotten by the Turks, yet all to gain his liberty, never received from his master either a blow or a harsh word; and yet we were always afraid, that even for the least of his pranks, he would get himself impaled; now, he himself sometimes was afraid of it too. And if it were not taking up too much of your time, I could tell such passages of his, as would divert the company much better than the relation of my adventures, and cause more wonder in them." Don Quixote, vol. ii. p. 134.

That Cervantes, during his captivity, was regarded as a person of some distinction, is evident from the high ransom which was demanded for his release. Nothing less than 500 crowns of gold would satisfy the Dey his master, but on condition of obtaining that sum, with immediate dispatch, he signified his willingness to resign the prisoner. In these circumstances, the parents of Cervantes sold what remained to them of possessions, in former times considerable, and aided by the benevolence of the Holy Fathers, who had it in charge from the king of Spain, to negotiate all matters respecting the liberation of captives, the stipulated ransom was paid. In the month of September 1580, the 500 crowns were put into the hands of the Dey, and Cervantes was restored to his country and his friends.

From this period we may date the commencement of his literary career. Disguised with a military life, he appears now to have devoted himself with unusual ardor to the business and labour of writing. The taste of his age demanded pastoral poetry, and accordingly his first attempt was a pastoral, to which he gave the title of Galatea. Like other pastorals, it fails in this, that the incidents have little or no resemblance to those which occur in real life; and in the conduct of the piece, there is a very great extravagance of fancy, and absurdity of combination. The shepherds of Cervantes pronounce long orations on the topic of love, with arguments logically disposed, all intellectual, all orderly; and they talk, in an utter confusion of chronology, of Ixion, of Minos, and of Mark Antony; of Caesar, Homer, and Hercules; of all the great captains of history, and all the heroes of romance. The events of the Galatea are by no means wholly of a pastoral nature. At the time when Cervantes wrote, the Spaniards were a brave and warlike people, the exploits of chivalry formed the basis of every tale; and among such a people, and in such an age, poetry, destitute of adventures and combats, was not likely to find many readers. The Galatea, therefore, is filled, not only with love, which belongs to the legitimate pastoral, but with battles, stratagems, and defiance; Mars and Venus preside alternately over the page, and duels and sonnets follow one another in discordant succession.

Notwithstanding these improprieties, however, the Galatea was favourably received. It was bought and read. And where a taste for romances has been acquired, it may still be perused with such pleasure as is to be derived from that species of writing. In consequence of his success, which was the more gratifying because it was unexpected, Cervantes appears about this time to have entered into the state of matrimony. His wife bears the name of Donna Catharina de Palacios; she was of a good family, but as she brought her husband no fortune, he was still obliged to depend, for his daily support, upon his literary exertions.

The next great work of Cervantes, was his famous History of Don Quixote. To the conception and execution of this work, the following incident is said to have given rise. Having occasion to travel into La Mancha, Cervantes unfortunately quarrelled with the inhabitants of a small village, named Argamasil, or, as some of his biographers have affirmed, contracted debts among them, and for the one or the other of these reasons, he was thrown into prison. While he remained in confinement, he wrote the first part of the adventures of Don Quixote, and in the height of his vengeance assigned to that redoubted personage, La Mancha, as his native province. But with a reserve, which may be accounted for in different ways, he abstained, throughout the work, from mentioning, or even alluding to the village where he had been so ignominiously, and, as he conceived, so unjustly treated. It is probable,
however, that the circumstance above alluded to, is to be regarded only as the occasion which brought the great work of our author to light. The composition of such a piece must have been often in his thoughts. The plan, the incidents, and the texture of the performance, must have been matured in elaborate reflection; but it may, perhaps, be said, with truth, that had not the circumstance in question taken place, the plan, the incidents, and the whole work, might have remained for ever lost to the world, and buried in the breast which conceived them.

To enter into any lengthened criticism on the history of Don Quixote, would, in a work of this kind, be improper. We shall not, therefore, detain our readers with many observations. The hero of the performance is represented as a person of most amiable dispositions, and naturally of a sound understanding, but whose mind had become so far disordered by the incessant perusal of the old romances, as to mistake the fictions which they contained for sober and authentic history. In the workings of his imagination, he forms the design of assuming to himself the character of a knight-errant, and of sallying forth in quest of adventures. Every thing he meets brings to his recollection something which he had read in his favourite books. The slightest name indicates an approaching encounter; trees, and windmills, and flocks of sheep, are metamorphosed into giants; and whenever untoward or disastrous incidents occur, they are referred at once to the power of enchantment. Out of the reality of the appearances of nature, and occurrences of actual life, and the extravagant fancies and conduct of Don Quixote with respect to them, the ridicule arises. Attached to the hero, and in the capacity of his squire, appears Sancho Panza, who had left his family and his home, to take upon him the government of a kingdom which the knight had promised him, and whose simplicity and credulity, whose vulgar jokes and vulgar acuteness, add much to the humour of the piece. The effect of the whole is irresistible; the absurdity of knight-errantry, relatively at least to the time when Cervantes wrote, is represented in the most glaring colours; and, in point of fact, soon after the book was published, knight-errantry disappeared from among the nations of Europe.

After making these observations, it may be reckoned almost unnecessary to enquire, whether the satire of our author be directed against a proper object; whether the ridicule be well founded. Should the question be entertained at all, it might be answered, that chivalry and knight-errantry ought to be distinguished from the abuse to which, in common with every thing of a similar nature, they are undoubtedly liable. When the power of the feudal aristocracy was at its height, when every baron was the enemy of every other baron, and murders and rapine were frequent, the institutions of chivalry must be regarded as of the highest benefit. Though the neighbouring lord was his hereditary, and perhaps his implacable foe, yet the knight who had imbibed the true spirit of the character, disdain'd to attack or to injure him by dishonourable means. He was too valiant, and too confident in his valor, to have recourse to stratagem. He challenged his antagonist to combat in open day, either alone or attended by a specified number of followers. All the little

arts of cunning men and of polished times were despised; and an elevation of soul, and an erect and open demeanour, were cultivated and acquired. As every man bore arms, and as the inferior persons attached to the great families were much addicted to plunder, the traveller could not pursue his path with safety, and the feeble were always at the mercy of the strong. Hence the true knight declared himself bound to protect the weak, and to succour the distressed; and hence bravery, open and witnessed, and compassion frequently exercised, gave the tone and aspect to this best period of the feudal times.

In the progress of society, however, the dominion of laws was gradually established; justice was obtained by other means than those of arms, and the blessings of peace came at length to be better known and duly estimated. It was no longer necessary that individuals should proclaim themselves the guardians of innocence and the protectors of the feeble; the law bore rule over the conduct of men, and the haughty baron himself was constrained to submit to its power. Chivalry, therefore, and knight-errantry, were no longer wanted; and to have continued the profession and the labours of knighthood, when the circumstances of society were changed, would have been to errwise make a new beginning or the disease had disappeared. Before Cervantes wrote, knighthood was become little more than a distinction; the young lord bore indeed the name or title; but was seldom or never required to discharge the duties which it formerly implied. The ancient building had for many years been decaying, some of its parts were already in ruins, and by the efforts of Cervantes, its last towers were shaken and fell to the ground.

When Cervantes was engaged in writing Don Quixote, he is said to have been under restraint from his fears of the Inquisition. In support of this assertion, there is an anecdote related in the second volume of the Curiosities of Literature, "M. du Boulay," says the author of that entertaining work, "accompanied the French ambassador to Spain, when Cervantes was yet alive. He has told me that the ambassador one day complimented Cervantes on the great reputation which he had acquired by his Don Quixote, and that Cervantes whispered in his ear, 'Had it not been for the Inquisition, I should have made my book much more entertaining.' But if this was actually the case, it may be questioned whether the restraint alluded to was not, upon the whole, of a salutary nature; for had Cervantes felt himself at perfect liberty when writing his Don Quixote, we might perhaps have been disgusted with profanity and blasphemy in the perusal of that inimitable work.

Besides Don Quixote, Cervantes wrote also several novels and comedies, and a satirical poem, entitled, "A Voyage to Parnassus." The novels have been read, but the comedies were not very favourably received. Perhaps the talents of our author were not fitted for dramatical writing, or perhaps the reputation of Cervantes was marred by the successful attempts of Lopez de Vega. And with regard to the satire, it had no other effect than that of provoking for its author very many and powerful enemies. The last work of Cervantes bears the title of, The Troubles of Persiles and Sigismunda. While employed in the composition of this work, he per-
Cervantes ceived the approaches of the disease which terminated his existence. He appears to have contemplated his dissolution with serenity, and even with gaiety; though an angry or perhaps a just critic would say, with a blameable hardness or indifference. There is some proof of the insinuation now made, in the letter which he addressed to the Count de Le- 
mos a short time before his death. And in his last performance, The Troubles of Persiles and Sigis-
manda, he mentions, that being on a journey to To-
leedo, a scholar, on learning who he was, sprung in 
rapture from his mule, and communicated to him a 
regimen for the dyspepsia, under which he laboured. 
But Cervantes declined complying with the advice, 
adding these words, not remarkable for their serious-
ness: “My life is drawing to a period; and by the 
daily journal of my purse, which I find will have fi-
nished its course by next Sunday at farthest, I shall 
also have finished my career; so that you are come in 
the very nick of time to be acquainted with me.”

CERVANTES, a genus of plants of the 
class Pentandria, and order Monogynia. See Bot-
Any. p. 177.

CERVUS. See Mammalia, Index.

CESSAVIT, in the law of England, is a writ 
which lies, by the statutes of Gloucester, 6 Edw. I. 
c. 4. and of Westm. 2. 13 Edw. I. c. 21. and 41., 
against the tenant of a lord by rent or other services, 
on the ground that he hath, for two years together, 
neglected to perform his services, or to pay his rent, 
in terms of his tenure; or against a religious house, 
having lands given it on condition of performing cer-
tain spiritual service, which it neglects. In either 
of these cases, if the cesser, or neglect, have continued 
for two years, the lord or donor, and his heirs, shall 
have a writ of cessavit to recover the land itself, co 
quod tenens in faciundis servitut per bimennium jam 
cessavit.

By the statute of Gloucester, the cessavit does not 
lie for lands let upon fee-farm rents, unless they have 
lay dereliction and uncultivated for two years, and that 
be no sufficient distress upon the premises; or unless 
the tenant hath so inclosed the land that the lord can-
not come upon it to distress. And if the tenant 
come into court before judgment, and tender the ar-
rears and damages, and give security for the future 
performance of his services, the process shall be at 
an end, and the tenant shall retain the land. If the 
lord distresses while the writ of cessavit is depending 
against his tenant, the writ shall abate. Blackst. 
Comment. b. iii. ch. 15. Jacob’s Law Dict. (z)

CESSIO BONORUM, in the civil and Scots law, 
is a process whereby persons who have become in-
solvent, by misfortune, may obtain their liberation 
from imprisonment, upon surrendering their whole 
estate, real and personal, to their creditors.

During the period of the Roman republic, the 
laws against insolvent persons were exceedingly se-
vere; indeed, so hardly were they dealt with, that they 
were left almost entirely to the mercy of their cred-
itors. By a law of the twelve tables, it had been 

enacted, that debtors, if they were not solvent within 
in a specified time, should be delivered over to their 
creditors, to be kept in chains, and subjected to the 

This law produced great discontent among the people, 
which necessarily occasioned the introduction of 
the Lex Paeliella, by which it was enacted, that the 
persons of debtors should not be given up to the 
creditors, but only their effects. As this law, how-
ever, provided no means of liberation from imprison-
ment, and the people were still clamorous for some 
new enactment on the subject, the cessio bonorum 
was at length introduced by Julius Cesar, which, 
at first, was only intended for the benefit of Rome and 
Italy, but was afterwards, before the time of Dio-
clesian, extended to the provinces. The provisions 
of this remedy are expressed in the following law of 
the code: "Qui bonis cesserint, nisi solidum creditor 
recepserit, non sunt liberati. In eo enim tantummo-
do hoc beneficium eis prodet, ne judiciati detraha-
tur in carcere." L. i. Cod. Qui bonis cedere pos-
sunt. See also Digest. lib. xlii. tit. 3. This law was 
adopted, in substance, by those among the modern 
European states, whose systems of jurisprudence 
were formed upon the model of the Roman code.

It would appear, however, that a certain degree of 
infamy was always attached to those who had re-
course to this process. The Italian lawyers describe 
the ceremony of cessio to consist in striking the 
bare breach three times against a stone, called lapis 
vituperis, in the presence of the judge. Formerly it 
consisted partly in giving up the girdles and keys in 
court; as the ancients used to carry at their girdles 
the chief utenails wherewith they got their living. 
The following is said to have been the form of ces-
ion among the ancient Romans and Gauls: the ces-
ionary gathered up dust in his left hand, from the 
four corners of the house, and standing on the thresh-
old, holding the door-post in his right hand, threw 
the dust back over his shoulders; then stripping to 
his shirt, and quitting his girdle and bag, he leapt 
with a pole over a hedge; hereby giving the world 
to understand that he had nothing left, and that 
when he jumped, all that he possessed was in the air 
aver with him.

In modern France, every debtor who claimed the 
privilege of a judicial cessio des biens, was required 
to appear personally in court, in the most humiliating 
garb, with his doublet unbraced, and no hat on his 
head. Afterwards he was carried to the market-
place, where the cessio was published. Even the 
most innocent was compelled to wear a green bonnet, 
which was his sole protection against imprisonment. 
In course of time, however, the green bonnet fell 
into disuse in the case of innocent debtors.

By the law of Scotland, the process of cessio bo-
norum is competent only before the supreme court; 
and the privilege is granted only to those against 
whom no fraud can be proved. The debtor must 
have been a month in prison, at the time of bringing 
his process. The cessio, both by the civil and Scots 
law, operates only as a security against imprisonment, 
and not as an extinction of the debt; for if the debt-
or acquire any estate, subsequently to his release, it 
may be attached by his creditors.—Persons liberated 
on a cessio bonorum, are obliged to wear a particu-
lar dress, called the *dywurs habit*, unless the court
dispense with this mark of ignominy, which they gen-
erally do. See Heineccius *ad Pandect*, lib. xliii. tit.
tit. 3, § 26, 27; Bell's Comment. on the Bankr. Law,
book v. ch. 5. (z)

**CESSION**, in a legal sense, signifies an act
whereby a person surrenders up, and transmits to
another, a right which belonged to himself.

In the ecclesiastical law, *cession* denotes the void-
ing of one benefice by taking another. For, by
statute 21 Hen. VIII., if any one having a bene-
fixe of L. 8 per annum, or upwards, according to
the present valuation in the king's books, accepts
of any other, without dispensation, the first shall be
adjudged void by cession. When an incumbent is
made a bishop, all the benefices he before held be-
come void by consecration, unless he obtain a dis-
ensation. When a benefice becomes void by con-
secration, the king is entitled to present, for that
time, who ever happens to be patron: In the case
of voidance by cession, the patron may present. (z):

p. 47.

---

**CETOLOGY.**

The animals called *Cetacea*, or Cetaceous Animals,
constitute the last order of the class MAMMALLA,
or mammerous animals, in most of the modern systems
of Zoology; especially in those of Linneé, Blumen-
bach, and Cuvier; while, in the writings of the older
naturalists, they have been regarded as an order of
fishes. A more attentive examination of their intim-
ate structure has, however, proved the impropriety
of both these arrangements; and seems to point out
the necessity of forming these animals into a distinct
and independent class.

They resemble fishes in almost nothing but their
habitation; while they are distinguished from those
animals by the structure of their atlantal or anterior
extremities; by the form and position of their tail;
by their mode of breathing; and by producing their
young alive, and suckling them by teats. On the
other hand, while they possess the respiratory and
generative organs of quadrupeds, they are essentially
discriminated from these by the form of their bod-
ies; by their total want of *sacral* extremities, or
hind feet; by the peculiar structure of their tail;
and by that characteristic mechanism attached to
their organs of respiration, which gives them the
power of ejecting through appropriate outlets the
water received into their mouths while swimming, or
seizing their prey.

**Cetology**, then, is that department of Zoology,
which treats of the structure, economy, and history
of cetaceous animals, or of *whales*, and other inhab-
tants of the deep, which resemble these in anatomical
structure.

As few of these animals appear to have been known
to the ancients, we meet with but little respecting
them in the writings of the first naturalists. Both
Aristotle and Pliny, however, mention several of
those species with which we are now most intimately
acquainted. Thus, the former, in his *Historia Ani-
malium*, lib. iii. cap. 12, speaks of the great Green-
land whale, under the name *Mucrdnae*, which, in
the twelfth chapter of his sixth book, he treats of the
*Delphin*, *Delphinus*, and the *Porpesse*, *Cetius*.
Though this writer gives us but an imperfect account of all
those species, and mixes a good deal of the marvell-
ous with his descriptions, he is much more to be re-
lied on than any of his successors of the ancient
school. In particular, his natural history of the
dolphin is the most faithful of any that we find in

ancient writers, and proves, that Aristotle, either
from his own observation, or that of his assistants,
was well acquainted with the true form and manners
of the animal which he describes.

The *Natural History* of the Elder Pliny abounds
in observations on several species of whales, espe-
cially the *great whale*, which he describes in the 37th
chapter of his eleventh book, under the name of
*Musculus*; the *Delphinus* (*Delphinus*), lib. ix. cap. 9;
the *Porpesse* (*Tursio*), in the 8th ch. ; and the *Grampus*
(*Orca*), in the 6th chap. of the same book. We
are by no means certain, however, that modern writers
are correct in assigning the *Musculus* of Pliny as a
synonyme of the *Mysticete*, or great whale; for he
speaks of the former as preceding another species,
which he calls *Balana*, by way of leader; and, in se-
veral parts of his work, he denominates the largest
species of whale *Cete*. The descriptions and rela-
tions of Pliny, respecting these animals, are exceed-
ingly fanciful, and show that disposition towards the
marvellous for which this naturalist is so celebrated.
His account of the dolphin, in particular, is little
better than a collection of fables, gleaned from the
poets and travellers of the time; but, on the other
hand, his account of the grampus, and the contests
between this species and the large whales, is very re-
spectable, and tolerably authentic.

Among the earlier naturalists of modern times,
many have treated, more or less minutely, of ceta-
cesous animals, as Aldrovandi, in that part of his
general work entitled *Ceta*; Gesner, in his work *De
Piscibus*; Johnston, in his *Historia Naturalis De
Piscibus et Cetis*; and Rondelet, in his *Histoire des
Poissons*. Of these, the most respectable is Ronde-
let, whose work is still quoted with approbation by
most succeeding writers. He does not, however,
add much to our stock of information respecting
the number of species, though he mentions some,
especially the *Gilbar*, not known to the older
naturalists. The work of Aldrovandi is perhaps the most
imperfect and inaccurate of the four. He quotes
largely, and apparently with implicit credit, from
the writings of Aristotle and Pliny, and even from
the fictions of the poets.

Among the naturalists of the 17th century, we
may mention three of our countrymen of distinguis-
hed eminence in most branches of the science.—Wil-
lugby, Ray, and Sibbald. Mr Willughby's work,
Cetology.

De Historia Piscium, edited by his friend Ray, contains many valuable remarks on cetaceous animals, especially on the great whale, the dolphin, the porpoise, and the grampus. This learned writer was one of the first to mark distinctly, the similarity of anatomical structure in whales and quadrupeds.

Ray, in his Synopsis Piscium, follows his predecessors in natural history, in the error of including cetacea among fishes, though he seems to be among the first that have doubted of its propriety. His reasons for this arrangement, from which we infer his hesitation, are, that the form of their bodies agrees with that of fish; that they are entirely naked, or covered only with a smooth skin; and that they live entirely in the water, and have all the actions of fish. Now, in this last circumstance, our distinguished naturalist is mistaken; and, as he found their mode of respiration formed to his arrangement an objection not easily to be overcome, he divides fishes into those that breathe by lungs (pulmonis respirantia); and those that breathe by gills (brachis respirantia); thus establishing the former of these sections, for the purpose of including the cetaceous animals. The number of species enumerated by Ray is considerable, and he has noticed almost all those which have occasionally been thrown on the coasts of our islands.

The first work of any distinguished eminence as a separate treatise on cetaceous animals, is the Phalainologia Nova of Sir Robert Sibbald, first published at Edinburgh in 1692, and reprinted in London so lately as 1773. In this work, the writer professes to describe the rarer species of whales that had been cast on the shores of Scotland, distinguishing them according to their natural characters into genera and species, and adding some observations on the nature, origin, and use of spermaceti and ambergris. Considering the time at which this was written, it is a valuable work, containing accurate descriptions, and, in general, judicious remarks. It first treats of whales in general, then distinguishes those into such as have teeth, and such as have teeth only in the lower jaw, and such as want teeth altogether, the proper Balanae. He particularly describes the grampus; the small spermaceti whale, or round-headed cachalot; the black-headed spermaceti whale, or great-headed cachalot; the high-finned cachalot of Pennant; the common or Greenland whale; the pike-headed whale; and the round-lipped whale.

As far as Sir Robert depends on his own observations, we believe he is in general perfectly correct; and his work must be considered as one of the best treatises on cetology, and far superior to any thing that appeared on the subject for nearly 100 years afterwards.

Early in the 18th century, Arcted, the friend and companion of Linne, composed his Synopsis Piscium, into which he has introduced the cetaceous animals as an order of fishes, and where he has distinguished a greater number of species than had been enumerated before. His specific characters are, in general, highly expressive, and very accurate, though, in describing the grampus as having broad serrated teeth, (dentibus latis serratis,) a mistake into which Linne has also fallen, he seems to have copied the erroneous account of Rondelet.

Among the last writers who have considered the cetacea as an order of fishes, is Mr. Pennant, who, in the third volume of his British Zoology, describes twelve species of those animals as his first division of fishes, under the title of cetaceous fish. His principal reason for this arrangement is, that in this way we preserve entire the chain of being, since as the seals and manati resemble quadrupeds in the structure of their fore feet, and fishes in the structure of their tail, so cetaceous animals resemble the manati in the former circumstance, and, still more than they, resemble fishes in the form of their body, and structure of their tail. Pennant has borrowed much of his information from Sir Robert Sibbald's work, and has also gleaned freely both from the ancients, and from some modern histories and voyages, as Dale's Account of Harwich; Marten's History of Spitzbergen; Grantz's Greenland; and Borlase's Account of Cornwall. In one instance, the blunt-headed cachalot, he seems to have described entirely from his own observation, and has given a figure of the animal and its teeth.

The most complete and scientific work on cetology, La Cépédé, is undoubtedly the Histoire Naturelle des Cétacés of La Cépédé, published at Paris in 1764, in the year 1804, (12th year of the republic.) John Hunter had given the best account of the anatomy and physiology of these animals, in the 77th volume of the Philosophical Transactions; and Bonnaterre had described, in a masterly manner, their natural history, in that department of the Encyclopédie Methodique allotted to Cetology; but it was reserved for La Cépédé to bring together every thing valuable that had been written on the subject; to reduce it to form and method; and improve the whole by systematic arrangement, and animated description. He has distributed the thirty-four species (or varieties) of cetacea, which he describes, into two orders, the toothless and the toothed. Of the former, he makes two tribes and eight species; of the latter, eight tribes and twenty-six species. His division of the genera, of which we shall say more presently, is certainly more accurate and scientific than that of any of his predecessors, inasmuch as it is founded on anatomical differences; and though his generic and specific characters are often unnecessarily long, and involve circumstances that are implied in the preceding characters of the order, or the genus, they are more accurate and more descriptive than those of any other author with whom we are acquainted.

These are the principal writers on zoology, who have treated on cetaceous animals; but there are several works on the productions of particular countries, which contain useful or curious information on the same subject. Of these, we shall notice a few of the most respectable, and thus conclude our historical sketch of cetological writers.

Among the earliest of these is the History of Iceland, drawn up by John Anderson, a German naturalist of considerable reputation. He has described several species that were little known before his time, particularly the nordeaper, or Iceland whale, the knobbe fish, or scrag whale, and the Jupiter fish, or pike-headed whale; and he has interspersed some amusing particulars respecting their manners, and the methods employed by the Icelanders in taking them, though these latter cannot always be received with implicit credit.
Cetology.  

Frederick Martens, another German, published an account of Spitsbergen and the neighbouring arctic regions, which is frequently referred to by Pennant and other zoological writers, particularly as containing the best account of the gibbon, or fin-fish, and the butskopf, or beaked whale.

About the middle of the eighteenth century, John Egeude, a Danish missionary, who had passed many years in Greenland, successfully labouring for the conversion of the natives, and who had acquired a thorough acquaintance with the productions of the country, and the manners of the inhabitants, published his Description of Greenland, which was speedily translated into English, and published in 8vo, with tolerable plates, in 1743. This work contains an account of the black or Greenland whale, the fin-fish, and the narwhal, or unicorn fish, which, though not very particular, is more to be relied on than that of his predecessors.

The History of Greenland, in two volumes, published in German by David Crantz, a missionary of the United Brethren, in 1765, and translated into English in 1767, gives the best account of the natural history of those frozen regions. This account is contained chiefly to the first volume, which contains descriptions of 13 species of cetaceous animals. Only two of these, however, the white fish and the porpoise, are described from the author's own observations; the account of the rest being copied from Martens's Spitsbergen, Anderson's Iceland, and similar works of established reputation.

In 1751, Erich Pontoppidan, bishop of Bergen, published, in the Danish language, his Natural History of Norway, of which an English translation appeared at London in 1755. The second part of this work is devoted chiefly to zoology, and contains many particulars respecting some of the cetaceae, as the hval-fish, or great whale, the nebbe-hual, or beaked whale, the narwal, or sea unicorn, and the marsvin, or porpoise. His account of the great whale is very minute, and tolerably accurate, though, like most of the good bishop's relations, it sometimes savours too much of the marvellous to be received without limitations. His description of a bladdar beneath the back bone, by means of which the whale renders himself more or less buoyant; and his account of the "terrible roar" sent forth by this animal when bitten by the speckhuggeren, (gladiators,) or when ready to burst from repulsion after a full meal of herings, are erroneous. His figures are worse than his descriptions; for by way of representing the Greenland whale, he gives a bad figure of the cachalot, and his figure of the narwhal has the body spirally twisted as well as the horn.

Among the British Fauna, we may particularly notice Dale's History of Hmswich, Borlase's History of Cornwall, with two works of our contemporaries, Neill's Tour to the Orkney and Shetland Islands, and Fleming's Natural History of the Zetland Islands. The former of these two last works contains the distinguishing marks of a species or variety of the dolphin tribe, called by the Scottish islanders the ceting whale, and the latter notices the several species of cetaceous animals that have appeared on the shores of Zetland. Mr. Fleming has also given an excellent account of a species of narwhal in the Memoirs of the Wernerian Natural History Society of Edinburgh.

In the account which we are here to give of cetaceous animals, we shall first describe their general structure and economy, and shall afterwards give a comprehensive view of each tribe, and of the more important species, distinguishing whatever is most remarkable in what is called their natural history, including their form, size, proportions, and colour; the particular situations where they are most generally found; their manners and way of life; the enemies to which they are most frequently exposed; and the uses to which their spoils have been applied by their most powerful enemy, man.

PART I. ANATOMY AND PHYSIOLOGY OF CETACEOUS ANIMALS.

In their general form, these animals nearly resemble the ordinary tribes of fishes, and like these, are enabled, by their conformation, to move through the water with great velocity. In most species the head is conical, and more or less pointed at the snout; though the great spermæci whale, and some others of the phœser genus, are an exception to this general rule. In most of them the head is extremely large, in proportion to the body, and swells out at the sides towards the insertion of the lower jaw. The head is joined to the body by a neck, so short, as to be scarcely perceptible. There is no appearance of external ear, but only a small orifice, leading to the internal organ of hearing. The eyes are, in general, extremely small, in proportion to the size of the animal, and are commonly situated very far back, near the articulation of the lower jaw. There is always one hole, and in some species two holes, opening in some part of the top of the head, and serving less for nostrils than for ejecting the water taken in by the animal's mouth.

The body is more or less conical or cylindrical, entirely without hair, and covered with a thick and dense cuticle. At the posterior or sacral extremity, the body terminates in a forked tail, that is flattened horizontally, and is very strong and muscular. In some species there is a fin, in others a protuberance, on the top of the back, and all of them have two members, one on each side of the chest, which are usually denominated pectoral fins; but are better entitled to the name of swimming paws, as they nearly resemble the atlantal extremities, or fore-feet of seals and walruses. These animals have evident external organs of reproduction, and in the males especially these are sometimes very large and prominent.

SECTION I. Motion.

The motive organs of cetaceous animals have Skeleton, many striking peculiarities. The skeleton has its parts joined together in such a manner, and is so deeply imbedded within the fat and muscles, that it does not, as in quadrupeds, much influence or discriminate the external form of the animal. The bones have a very loose and coarse texture, so that the fibres are readily distinguished, even on a superficial
Cetology.

view; and in some, as the jaw and ribs, easily loosened, and rendered extremely obvious by maceration. None of the bones have any medullary cavity. Though the neck in these animals appears extremely short externally, that part of the skeleton is composed of the same number of bones as in quadrupeds, namely seven; though in some of them, as the dolphin and porpessæ, the two next the head, and in others, as the several species of physisæ, the six last, or sacral vertebraæ, are united or anchylosed. Thus in the two former species, there can be no rotatory motion between the head and neck; and in the physisæ tribe, the motions of the head must be exceedingly obscure. The number of joints composing the back differs considerably in these animals. Some, as the dolphin and porpessæ, have thirteen; others, as the piked-whale, only twelve. The number of ribs also varies, depending on that of the dorsal vertebraæ. In some species Mr. John Hunter distinguished eighteen ribs on each side; while in some spermææ whales, thrown ashore on the coast of France, there were only eight ribs on a side.

There is no pelvis in the skeleton of these animals, and it is therefore impossible to distinguish the lumbar vertebraæ from those of the coccyx or tail. In many species, these sacral or posterior vertebraæ are very numerous. Thus, in the dolphin and porpessæ, they exceed fifty. The most remarkable part of the skeleton of cetaceous animals is, the atlantal extremitities or swimming pans, whose bones in number and articulation nearly resemble those of man. We can clearly distinguish a scapula or blade bone, an humerus or shoulder-bone, two bones similar to those of the fore-arm, and a hand consisting of five fingers. All these bones are, however, much flattened, and susceptible of but little motion on each other; though they are so connected by means of cartilage, that the whole number possesses considerable pliability and power of general motion.

The flesh which covers the skeleton is of a red colour, and nearly resembles that of the horse and cow. It is in general firm, dry, and tendinous. The muscles of these animals soon lose their fibrous texture after death, speedily running into putrefaction; though this change is apparent, more from the change of texture, than from the disagreeable odour which the flesh exhales. The most remarkable part of the muscular system is that which gives motion to the tail. This organ is composed of two oval lobes, formed of three layers of tendinous fibres, of which the two external or peripheral layers have a direction similar to that of the lobes, and are crossed by those of the internal or central layers. By means of this structure, the tail in these animals is susceptible of very extensive and rapid motion, and not only serves the purpose of a fin, to impel the animal forwards, but furnishes him with a most formidable and effectual offensive weapon. Indeed the force of the tail, in the larger species, where it sometimes measures above 20 feet from the tip of one lobe to that of the other, is so great, that a single stroke with it, well aimed, is sufficient to cut a boat in two, or sink it to the bottom.

When we consider the enormous bulk of some species of whales, we shall be surprised at the celerity with which they make way through the water. It is computed by the French naturalists, that some of them are capable of rushing through 83 feet in a second of time, and that, supposing them to move with a uniform and uninterrupted motion, 23 days would be sufficient for enabling them to circumnavigate the globe.

SECT. II. Of Sensation.

The brain in these animals has pretty much the same structure as that of quadrupeds, though in most of the species it is very small in proportion to the size of the animal, and especially that of the head. It is proportionally largest in the porpessæ, and smallest in the great spermææ whale. Its substance is compact, and more visibly fibrous than perhaps in any other animal. The distinction between cortical and medullary matter is well marked, and of these the latter is very white. The lateral ventricles and thalami of the optic nerves are large; the corpora striata, small. The medulla oblongata is in general extremely small, when compared with the rest of the encephalon, especially in the dolphin, where the latter is to the former as 15 to 1. The spinal marrow is comparatively small, though in some species, as the large spermææ whale, it is proportionally very large. In structure it agrees with that of quadrupeds.

The nerves of cetacea differ little from those of other mammals, except that the olfactory nerves are wanting, and their office seems to be supplied by the first branch of the fifth pair.

It is probable that these animals possess none of the external senses in any exquisitè degree, except that of sight. In many, it would seem as if the sense of smelling were entirely wanting; and by reason of their defect in external auditory organs, their hearing cannot be acute.

It does not appear that these animals possess any particular organ of feeling; for though the swimming paws are composed of a great number of separate bones, these are neither so delicate, nor so moveable, as to enable the animal to employ those members in the way of fingers, though they are often used as a hand or arm to support and protect their young. It is in the skin, therefore, that covers the general surface of the body, that the sense of touch of which these animals are capable seems to reside; and from the numerous papillæ which cover the whole peripheral surface of the skin, it is probable that they possess the sense of feeling, in no small degree, especially considering the element in which they live.

From the size, softness, and humidity of the tongue in these animals, we may suppose that they are by no means defective in tasting, though this is a point that must rest entirely on conjecture. The organs that appear subservient to this and the former sense, as they are certainly better adapted for other purposes in the economy of these animals, will be considered more at large in future sections.

Though there be no distinguishable organ of smelling in the cetacea, it is thought by some naturalists, that the sense of smelling is by no means wanting in these animals; and this seems to be confirmed by an anecdote related by La Cépède.

It appears pretty certain that these animals perceive sounds, even though weak, at a considerable distance. The internal structure of their organs of hearing is by no means ill calculated for receiving im-
pressions from the vibrations of the atmosphere. They have a very large auditory canal, and a eustachian tube of great diameter. Besides these, most species possess a labyrinth with three semicircular canals, a cochlea, a vestibule, and a tympanum lined with a membrane, and provided with little bones articulated together. The eustachian tube communicates internally by the tympanum with the mouth, and ascends upwards towards the top of the spout-holes, into the cavity of which it opens; and that part of it which is next the internal ear, exhibits, on its inner surface, a pretty large hole, or empty depression. Both the tube and its cavities are lined with a blackish delicate mucous membrane. It is supposed by some, that this organ assists the animal in receiving impressions from odorous bodies. All the bony parts of the internal ear are exceedingly hard.

The element in which these animals reside is well calculated for communicating sonorous vibrations, and it is probable that when they remain in their usual position, with the head, or at least the external auditory orifices, several feet below the surface of the water, their hearing is much more acute than when the head is elevated into the air.

The most perfect sensitive organ in cetaceous animals, is undoubtedly the eye; for though this organ is, in some species, extremely small in proportion to the bulk of the animal, that of the largest whale scarcely exceeding in diameter the eye of a bull, yet its conformation is as perfect as that of quadrupeds, while it possesses, in common with that of fishes, a peculiarity of structure, for the greater refraction of the rays of light.

We have already remarked (See Anatomy, Part II. vol. ii. p. 13) the unusual thickness and closely interwoven fibres of the sclerotic coat of the eye in these animals, and their want of lachrymal glands or ducts. We may add, that the union between the sclerotic coat and the cornea is much closer than in quadrupeds, consisting of long and very delicate filaments, that penetrate the substance of each membrane, and fasten them together; that the fibrous and vascular structure of the choroid coat is extremely evident; and that the crystalline lens, like that of fishes, is nearly spherical.

Sect. III. Digestion.

The digestive organs of cetaceous animals differ very considerably, according to the food on which they live, and their manner of seizing it. Those of mastication, in particular, are so various, as to constitute the principal differences that discriminate the orders and genera.

The general form of the mouth is very different in different species. In some, as the dolphin, and most of its congener, it is long, narrow, and shallow; while in others, as the proper whales and cachalots, it is nearly of an oval form, and often extremely broad and deep. The opening of the jaws in the balaenæ and the cachalots is exceedingly wide, so as, in some of the former, to admit of several men entering erect into the open mouth, and standing upright within the cavity.

The form and proportions of the jaws are very various. In some, they are nearly of the same length; while in others, the lower jaw extends beyond the upper, or lies within it as in a groove. Sometimes the snout, formed by the anterior extremity of the jaws, is pointed; but in most cases it is more or less round and obtuse.

In those cetacea that have many teeth in both jaws, the teeth are so situated, as, when the jaws are close, to lock into each other. They are most nu-

merous in the dolphin, in which some naturalists have reckoned above 180, while others saw only about 40 in both jaws,—a difference which probably depends on the age of the animal. They are almost always cy-

lindrical, or rather conical. Mr Hunter describes them as composed of a double cone, one part of which

extends beyond the gum, while the other constitutes the fang by which they are inserted into the jaw. In some species, as the dolphins, they are straight, and more or less pointed; in others, as the cachalots, they are usually curved and obtuse.

The formation and progress of the teeth, in these animals, appear to differ from those of quadrupeds. They seem to be formed within the gum, and either to sink thence into the sockets, or remain fixed till these latter rise to inclose them. As in other ani-

mals, the number of the teeth seems to increase as the jaws advance in length, though Mr Hunter is of opinion, that they do not, like quadrupeds, shed their teeth.

Phil. Trans. vol. lxxvii. p. 599.

Most naturalists describe the body projecting from the upper jaw of the narwhal as a tooth, though it

appears to us to have very little analogy to these or-

gan, and certainly does not assist in the process of mastication. It is clearly a horn or tusk, similar to those of the elephant and other quadrupeds, and is calculated to serve the purposes of an offensive and a defensive weapon.

The balena, instead of teeth, have a curious ap-

paratus, consisting of horny plates, with fringed or

hairy borders hanging from the edge of the upper

jaw. The description given of this substance by dif-

ferent naturalists, varies in several respects; but the most accurate account appears to be that of Cuvier, which is as follows:—

The maxillary and palatine bones, in this tribe, form on their inferior surface two inclined planes, which give to the palate the appearance of the roof of a house reversed, and their two surfaces are con-

cave. It is to those that the laminae of the whale-

bone are attached; these are all parallel to each other, and have a transverse direction with respect to the axis of the body. Several hundred of laminae may be counted on each side, and in the Greenland whale they often exceed 10 feet in length. They are fixed to the bone by a kind of fleshly or ligamentous sub-

stance. Each lamina presents, on its internal side, a layer of horny fibres, growing from the horn plate, but less fine, and more divided than the plate from which they proceed. These plates extend between the plates, and form a fringe or loose border on the lower part of the plates, so that these fringes hang down from every part of the plate, which is above the tongue, and entirely invest this organ. The use of this horny substance, or whalebone, seems to be to retain, as with a net, those small animals which the whales seize and swallow for food. Anat. Compar.

tom. iii. p. 199.

The above description differs in several respects from that of Mr John Hunter, in the Philosophical
CETEOLOGY.

Transactions for 1767, and from that given by Mr. W. Scoresby in the first volume of the Memoirs of the Wernerian Natural History Society. According to the description of the latter writer, the longest blades of whalebone are nearer the throat than the snout, and they become gradually shorter before and behind this point. They are curved in two directions, both longitudinally from the sides to the centre of the mouth, and transversely. The whalebone is covered below by the under or basilar lips, which, when the mouth is shut, overlap the upper part in a squamous manner.

The plates of whalebone are of a black colour, mottled with shades of a lighter hue; but they often appear of a greyish cast, from the thin skin with which they are invested, and which is of this latter colour.

The tongue of these animals is most remarkable for its size, being comparatively large in all the species, but particularly so in the balena. In substance it varies in the different tribes, being of a firm texture in the porpesea, grampus, and other dolphins, but soft and spongy in the proper whales. In these latter the tongue, both in size and substance, has been compared to a feather bed. It is composed partly of muscle, and partly of fat, with which it is abundant in the balena, as often to produce several tons of oil. In some species it is covered with a fine smooth skin, while in others it is rendered rough on the surface by numerous papillary protuberances. It is usually pointed at the anterior, or anterior extremity, and serrated on the edges. It projects most in those species that are furnished with teeth.

The esophagus, or gullet of cetaceous animals, has, with respect to its general structure, been sufficiently described under Comparative Anatomy. Its diameter differs considerably in different species. In the Greenland whale, the largest of the class, it is so small, as with difficulty to admit the passage of a hen's egg, while in the piked whale it has been observed 33 inches wide, and in some other species it is probably much wider. It is proportionally widest in the dolphin tribe, especially in the dolphin and the porpesea.

The cetacea resemble the ruminating quadrupeds in the complicated structure of their stomach. This organ consists of four, and sometimes five distinct cavities, connected with each other in a manner somewhat different from those of the ruminating quadrupeds. In the dolphin and porpesea, (which we may quote as among the most familiar and procurable examples,) the first stomach is the most extensive, and of an oval form, having on its central surface thick circumvolutions, and elevated ridges round the orifice, by which it communicates with the second stomach; thus preventing the return of the food from the latter into the former. The second stomach is also oval, and rather less than the first; marked internally with longitudinal rounded channels, united by others that cross them transversely, like the fingers of the two hands when joined together. Between the second and the first stomach, and between the former and the third, there is a short canal, which forms a narrow passage from the one to the other. The third stomach is lengthened out like an intestine, and curved in the form of a co; its sides are much fatter than those of the two preceding, and its central or internal surface is smooth, soft, and without wrinkles. Its outlet in the fourth stomach is contracted by a sort of pad, formed by the three membranes. The fourth stomach is the least of all in capacity; it is short and small externally, and its structure appears the same with that of the third. Its outlet is marked by a simple structure, without any elevation or valvular fold.

The rest of the intestinal canal is usually very long, and the folds of its central membrane remarkably distinct and protuberant, so as to render the whole cavity of a cellular structure, the folds acting as so many valves that impel the contents forward, but prevent their return. The distinction into small and great intestines is also very evident. The most partial part of the intestines, or rectum, appears contracted, is glandular, and covered by a soft cuticle, and its termination in the anusa is very small.

The food of cetaceous animals is different, according as they are furnished with teeth, or destitute of these organs. The dolphin tribe live on various species of fish, especially cod-fish, flat-fish, and dog fish. Some of the more ravenous of this tribe, as the grampus, will prey on others of their own tribe, and will even attack the larger whales, and suck their blood. Those of the physter tribe, or the spermaceti whales, are said to feed on the smaller of the dolphin tribe, and on seals; and the large spermaceti whale is said to pursue with avidity the shark, which is supposed to constitute a great part of his natural food. The balena and the narwhals live chiefly on various species of mollusca, such as actiniae and medusae, though some of them certainly devour large quantities of herrings, and other smaller fishes. These they swallow whole.

SECT. IV. Circulation.

There is little remarkable in the conformation of Heart and the circulating system of the cetacea, which differs arterio-

ciles of the heart, and which has been called by anat-
omists foramen ovale (see Anatomy, vol. i. p. 580.) con-
tinued open after birth in the cetacea, and other

animals that pass much of their lives under water;

but this opinion, at least with respect to the cet-
acae, is erroneous. Indeed, if we consider the short
time during which these animals can keep entirely
below the surface of the water, (which seldom ex-
cceeds twenty minutes,) it must be evident, that their
necessity for frequent respiration is nearly equal to

\[\text{VOL. IV. PART II.}\]
that of quadrupeds; and that they therefore possess a similar system of circulating and respiratory organs.

**Respiration.**

The structure and physiology of the respiratory organs in cetacean animals, deserve particular attention, as they exhibit peculiarities not to be found in any other class of animals, and are in themselves sufficient to distinguish the cetacea from the mammalia.

Many of the amphibious quadrupeds, especially the *manate*, have fins resembling those of the cetacea, but none of them possess the peculiar *larynx* and spout holes of the latter.

The *larynx* consists of the same number of cartilages with that of quadrupeds, but their appearance and articulation are somewhat different. In some species, as the porpoise and piked whale, the *ost hyoidea* consists of one piece, while in the dolphin, or bottle-nosed whale, it is composed of three pieces, besides two additional cartilages attached to it from above. This bone has no attachment to the head by means of other bones, as is the case in many quadrupeds. The thyroid cartilage differs in figure in the several tribes, but in general it is broad and lateral, than from the attachment to the sacral edge (from above downward). The cricoid cartilage is broad and flat, and deeper laterally and on its dorsal part, than on its sternal side. It is extremely thick and strong. The two arytenoid cartilages project considerably, and are united to one another almost to their extremities. The epiglottis is sometimes not attached to the arytenoids, while in others it is so united to them, as to form with them a complete canal, terminating in the glottis. In this latter case, the passage through the glottis is very much contracted, and below this operation the *trachea* swells out into a tube of considerable size. From this peculiar structure, Mr Hunter was of opinion that these animals possess no voice; though we are assured by many observers, that they emit sounds resembling a sort of dull bellowing or roaring.

The lungs have little peculiar, except that they are long and thin, and closely attached both to the pleura and the diaphragm. They are also not divided into lobes, as in man and quadrupeds, and are of a firmer texture.

**Diaphragm.**

The diaphragm is attached at its sternal edge to the abdominal muscles, whence it passes obliquely backwards, and is inserted into the spine much more sacral or lower than in quadrupeds. This muscle, and all those parts concerned in inspiration, are, in the cetacea, exceedingly strong.

There is something peculiar in the structure of the thorax, which is not entirely surrounded by the ribs; hence its cavity is less easily enlarged. This defect is supplied chiefly by the greater proportional strength in the diaphragm, which is hence supposed to be the principal organ of inspiration.

What are called the *spout holes* or *blow holes*, are two canals situated near the middle of the arch formed by the bones of the cranium, a little behind that part where rises the protuberance in which they terminate by the external orifices. They proceed from the back of the mouth, and after traversing in a curved direction the interior of the skull, open externally in some part of its upper surface. In most species the bony canal is double, and in some the two parts continue distinct as far as the external opening; this is the case in the baleen. In most, however, the two canals unite near the top of the head, and terminate by a single external orifice. This orifice differs both in form and situation in the several tribes. In the porpoese, grampus, spermacteri whale, and some others, the orifice is transverse; in the baleen it is longitudinal. It is always situated on that part of the head which is most protuberant. In some tribes this part is near the forehead, in others near the middle of the head. In some, as the balaena and physcer tribes, its course through the cranium is straight; in others, as the narwhals and dolphins, it is curvilinear.

The most curious part of the mechanism of the blow holes remains to be described, viz. the connection between the bony parts of these passages, and the contiguous membranes and muscles. We have already seen, that the eustachian tube ascends towards the top of the nostrils, and have noticed the cavity or empty space on its internal surface. With this hole are connected several membranous cavities or sinuses, and this compound cavity communicates with the frontal sinuses, by a canal which ascends forwards towards the orbit; but the sinuses have no immediate communication with the nostrils properly so called.

On examining the gullet in these animals, we find that when it reaches the top of the larynx, it seems to divide into two tubes, one of which is continued into the mouth, while the other ascends towards the nose. This latter is surrounded with glands and fleshly fibres, that form several muscles. Some of these fibres are longitudinal, and are attached round the posterior orifice of the bony part of the nostrils or blow holes, and descend along the tube as far as the pharynx, and down the sides of this cavity; the other fibres are annular, and appear to be a continuation of the proper muscle of the pharynx. Now, as the larynx rises into this canal like a pyramid, these annular fibres are able to compress it by their contractions. The two bony canals near their upper or external orifice are closed by a fleshy valve, in the form of two semicircles attached to the anterior border of the orifice, which the valve closes by means of a very strong muscle, inserted into the upper surface of the inter-maxillary bones. To open the orifice, requires a strong effort from below upwards. When this valve is closed, it intercepts all communication between the blow holes and certain cavities placed above the valve.

These cavities are two large membranous bags, formed of a blackish mucous skin, which are much wrinkled when empty, but when inflated assume an oval form, and are of considerable capacity. These two bags are concealed below the skin in the forepart of the blow holes. They both open into an intermediate cavity, placed immediately in the blow holes, and communicating with the external air by a narrow circular chink. There is an expansion of very strong fleshy fibres, which covers the whole of this apparatus, proceeding in a radiating form by the neighbouring parts of the cranium, and uniting over the two bags, so as to be capable of compressing these with great force.

Such is the mechanism of the blow holes as descri-
Cetology.

As an image is not provided, I am unable to describe the image. If you have any text or specific questions about cetology, feel free to ask!
In the organs and function of reproduction or generation, these animals very nearly resemble quadrupeds, especially those of the ruminating order. The male has a penis, testicles, and vesica deferentia; the female a vagina, a clitoris, and a uterus, with its ovaries and Fallopian tubes; but from the different form of these animals, the situation of those parts, especially in the female, is different from that of the same organs in quadrupeds.

Milk of the female. The milk of the female cetacea resembles that of the cow, but is said to have a richer taste, like cow's milk with the addition of cream.

The function of generation in these animals is involved in much obscurity, and various conjectures have been advanced respecting their mode of copulation, their period of gestation, and the posture in which they suckle their young.

By some it has been affirmed, that they copulate in an erect posture, with their heads far out of the water; and there seems no doubt that they have been observed in this strange posture, embracing each other with their swimming paws. Others, with much less probability, have pretended that, during copulation, the female is extended on her back, a position which cannot be long preserved, from the necessity of frequent respiration.

Their period of gestation is not known, but it is conjectured that they carry their young ten months, and admit the male only once in two years, being thus supposed to give suck above a year. They generally bring forth only one at a birth, though they have sometimes been seen with two under their protection.

Some authors pretend to describe the method in suckling which the female suckles her young. We are told by Gerardin, that when she wishes to give suck, she approaches the surface of the water, and turns herself upon one side; she then swims sidewise, and by frequent and gentle oscillations, she places herself sometimes above and sometimes below her young one, according as she or it can spit out through their blow-holes the water which rushes into their mouths, and thus alternately respire.

Nothing can be more uncertain than the age which longevity these animals are capable of attaining. They have been considered as the very emblems of longevity, and the larger species are described as passing above 1000 winters among their native ice. All this, however, must be purely conjectural; and it is only from the analogy supposed to subsist between them and the larger quadrupeds, that we can at all guess at the duration of their lives. In this way we may suppose, that if the elephant lives above 100 years, the Greenland whale, which is nearly ten times the size of that vast quadruped, should live about ten centuries.

**Explanation of Plate CXXXIII.**

The figures of this Plate are intended to illustrate the structure of cetaceous animals, described in the preceding pages.

**Fig. 1.** A view of the bones of the atlantal extremity, or swimming paws, of the dolphin. a, the humerus; b, the radius; c, the ulna; d, \( e \), \( f \), \( g \), \( h \), the metacarpus; i, k, l, m, n, the phalanges of the fingers.

**Fig. 2.** A horizontal view of the tail of the piked-whale, figured in Plate CXXXIV. Fig. 2.

**Fig. 3.** The skull, jaws, and teeth of the dolphin.

**Fig. 4.** The usual position and form of the teeth in the physeter tribe.

**Fig. 5.** The tusk or horn of the narwhal.

**Fig. 6.** The general appearance of the horny plates of whalebone in the balene, showing their relative situation, and the hairy edges in which they terminate.
Fig. 7. A view of the general form and proportions of the complicated stomach of cetaceans, as seen in the purse. a, the gullet, where it joins b, the first stomach; cc, the second stomach; ddd, the third stomach; e, the fourth stomach; f, the pylorus.

Fig. 8. A side view of the muscular and bony parts connected with the blow-holes in the dolphin. a, the tongue, seen from above; bb, the nostrils; c, the pharynx; d, the larynx; e, the left horn of the os hyoideus; f, the stylo-glossus muscle.

Fig. 9. A horizontal view of the same parts dissected, so as to shew, a, the common opening of the blow-holes; b, the right membranous bag; c, the left bag inflated; dd, the second layer of muscular fibres attached to the membranous bags.

Fig. 10. A view of the organs of reproduction in the male porpoise. a, the urinary bladder, seen from above; bb, the ureters; cc, the vasa deferentia; dd, the commencement of the two branches of the corpus cavernosum penis; ee, the muscle which envelopes the prostate gland, and the beginning of the urethra; ff, the two bones that answer to the pelvis of quadrupeds; g, the rectum; h, the anus; ii, the two retractor muscles or ligaments; kk, the glans; l, the external orifice of the urethra.

PART II. NATURAL HISTORY OF THE SPECIES.

The number of tribes and species into which cetaceous animals have been divided, varies in different authors. In the last edition of Linne's Systema Naturae, edited by Gmelin, the genera are still only four in number, viz. Balaena, Physeter, Delphinus, and Monodon; but the whole number of species is fifteen. In the Cetologie of Bonnaterre, forming the description of the plates of cetacea in the Encyclopédie Méthodique, the species of Linne's four genera described amount to twenty-five. La Cépède, in his Histoire Naturelle des Cétacés, has augmented the genera to ten; dividing Linne's genus Balaena into two, Balaena and Balænoptera, forming the Monodon spurious of Bonnaterre into a new genus Anarhacius; dividing the Physeter of former naturalists into three tribes, Cetodon, Physalus, and Physeter; and their Delphinus into two, Delphinapterus and Delphinus; and constituting a new genus, Hyperoodon, for the sake of an anomalous species, which some have ranked as a Delphinus, while others have considered it as a Balaena. This distinguished naturalist has swelled the list of species to thirty-four; but he has done this by introducing as species what the best writers before him have, we think very justly, regarded as varieties. Though La Cépède's Genera have been adopted by the author of the article Classification in Reeve's Cyclopaedia, we have not ventured to follow him implicitly, as we are not satisfied with this minute fretting down of the established divisions. We have, however, adopted three of his new genera, thus forming seven tribes.

Order I. EDENTATÆ, or Toothless Cetacea.

Genus I. Balaena, Common Whales.

In this tribe there is no appearance of a fin on the back, though two of the species have there one or two protruberances. There are always two distinct blow-holes, situated on the most prominent part of the head. Their head is very long and large in proportion to the size of their body, occupying a third or fourth part of their whole length; exceedingly deep from the crown to the base, but compressed upon the sides; broadest near the middle, and diminishing a little towards the snout. The jaws are nearly equal in length; but the lower jaw is broader than the upper, and has a furrow for receiving the lower edge of the horny plates or whalebone, that are suspended from the palate. The eyes are small, and placed a little above the angles of the mouth, and there are two small external orifices behind the eyes, that form the external auditory passages.

There are four species, all confined chiefly to the northern ocean; off the coasts of Greenland, Iceland, and North America.

The following are the most deserving of notice.

Species 1. Balaena Mysticetus; Black, or Greenland Whale.

This is supposed to be the largest animal which has yet attracted the observation of naturalists; and unless we can attach more credit than they seem to deserve to the wonderful accounts given by Pontoppidan and some other northern writers of the kraken, whose immense body lies stretched like a moderate-sized island, and the sea-snake, that rears its head above the topmast of a man of war, there appears little reason to doubt the supposition. Individuals of this species are often caught, that measure about 60 feet in length, and nearly 40 in circumference; and we are informed, on very credible authority, that whales of at least twice these dimensions have formerly been taken. To this latter size we must at present limit our belief; though ancient naturalists have given accounts of whales above 500 feet long. We are, however, disposed to think, that those writers who discredit the accounts of voyagers and historians of the whale fishery respecting the great size of whales formerly taken, are not warranted in their disbelief, because they themselves have not seen any of those large dimensions. There can be little doubt, that one natural effect of the long war which man has carried on against these animals, must be to diminish their number, and more especially that of the larger individuals, which, from being more profitable, would be more coveted. Hence it may readily be conceived, that the whales now taken are very inferior in size to those killed at or near the commencement of the whale fishery.

When this species is seen from a distance out at sea, it appears like a dark unformed mass, floating a little above the surface of the water; but when view-
Cetology.

ed under favourable circumstances, he is seen to have a cylindrical body, the diameter of which is greatest a little behind the swimming paws, whence it tapers considerably towards the tail, and slightly towards the insertion of the head. Near the junction of the tail and body, the skin has a ridged appearance.

The head is of a triangular shape, with the vertical angle at the snout considerably rounded. It is convex above, where, near the neck, there is a considerable protuberance, in the fore part of which are seen the blow-holes. The under part of the head, or lower jaw, is flatish, and the two bones by which it is formed are curved, and pointed at the anterior or antimal ends. The lips are of enormous size; are fixed at right angles to the base of the head; are firm and hard, and overlap each other in such a manner, that when their opening is viewed sideways, it has nearly the shape of an \( \infty \) placed horizontally, this opening extends towards the base of the swimming paws, till it reaches beyond the protuberance at the top of the head. The eyes are covered with large thick eye-lids, though, from the quantity of fat below the skin, these lids are scarcely movable.

The tail resembles a cone, with its base arising from what may properly be called the body; and the two fins in which it terminates behind are broad, and curved at the farthest edge, so as to resemble an Italic S. The whole tail is extremely movable, and has very powerful muscles attached to it.

The prevailing colour of this species is a shining black on its upper or back parts, while the fore-part of the under jaw and a little of the belly are white; and the under part of the body, towards the origin of the tail, is generally grey. The blubber of a healthy whale is generally of a yellow colour.

The female whale is said to be usually larger than the male, and is generally known at a distance by having a young one under her protection. These young whales are of a lighter colour than their dams. They have received from the fishermen various names, according to their age. For the first year after birth, while they remain with the mother, they are called short-heads, and are so fat, that one of an ordinary size will yield 60 barrels of blubber. When two years old, they are denominated events; as they thrive so little for some time after quitting the dam, that they will not yield more than twenty barrels of blubber. After this, till nearly full grown, they are called skull fish.

At present, the large whale seems to be confined to the regions about the north and south poles, especially off the coast of Greenland, Iceland, Spitzbergen, and Davis's Straits, in the neighbourhood of the former. There is no doubt, however, that this enormous animal has been occasionally seen in almost all the watery regions of the globe; especially at the mouth of the river St Lawrence, off Newfoundland, on the western coast of Mexico, off Ceylon, and the island of Socotra, in the neighbourhood of the Persian Gulf, on the eastern coast of Africa, and near Madagascar, in the Bay of St Helena, and even off the coast of Guinea. Individuals have now and then appeared in the Baltic, and in the Mediterranean sea; and more than one instance has occurred of the whale appearing off the British coast. Indeed, if we are to credit the relations of the ancients, the largest whales were formerly seen near the coast of Britain. Thus Juvenal, comparing great things with small, uses the following illustration:

> Quanto Delphinus Balena Britannica major.—Sat. x.

Various accounts have been given of the food of the whale; but it is generally believed, that it subsists almost entirely on various species of mollusca, especially medusae, the cito-limoina, shrimps, and crabs. When it feeds, it swims with considerable velocity, with its head below the water, and its mouth wide open. Thus, the animals that enter its mouth are entangled by the hairy parts of the whale-bone, as in a net, while the water that enters with them either runs out again at the corners of the mouth, or, when the animal attempts to swallow, is ejected with great force through the blow-holes.

The whale is said to be capable of swimming at the rate of eight or nine miles an hour. It seldom remains long at the surface, nor can it stay below water above twenty minutes. It is, however, said to sleep at the surface, with its back and the summit of its head just out of the water. When the female whale has a young one under her protection, she is extremely tender of it, carrying it with her wherever she goes, protecting it from injury, and even when pursued supporting it with her swimming paws. When wounded, she still continues to clasp it; and when she plunges below the surface, and in vain endeavours to escape her pursuers, she carries her young one with her to the bottom, though, more mindful of its necessities than her own safety, she emerges sooner than usual, to allow it to repose. It is considered very dangerous to attack a mother whale, as she is extremely ferocious in defence of her young one, lashes with her tail in the most furious manner, and, in rising from the bottom, not unfrequently endeavours to overset the boats with her enormous back.

One might imagine, that an animal of such vast bulk and prodigious strength, might roam through the ocean without the dread of any other created being; and yet, besides his most formidable enemy, man, he is exposed to the attacks of a great variety of foes. The sword fish (Xiphias Platypurus, Lin.), the saw fish (Squalus praeitus, Lin.), and the gladiator dolphin, or sea sword, attack him with the formidable weapons with which nature has provided them, and cut and tear his flesh, till, overcome with pain, fatigue, and loss of blood, he yields to an enemy as insignificant in bulk, when compared to himself, as a pigmy when set aside a giant, and whom a single blow with his tail, were he allowed to strike it fairly, would almost instantly destroy. The gladiators beset him in numerous packs; and, when overcome with fatigue in resisting these assailants, he loses out his tongue, the ravenous animals seize on it, and tear it piecemeal from his mouth. Another species of shark, commonly called the sea-bear, attacks the whale in its belly, where it fastens itself by its five-fold range of pointed teeth, and either gnaws off pieces of flesh and blubber, or sucks the blood of its helpless prey.

There are two other animals, much less formidable, indeed, than those which we have mentioned, that feed on the whale; a species of lepas, which adheres to his body, especially below the swimming paws, and a crustaceous animal, called the whale-louse,
CETOLOGY.

which attaches itself so firmly to the skin, that it is almost impossible to tear it away. It is probable that these parasites occasion an intolerable itching, as the whale is said to strike himself against rocks and ice-hills, with the view of freeing himself from such troublesome companions, and often receives considerable injury in these fruitless endeavours.

In speaking of man as the great enemy of the whale, we shall not at present enter on any account of the WHALE-FISHERY, which we shall reserve for a future article; but it may be proper here to notice, as an interesting part of his manners, the way in which he conducts himself when attacked by the fishing-boats. As soon as he perceives himself wounded, he flies off with extreme rapidity, swimming to a distance, and at the same time diving towards the bottom. His flight is so rapid, that were the coil of rope to which the harpoon is fastened to be in the least entangled, the boat and her crew would be instantly over-set, or hurried to the bottom; and, were it not for the precaution of continually wetting the rope, its friction against the gunwale would set the boat on fire. When fatigue and want of breath compel him to reascend to the surface, he is immediately, on coming into sight, attacked by another harpoon from the same, or another boat, and flies off with the same rapidity as at first; but from his second flight he is soon obliged to return: thus, by successive wounds, and the consequent fatigue and loss of blood, he is rendered incapable of farther resistance. He is then secured by a hawser, or small cable, and towed by several boats towards the ship. Even then, however, it is dangerous to approach him, as he lashes furiously with his tail, and would soon sink or disable the largest boat. When dead, the carcase floats on the surface of the water, with the belly upwards.

There are few parts of the whale which may not be converted to some use. The consumption of the oil drawn from its blubber, in the burning of lamps and the dressing of leather; and of the horny plates, or whale-bone, for stays, corsets, umbrellas, handles of whips, and ramrods for fowling-pieces, is well known. The intestines are used in some countries instead of glass for windows; the tendons split into fine fibres, to supply the want of thread; the hairy part of the whale-bone in constructing fishing nets and lines; and the ribs and jaw-bones as beams and rafters for houses. Even the flesh is eaten by the inhabitants of Greenland, and the heart and tongue are esteemed great delicacies.

Species 2. Balena Nordcaper, Iceland Whale.

This species differs from the preceding, chiefly in having a more lengthened body, and a proportionally smaller head. It seems to agree with it in the absolute length of the body. Its head has the appearance of an ovoid, truncated behind; and this form is given it more particularly by the under jaw, which is very round and deep, and very broad in proportion to the upper. The point of the snout appears a little hollowed, and the plates of whalebone are much shorter than those of the common whale. The two blow-holes are separated by a little distance from each other, and have the form of two crescents with the concavities opposite each other. The inner surface of each plate of whalebone is beset with black hairs, but its external surface is entirely destitute of hair, and is smooth, and even soft to the touch. The eye, which is very small, has its largest diameter placed obliquely.

The swimming paws are situated at about a third part of the whole length of the animal from the snout, and are so long as to equal a fifth part of the whole length.

The tail, which is slender and very tapered, is terminated by a hollow fin, the lobes of which, measured from tip to tip, extend to about \( \frac{1}{4} \) of the whole length of the animal.

The general colour of this whale is a grey, more or less bright, shaded occasionally with irregular and confused spots of grey and black, but the lower part of the head is of a brilliant white colour.

The Nordcaper inhabits the northern ocean, especially about the coasts of Norway and Iceland.

It is said to live chiefly on herrings, medusez, and some species of helix. When this animal swims at the surface of the water, every part of its body is plunged below the water, except the top of the back and the orifices of the blow-holes. He swims with great agility, and is so ferocious as to render it difficult and dangerous to approach him. Hence his pursuers are obliged to use considerable caution; and when the harpooner has struck the animal, the boat instantly retreats, and a fresh wound is inflicted by the harpooner of another boat, and so on till the animal is dispatched. Each harpoon is distinguished by a particular mark, and that which appears to have inflicted the fatal wound, entitles its owner to a certain reward. Anderson, in his account of Iceland, gives an account of the Icelanders method of taking this animal, which has too much appearance of the marvellous to be easily credited, and is contradicted by Horsebow, who describes the method we have already mentioned from his own observation.

GENUS II. BALENOPTERA. Finned Whales.

The animals of this tribe agree with the Balæna, in having the upper-jaw furnished with horny laminae, being entirely destitute of teeth, and having two distinct orifices to the blow-holes, placed towards the middle of the upper part of the head. They are distinguished from the Balæna, in being provided with a dorsal fin.

La Cépède divides this genus into two sections. The first of these is distinguished by having the throat and belly destitute of folds. The second has longitudinal folds under the throat and belly. There are four species, one belonging to the first subdivision, and three to the second.

Species 1. Balenoptera Gibbar, Fin-fish.

This species is about 50 feet long, but is not so thick in proportion to its length as the common
Piked whale. The whole animal is of a shining brown colour on the upper surface, and a brilliant white below. The head resembles a sort of cone, and is equal to about a third of the whole length of the animal. The eye is situated very near the corners of the mouth, and not far from this point is seen the insertion of the swimming paws, which are of an oval form, and of a length equal to about a ninth part of the whole body. The tongue is not very large. The horny plates are of a blueish colour in the young animal, but of a brown, bordered with yellow, in those more advanced. They are so short as often to be as broad as they are long; but their hairy extremities are long, and appear as if twisted round each other.

This animal is particularly remarkable for its dorsal fin, which is of a triangular form, with the point turned backwards, and is situated at the posterior extremity of the back. It is of considerable length, being, in an individual of the usual size, from three to four feet long. It is from this circumstance that seamen have given to this species the name of fin-fish.

It has been found in a great variety of situations, as the Greenland seas, the seas of North America, Indian Ocean, and even in the Mediterranean Sea, one of them having been seen by Marten in the Straits of Gibraltar. Pennant describes it as a British species, and it appears to have been seen off Harwich.

It feeds on herrings, mackerel, a species of salmon, and other small fish.

The fin-fish has very considerable power in the muscles attached to its blow-holes, and is said to eject the water with much more violence, and to a much greater height than the common whale. It also swims with extreme velocity, and easily escapes pursuit.

Whether any particular enmity subsists between the fin-fish and the common whale, is not certain; but it has been remarked, in the seas about Spitzbergen, that when the former makes its appearance, the latter is no longer to be seen.

From the thinness of the body, and of the blubber below the skin in this species, it is not considered as a profitable object of pursuit. An ordinary sized fish is said to yield only 10 tons of oil. The flesh, however, especially that of the swimming paws, is said to be well tasted, resembling that of the surgeon, and as well as the skin, is eaten by the inhabitants of Greenland.

cau-pintu, La Cépède, p. 134.

Of all the whalebone whales, this appears to be the smallest species, seldom exceeding 24 or 27 feet in length. It receives its name from the pointed form of its snout, which is still more acute than that of the second species.

The upper jaw is much narrower and shorter than the lower, though both are lengthened, and terminate in an acute point. The plates of whalebone are very short, of a triangular form, and of a whitish colour, ending below in very long whitish hairs.

The number of plates on each side is about 200. The tongue is thick, fleshy, and susceptible of being raised, inflated, and thrust forward to the extremity of the mouth.

The under part of the head, and of the fore part of the body, is covered with a skin that is plaited longitudinally into numerous parallel folds, that extend the whole breadth of the body, from one swimming paw to the other. These folds disappear when the skin is stretched, which, both in this and the third species, is effected by a particular pouch, placed within the skin of the mouth, between the two branches of the lower jaw, extending below the belly, and which the animal has the power of inflating whenever he finds it convenient to diminish his specific gravity. The whole upper part of the body is of a fine black colour, the lower portion is white, shaded with black, while the furrows between the longitudinal folds, as in the third species, are of a red colour.

The swimming paws appear to be situated higher or lower, according as the animal swims more or less above the surface of the water. The dorsal fin is triangular, a little hollowed in the back part, placed above the anus, and inclined towards the tail. The lobes of the tail are divided from each other by a deep, but narrow cleft.

This is also an inhabitant of the Greenland seas, but has occasionally visited the German ocean. A beautiful individual of this species was caught about 30 years ago, on the Dugger Bank, and was brought to London, where it was purchased by Mr John Hunter, and is described and figured by him in the Philosophical Transactions for 1787.

The flesh of this species is considered as a great delicacy by the Greenlanders, and they accordingly pursue it with great eagerness. In this pursuit they do not employ the harpoon, but shoot at the animal with arrows.

The piked whale feeds on most kinds of small fish, which it pursues with such keenness, that its prey is often seen leaping out of the sea, in endeavouring to avoid their merciless pursuer.

ORDER II. PREDENTATE CETACEA, OR THOSE WITH TEETH ONLY IN THE FORE PART OF THE UPPER JAW.

GENUS III. MONODON. LINN. NARVALUS; LA CEPÈDE, NARWHALES.

The animals of this tribe have a single opening for the blow-holes, situated over the nape of the neck, and instead of teeth have generally a single tusk or horn, (rarely two,) proceeding from one side of the snout, a considerable length, more or less pointed at the end, and spirally twisted. Their head is not so thick or long in proportion to their body, as that of the two preceding tribes, and terminates in an obtuse rounded snout. Their mouth is small, and entirely destitute of teeth, or horn plates. The upper surface and sides of the body are variegated with spots of different forms, and a longitudinal ridge extends from the origin of the tail to a considerable distance along the back. The proper narwhals have no dorsal fin.

These animals live chiefly in the seas about Greenland and Iceland. They feed on the smaller fishes.
and mollusca. They swim with great velocity, and appear to employ their horns both as weapons, and as instruments for dislodging shell-fish, &c. from the rocks.

There is some ambiguity respecting the species of this genus. Linne described but one species, and naturalists are not yet agreed whether more should be admitted. As, however, there are at least two varieties of these animals, which appear to differ by characters that are sufficiently fixed and permanent, it seems proper that they should be considered as separate species. Accordingly La Cépède has so distinguished them, and Mr Fleming, in an excellent paper on one of these species, in the Memoirs of the Wernerian Natural History Society, has followed his example, though his specific characters differ from those of the French naturalist. The names and characters given by Mr Fleming, which we shall here adopt, are as follows.

1. Monodon vulgaris, of a figure approaching to ovoid, with the head equal to \( \frac{1}{4} \)th of the whole length; the dorsal ridge extending from the tail to the blow-hole, and the lobes of the tail rounded. 2. Monodon Microcephalus, with the body of a conical shape, a blunt head equal to \( \frac{1}{4} \)th of the whole length, the dorsal ridge extending from the tail only to the middle of the back, and the lobes of the tail pointed.

Species 1. Monodon vulgaris, common narwhal, or unicorn-fish.

The common narwhal grows to the length of from 20 to 22 feet, and is about 12 feet in circumference. Individuals of greater dimensions are said to have been seen, but the relations appear not to be authentic. The general figure of the body is oblong and oval, with a broad convex back. The prevailing colour is grey, or light brown, with numerous spots of a darker colour on the back and sides, while the lower part of the head and body is of a uniform shining white.

The head is scarcely to be distinguished from the rest of the body, except by a slight depression, a little behind the opening of the blow-hole. The forehead is low, and not very prominent; the snout is rounded, and obtuse; the mouth so small as, according to some accounts, to be incapable of receiving a body much larger than a man’s hand; and the opening of the blow-hole is in the form of a crescent.

The swimming paws are about a foot long, and eight inches broad. The lobes of the tail have a direction away from the body, and are blunt and rounded at the tip. A very conspicuous ridge, several inches high, extends from the blow-hole to the origin of the tail, diminishing gradually in height as it approaches the tail.

The skin is thin, and the blubber in small quantity, though it is said to yield an oil superior to that of any other whale.

The most curious part of this animal’s structure is its horn or tooth. This organ is inserted to the depth of a foot or more into the bones of the skull, and from its insertion to near its exit from the head; it is smooth and hollow. From the snout it gradually tapers to its other extremity, and is regularly and gently twisted. It does not stand out from the head in a perpendicular direction, but diverges considerably towards one side, so that in those cases where there are two teeth, their farther extremities are at least eighteen inches asunder, while at the snout their distance is only about two inches. The substance of this horn is exceedingly hard and dense, nearly resembling the tusk of the elephant, but of a finer grain, and less liable to become yellow.

This species has not, we believe, been found beyond the limits of the northern ocean, where it frequents the bays, and those parts that are most free from ice. Here the animals assemble in considerable numbers; and when frightened or pursued, they huddle together, so as often to wound each other with their formidable horns. When this happens, they extricate themselves with difficulty, and become an easy prey to their pursuers. When alone and at liberty, however, they are not easily taken, as they swim with great swiftness, and frequently dive below the surface.

The narwhal is said sometimes to attack the whale. We have some doubts of the accuracy of this assertion, and suspect that the sword-fish, already mentioned as the chief terror of that monster of the deep, has been mistaken for the present species, which seems to be a harmless and inoffensive creature, except when provoked, or rendered desperate by aggression.

The spoils of this animal are of great value. We have already said that its oil is of a very fine quality. Its flesh and intestines are greedily eaten by the Greenlanders, and its horn affords a much finer and better coloured ivory than the tusk of the elephant, and has been employed for making various articles of luxury. Among others, we are told of a magnificent throne entirely composed of narwhals horns, which belongs to the kings of Denmark, and is carefully preserved in the royal castle of Rosenburg at Copenhagen. The Greenlanders employ these horns for more homely purposes, as parts of their buildings.

This species is of considerable size, varying from 12 to 26 feet in length, and of proportional circumference. Its body is of a narrower and more conical shape than that of the former species, and its head considerably smaller. Its upper surface is more flat and even. The colour of its upper parts is usually a dusky black, variegated with spots which, from being of a darker hue, are not very apparent. On the sides the spots are more conspicuous, and of an oblong form. The belly is of a white colour. The whole skin is smooth and glossy, very thin, and closely united to the fat. The forehead is high, and rises abruptly from the snout, proceeding afterwards for a few inches in nearly a horizontal direction, till it rises into a slight elevation, in the fore part of which is situated the blow-hole. The mouth is extremely...
small, and the upper lip extends a little beyond the lower. The eye is situated almost below the opening of the blow-hole, is about an inch in diameter, and has the iris of a chestnut colour.

This species is also a native of the northern ocean, but several specimens of it have occasionally been thrown on the British coast. One of these was cast on shore at Friston, a village near Boston in Lincolnshire, and an account of it was transmitted by Sir Joseph Banks to M. La Cépède, though this gentleman has, with unaccountable carelessness, described it as having been found in the seas which wash the coast of Boston in America. Another specimen was cast on shore at the entrance of the sound of Weesdale in Shetland, in the year 1808, and is particularly described by Mr Fleming in the Memoirs already quoted. This individual was only 12 feet long, and apparently had not attained its full size.

The narwhal is mentioned by the late Professor Walker of Edinburgh, (see Walker's Essays, p. 227,) as having been frequently seen about the Zetland islands, and he alludes to the common species or Monodon Monoceros, Linn. the only species then known.

**Genus IV. Anarnacus. Anarnak.**

Otho Fabricius, in his Fauna Greenlandica, described a species of whale, called by the Greenlanders Anarnak, from the purgative quality of its flesh and fat. M. Bonnaterre, in his Cetologe, considered it as a species of narwhal, and called it Monodon Stuprarius; but M. La Cépède, with more propriety, has formed of it a new genus, with the following character:

One or two small crooked teeth in the upper jaw; no teeth in the lower jaw; a fin on the back. *Hist. Nat. des Cétacés*, p. 164.

**Species. Anarnacus Greenlandicus, Greenland Anarnak.**

*Monodon Stuprarius*, Bonnat. Encycl. Method. Shaw. Gen. Zool. v. ii. part 2. *Anarnak. Greenlandicus*, La Cépède, p. 164. This is one of the smallest cetaceous animals. It is of an oblong rounded form, and of a black colour. The inside of the mouth is destitute of teeth, the two tusks which characterise the genus being attached to the upper jaw, and each about an inch in length, and covered at the top. It has a single orifice for the blow holes situated on the top of the head. It inhabits the seas that wash the coasts of Greenland, but seldom approaches the shore.

**Order III. Subdentate Cetacea, or those with teeth only in the lower jaw.**

**Genus V. Physeter. Cachalot, or Spermaceti Whales.**

The animals of this tribe are remarkable for the size of their head, which in some species is equal to the half, and in others to the third of the whole animal. The upper jaw is excessively broad and deep, and has usually a few indistinct teeth almost entirely covered with the gum. The lower jaw is long and narrow, enters into a fissure in the upper jaw, and is furnished on each side with a row of thick conical teeth, more or less obtuse. The blow holes approach each other within the skull towards the fore part of the snout, where they terminate in a common external opening. Below the snout is the principal cavity that contains the substance called spermaceti; and it is chiefly from these animals that ambergris is obtained. Some of them have a fin, and others a callos protuberance on the back.

Eight species of this tribe have been distinguished. The following are the most important.

**Species 1. Physeter Macrocephalus, Great-headed Cachalot, or Great Spermaceti Whale.**

*Grand Cachalot*, Bonnat. Encycl. Method. *Cachalot Macrocephale, La Cépède*, p. 166. This species grows to the length of nearly 60 feet, and is often 30 in circumference in the largest part of the head. Its head forms by far the most conspicuous part of the animal, and may be said to exceed the rest of the body in magnitude. The back is more or less convex, and near its middle there are the rudiments of a fin, which is short, directed backwards, and appearing as if cut off abruptly at the end. The back of the animal is of a black or slate blue colour, sometimes spotted with white, and the belly is white. The head has the appearance of an immense box, rounded and obtuse at one end, and rising into a slight convexity at the neck. On each side of the upper jaw is a row of holes for receiving the teeth of the lower jaw, and the intervals between these cavities are filled up with the rudiments of teeth, just appearing a little beyond the gum. The eyes are small, furnished with eye-lids, and situated at a prodigious distance from the snout; the external orifices of the ears are scarcely perceptible; the tongue is of a square form, and of a livid red colour; and the breathing hole is about 6 inches in diameter, and placed just above the end of the snout.

Both the swimming paws and tail are comparatively small, and the lobes of the latter are long and pointed, and have a waving margin. The genital organs resemble those of the other cetacea, and the penis of the male is sometimes eight feet in length.

The great spermaceti whale is found most commonly in the Greenland seas, and about Davis's Straits in North America; but has occasionally been seen in the German ocean, and the British channel. A considerable number of them were cast on shore on the coast of Lower Britannia in France, in the year 1784.

This species feeds on lump fish and dog fish, and is said even to attack and swallow the shark. One of these animals was vomited entire by a spermaceti whale, on being struck by a harpoon in the Greenland seas. The shark was four yards long, and, on opening the stomach of the whale, several fishes bones, nearly a fathom long, were found, in it. (Crantz's *Greenland*, vol. i. p. 113.)

It is said to swim with great velocity, and to rise very high above the surface of the water.

This animal yields a considerable quantity of spermaceti, for which chiefly it is taken, though its flesh, skin, tongue, and intestines, are eaten by the Greenlanders. The flesh is of a pale red like that of pork, and the tongue is esteemed a great delicacy when roasted. The blubber is about five or six inches
CETOLOGY.

691

The length of this species is nearly sixty feet, and its breadth about fifteen. The head is of such an enormous size as to equal the half of the whole animal. The upper jaw is at least five feet longer than the lower, round and obtuse at the snout, and about eight feet deep (from crown to base). The lower jaw is about ten feet long, very narrow, and having about 18 teeth on each side, all pointing outwards. There is a considerable convexity just above the eye, and a pronounced prominence below the articulation of the swimming paws. The eye is many feet behind the snout, but nearly in the middle of the breadth of the upper jaw.

The body is irregularly conical, with a prominence on the back, and another on the belly just before the anus. The swimming paws are proportionally larger than in the former species. The penis is eight feet long, and the lobes of the tail measure fifteen feet from tip to tip. The prevailing colour of the animal is a blackish grey.

This species yields a prodigious quantity of very fine spermaceti, and its blubber is very productive of oil of a finer quality than that of the Greenland whale.

It is found both in the Greenland seas and in those that wash the shores of New England; and is occasionally seen off the coasts of France and Britain. One was taken near Bayonne in France in 1741, and another was cast ashore on Blyth Sands on the English coast, in 1762.

The blunt-headed cachalot is a bold and daring animal, swims with great swiftness, and, when attacked, turns on its assailants with open mouth.

There is considerable confusion in the accounts which various writers have given of this animal. We have, therefore, given numerous synonyms, and shall take our description of the animal from La Cépède.

"The Physyter Microps, (says this author,) is one of the largest, most cruel, and most dangerous inhabitants of the deep. Adding to formidable weapons the two great sources of strength, bulk and velocity, greediness of carnage, a daring enemy and an in-}

trapid fighter; what part of the ocean does he not stain with blood?"

Its head is so enormous, as to equal the whole length of the animal, independent of the tail fin; and it is as large in circumference as any part of the body. The upper jaw, though not extending quite so far as the snout, properly so called, is a little longer than the lower jaw. The teeth which appear in this latter, are conical, curved, hollow towards the roots, and set into the jaw about two-thirds of their length. The part beyond the gum is white like ivory, and its tip acute, and curved first towards the throat, and then a little outwards. According to the most respectable naturalists, the teeth are 42 in number. The upper jaw has cavities for receiving the teeth of the lower; and between them there appear to be short blunt teeth, almost entirely hidden by the gum. The eye is extremely small.

The swimming paws are about four feet long. The dorsal fin is straight, high, and pointed. The whole length of the animal usually exceeds 50 feet, and the skin is of a black colour.

It is found in the Arctic Ocean, and has occasionally appeared in the North Sea. One is described by Sir Robert Sibbald, as having been cast ashore on the coast of Scotland; and so lately as 1769, one of this species was stranded at Cramond, a little above Leith, in the Frith of Forth. and attracted many thousands of spectators from Edinburgh and the surrounding country. La Cépède gives an account of 17 that appeared in 1723, in the mouth of the Elbe, and were mistaken by the fishermen of Cuxhaven for so many Dutch fishing-boats.

This animal attacks not only porpoises and other smaller cetacea, but even the largest species of balznopteræ, especially the pike-headed and piked whale, on which it fastens with its crooked teeth, and tears pieces from their bodies. It is said also to pursue the young Greenland whale, which it compels to fly for refuge through the boundless ocean.

Its flesh is esteemed a great delicacy by the Greenlanders, and it yields a great quantity of spermaceti, though but little oil.

La Cépède supposes this animal to have been the sea-monster from which Perseus delivered the fair Andromeda; and he labours to prove, that the Orca described by Pliny, as having been attacked in the port of Ostia, by the emperor Claudian at the head of his troops, was not a Grampus, but a *Physyter microps*.

ORDER IV. AMBIDENTATE CETACEA, or those with teeth in both jaws.

GENUS VI. *Delphinus*. Dolphins.

The animals of this genus are smaller than most *Dolphins* of those of the preceding tribes; the largest species *genus* scarcely exceeding 25 feet. Their jaws are lengthened considerably, but are of equal length, and are each furnished with a row of conical teeth, more or less numerous in the particular species. The blow-holes, after traversing the upper jaw, unite without in a single orifice, which is in the form of a crescent, and is situated at the top of the head. Their eyes are situated near the angle of the mouth. All the species but one are furnished with a dorsal fin, which is some-
times of enormous length. They are not confined to the northern ocean, but are found in most seas, and in the mouths of large rivers.

The number of species is variously marked by different authors; some, with Linne, reckoning only four, while others extend them to the number of eight or nine. We shall describe but four.

Species 1. Delphinus Phocana; the Porpesse, or Porpoise.

This is the best known of all the dolphin tribe. It is generally six or seven feet in length, thick in the forepart of the body, and gradually tapering towards the tail. Its colour is a bluish black, or very dark brown on the upper parts, and whitish on the belly. The snout projects a little, but is on the whole short and broad. In each jaw there are about 48 teeth, that are small, sharp-pointed, and a little moveable. The tongue is flat, jagged at the edges, and fastened below. The eyes are small. The tail is semilunar, and the dorsal fin is placed nearer the tail than the head.

This species is well known in all the European seas, and abounds in those of North America. They are seen in greatest numbers about the time when the migratory shoals of fish, as mackerel, herrings, &c., make their appearance, when they are sometimes in such great numbers, as to darken the surface of the water.

They feed on most small fish, especially herrings, whittings, salmon, and sand-eels. They pursue their prey with great eagerness; and in search of those which take refuge in the sand, they burrow with their snouts like a hog. Hence the names of Marsouin, Marsvin, and Porpesse, (Sea-swine,) given to them by most of the European nations. They are gregarious, and seem affectionate towards each other. They are often seen to frolic and gambol on the surface of the ocean, a circumstance which is considered by sailors as a sure prognostic of stormy weather.

The blubber of the porpesse is exceedingly thick, and affords a large quantity of excellent oil. The flesh is by no means ill-tasted. It was formerly considered as a sumptuous article of food, and was occasionally introduced at the tables of the English nobility. It was eaten with a sauce composed of crumbs of bread mixed with sugar and vinegar, and called porpesse sauce. In America, the skin is used by the poor inhabitants for making waistcoats and breeches, and is said to form an excellent covering for coaches. For these purposes it is pared on the flabby side till it becomes nearly transparent, and is afterwards tanned and dressed with considerable care.

The inhabitants of Canada, about the river St Lawrence, adopt an amusing method of taking porpesses. They collect together a considerable number of slender branches of sallows, willows, or similar trees, and stick them firmly into the sand-banks across the mouth of the river, which are commonly left dry at low water, so as to form a long line of twigs, having the upper end connected with the shore, and an opening left next the sea, by which the porpesses may enter. As the tide rises, the water covers the twigs, so as to keep them out of sight, and the porpesses entering the river in quest of their prey, get within the line, where they continue the chase till they find, by the ebbing of the tide, that it is time to retreat into deeper water. They now make towards the sea, but the twigs coming then into sight, and being all agitated by the current of the tide, form such an alarming spectacle, that they retire in great fright from this tremendous rampart. The tide continuing to ebb, the porpesses return from time to time, but not being able to conquer their dread of those terrific twigs, they flounder about till they are entirely deserted by the tide, when the inhabitants, watching the favourable opportunity, commence the attack, and soon overpower the defenceless animals. In this manner, more than 100 porpesses, each yielding about a hog's head of oil, are sometimes taken at a single tide. See Bingley's Animal Biography, vol. ii. p. 150.

Species 2. Delphinus Delphis; the Dolphin.

The figure of the dolphin has been greatly misrepresented by painters and sculptors. The recurved tail, the monstrous head with pendant lips, and eyes protected by enormous brows, which we see in the usual painted and engraved figures of a dolphin, are mere creatures of imagination.

The length of this species is often nine or ten feet, and its body is about two feet in diameter at the thickest part, thus being very slender in proportion to its length. It is of a black colour above, and white below. The nose is long, narrow, and pointed, something like the beak of a bird, whence Belon's name of Oye de Mer, or sea-goose; but there is a transverse fold of the skin across the upper part of the snout. The number of teeth varies; but according to Mr Pennant, there are usually 21 in the upper, and 19 in the lower jaw; we presume he means on each side. The mouth is very wide, reaching almost to the insertion of the head. The dorsal fin is high, and placed rather nearer the tail than the head; the swimming paws are situated low, and the tail is semilunar.

The dolphin inhabits the Atlantic and Pacific Oceans, and is often seen accompanying ships on their passage to the East or West Indies. It occasionally appears in the British seas.

Like most of their congener, they live on small fish, though they will eat any offal and garbage that is thrown into the sea. They are said to attack whales; though we suspect those who suppose they have seen such a circumstance, have mistaken another species for the dolphin. They are gregarious, and like porpesses often sport about on the surface, and leap out of the water, so as to be entirely visible. In these leaps, their back is a little curved, but not nearly so much arched as is commonly represented. They
Cetology.

are said to change their colour before they die, and again after they are dead: but this is probably a mistake, arising from a different reflection of the rays of light, when the body is in motion, or at rest.

At present the dolphin is scarcely sought after as an object of traffic. Some centuries ago, however, its flesh was reckoned a great delicacy; and we are told by Dr. Caius, that one taken in his time was deemed worthy of being presented to the Duke of Norfolk, who distributed part of it among his particular friends. It was roasted, and served up with porridge sauce. It is now seldom eaten, except when young and tender. The best parts are next the head, the rest being dry and insipid.

Perhaps no animal has been more celebrated among the ancient poets and naturalists than the dolphin. It has been held forth as the emblem of afflication and philanthropy; was honoured with the title of sacred, and consecrated to the gods, on account of its fondness for the human race. Among other instances, the preservation of Arion the musician, so prettily described by Ovid in his Fasti; and the story of Hippo, of whom a dolphin was enamoured, so beautifully related by the younger Pliny in his Epistles, book ix. epist. 33, may be recalled to the notice of our readers, though our limits do not permit us to dwell on these amusing fables. Those who incline to give them a fuller examination, may be referred to Pliny's Natural History, and the writings of Athenæus and Ælian.

Species 3. Delphinus Orca, the Grampus.

This is one of the largest species of dolphin, usually measuring from fifteen to twenty-five feet. It is also remarkably thick in proportion to its length, being from ten to twelve feet diameter in the thickest part of the body. From this clumsiness of figure, it has been called by Pliny an immense heap of flesh armed with dreadful teeth: *cujus imago nulla representatione exprimiri possit alia, quam carnis immensi dentibus trowulentis.*

In this species, the lower jaw is usually broader than the upper; and the snout is described by most writers as having a turn upwards, though this circumstance is not noticed in the description of La Cépède. Each of the jaws has thirty teeth; of which the foremost are blunt, round, and slender; those behind, sharp and thick. The description of the teeth given by Artedi and Linné, viz. that they are broad and jagged, or serrated, seems to be erroneous, and descriptive rather of the shark than the grampus. According to La Cépède, the number of teeth varies according to the age of the animal.

The dorsal fin is of considerable length, often measuring, according to Dr. Shaw, six feet, though La Cépède describes it as not so long. The swimming paws are broad, and nearly of an oval form.

The prevailing colour of the grampus, like that of most other dolphins, is black on the back, and of a snowy whiteness on the belly, while the sides are marbled with white and black; and there is usually a large white spot on each shoulder, or a little behind each eye.

This species inhabits both the northern and southern oceans, is not unfrequently seen in the Mediterranean Sea, and has often been observed in the British Channel.

This is the most ferocious of the cetaceous animals. It spares neither friend nor foe, making prey alike of small fish, seals, porporses, and dolphins. It is said also to attack the Greenland whale, though, according to the latest and best accounts, it is not the grampus, but the next species, which attack that monster of the deep in packs, as bull dogs bait a bull. The grampus is exceedingly active, and scarcely remains a moment above water; but sometimes, in its eager pursuit of prey, it is thrown off its guard, and allowed into the shallows. Under these circumstances, the voracious animal frequently continues to flounder about, either till he is knocked on the head by those who have observed him, or is extricated from his perilous situation by the tide's coming to his relief.

Waller, in one of his poems, has recorded a beautiful example of parental affection in the grampus. A female of this species and a cub having got into an arm of the sea, were deserted by the tide, and being observed in this situation from the shore, a number of men came down to attack them. Both animals were soon wounded in several places, so that the water was dyed with their blood. They made every effort to escape; and the old one, by superior strength, forced herself over the shallow into the deep water, but, instantly recollecting that she had left her young one among the bands of assassins, she rushed back, and seemed resolved, if she could not prevent the murder of her cub, that she would at least share its fate. Happy for the catastrophe of the tale, she succeeded in her endeavours, and the tide flowing in at the moment, carried their bodies off in triumph.

It does not appear that the grampus is in any request, even for its oil. Like the wolf among quadrupeds, he seems to be the enemy even of his own species, and his carcass is of no value after he is dead.

There are several varieties of this species. One of these is described and figured by Mr. John Hunter, in the 77th volume of the Philosophical Transactions; and another by Mr. Patrick Neill, in his Tour through some of the Islands of Orkney and Shetland. This latter variety is called among those islanders the *cating whale,* and has several marks that distinguish it from the ordinary grampus. The nose has no spreading or turning upwards; the upper jaw is broader than the lower; it has commonly only twenty-four teeth in each jaw; its swimming paws are long and narrow; the dorsal fin scarcely exceeds two feet in length; there is no white spot behind the shoulder, or near the eye, and it is often entirely black. It is also capable of remaining ten or fifteen minutes at the surface of the water, and is described as being a harmless inoffensive creature. From all these considerations, Mr. Neill is disposed to regard it as a distinct species; but as his description is drawn, not from personal observation, but from the
accounts of others, it is probable that the cæting
whale of Orkney and Shetland is only a variety of
the grampus.

Species 4. Delphinus Gladiætor, Gladiator Dolphin,
or Sea Sword.

Delphinus Orca, var. B. Lin. Syst. Nat. Dauphin
épée de Mer, Bonnat. Encycl. Method. Schwedt-
isch, Anderson Island, Crantz's Greenland. Da-
uphin Gladiateur, La Cépède, p. 302.

M. La Cépède has been at considerable pains to
distinguish this species from the preceding, and has
contrasted them in his table of the cetacea by the
following characters: In the grampus, the top of
the head is but little convex; the snout proportionally
less rounded; the upper jaw a little more projecting
than the lower; the teeth blunt-pointed; and the
dorsal fin placed towards the middle of the body,
and reaching in height to about the tenth part of
the animal's whole length: while, in the gladiator, the
forehead is very convex; the snout very much
rounded; the two jaws equally advanced; the teeth
sharp-pointed; and the dorsal fin seated very near
the neck, and extending in height more than one-
father of the whole length of the animal.

The gladiator dolphin measures from 23 to 25
feet, and its dorsal fin from 4 to 5 feet. The latter
is about 18 inches broad at the base, and gradually
tapers upwards to a point, so as to become a very for-
midable weapon. The body is of a brown-black
colour on the upper part, and a beautiful white on the
belly, with a remarkable streak of black, very long,
stripped, and pointed, extending from each side of the
tail to near the articulation of the swimming paws.

This species is found in the American seas, espe-
cially in Davis's Straits; as also about Spitzber-
gen, in the Arctic Ocean. It has occasionally been
seen in the North Sea; and not many years ago, se-
veral of them came up the Thames. In the year
1793, an individual of this species that appeared in
the Thames, was pierced with three harpoons, and
yet drew a boat, with four persons in it, twice from
Blackwall to Greenwich, and once as far as Dept-
ford, and at last expired at Greenwich.

The gladiator dolphin is possessed of amazing
strength and courage. We are told of one that
seized on the carcasse of a whale, which several boats
were towning away, and, in spite of the united efforts
of the rowers, bore it to the bottom. These animals
gugether in large troops, and seldom appear in a
smaller number than five or six. They usually live
on the smaller fishes, but will attack even the largest
whales. It is this species, and not the ordinary
grampus, between whom and the young Greenland
whale such noted combats take place. A number of
the gladiators unite in the attack, and, like a pack of
hounds, fasten on the whale in every part. One
seizes on the tail, in order to prevent its formidable
blows to the rest, while others crowd about the head,
and watch the moment when the whale rolls out its
tongue, on which the gladiators seize as a most deli-
cious morsel.

The blubber of this species is very thick, and
yields a considerable quantity of excellent oil.

GENUS VII. HYPEROODON.

This genus has been formed by La Cépède, for the
purpose of separating that singular animal the Buts-
kopf, or Beaked whale, concerning which so much
confusion has appeared among preceding naturalists.
The distinguishing characters of this genus are, nu-
merous small teeth seated on the palate, and a dorsal
fin. There is only one known species, viz.

Hyperöodon Butsköpf, or Beaked-whale.

Delphinus Orca (Butsköpf), Lin. Syst. Nat. Buts-
köpf, Marten's Spitzbergen, Anderson Island, Crantz's
Greenland. Bottlehead, or Flounder's head, Dale.
Harwich. Nebbe Hval, Pontopp. Norw. Beaked-
whale, Pennant, Brit. Zool. vol. iii. Dauphin Buts-
köpf, Bonnat. Encycl. Method. Hyperöodon Buts-
köpf, La Cépède, p. 319.

The general form of the body is that of a cone,
the base of which is seated near the articulation of
the swimming paws. The head is nearly as deep as
it is long, the forehead is very convex, and the snout
flattened and lengthened out like a beak. In the
lower jaw there are only two teeth, at the anterior
extremity, of a conical form, and pointed at the tip;
but round the margin of the upper jaw, and over
the whole surface of the palate, are numerous minute,
unequal, hard, and sharp teeth. The two jaws are
nearly of equal length; the tongue is serrated on the
margin, adheres to the lower jaw, and in substance
resembles that of a calf. The common orifice of the
blow-holes has the form of a crescent, with its horns
directed backwards. The eye is seated about the
middle of the height of the head, a little above the
corner of the mouth. The swimming paws are
placed very low, at about the same distance from the
eyes as these latter are from the snout. The dorsal
fin is nearer to the head than the tail, is curved back-
wards, and is of considerable height. The two lobes
of the tail fin are hollowed at the posterior margin,
and extend about one-fourth of the length of the ani-
mal, from tip to tip.

The butsköpf is generally about 24 feet long, by
a circumference of about 15 at its thickest part. The
prevailing colour is brown, or blackish, with whitish
shades on the belly. The skin is thin; the blubber
yellowish; and the flesh of a deep red colour. This
animal has been found in most parts of the Northern
Atlantic, and the icy sea.

star # Ceti.

CÉVENNES. See France.
CEYLON.

CEYLON, an island in the Indian Ocean, at the entrance of the bay of Bengal, situated between 79° 50', and 82° 10' East Long., and 5° 50', and 9° 51' North Lat. It is separated from the Coromandel coast, by the Gulf of Manaar, a narrow strait, full of shoals, which receives the name of Adam's Bridge, because the natives generally believe that at this place the greatest ancestor of the human race, after his fall, passed from this island, which they imagine to have been the seat of the terrestrial paradise, to the shores of the continent. Many suppose that Ceylon, at a distant period, formed part of India, and was afterwards separated from it by some great convulsion of nature. This island is computed to be about 900 miles in circumference; its greatest length is 280, and its greatest breadth 150 miles.

Mention is made of this island by some of the writers of antiquity; but the accounts which they give of it are very incorrect and contradictory. In modern times, the Portuguese were the first Europeans who visited Ceylon. It was discovered in 1505 by Almeyda, who was accidentally driven from his cruise off the Maldivie islands, by the violence of the currents, into one of the harbours of this country. The situation of the island, and the productions in which it abounded, excited him to cultivate a closer connection with the natives, while the difficulty they found in repelling the attacks of the Arabs, rendered them willing to form an alliance with this powerful and enterprising nation. Accordingly, when Almeyda was introduced to the king, he easily succeeded in persuading him to pay the Portuguese an annual tribute of 250,000 lbs. of cinnamon, on condition that they would protect his coasts from every hostile invasion. In order, however, to obtain a monopoly of this valuable article, these ambitious adventurers soon attempted to form a settlement on the island. This naturally excited the jealousy and indignation of the native princes; but, after a long and bloody struggle, the Portuguese succeeded in reducing the whole of the coast under their dominion, and drove the Ceylonese to the mountains in the interior parts of the country. From thence the natives made frequent incursions on the coast, and destroyed the plantations of their invaders, while they, in return, exercised towards the inhabitants every species of oppression and barbarity. This desultory warfare was carried on for upwards of a century, and though productive of little advantage, was attended with much bloodshed to both parties. In this state of distress, the Ceylonese were eager to accept the offer of assistance from the Dutch. In 1632, the States, agreeably to a previous treaty, sent a powerful armament to act in concert with the native princes against their oppressors. The struggle which ensued was violent and bloody; every pass, every fortress, was warmly disputed with them; and after the Portuguese were driven from all their stations, except Columbo, the seat of the government, they seemed determined to perish rather than yield it up. The Dutch invested the town, but the besieged baffled all their attempts, and rejected every proposal of surrender with disdain. At length, however, famine and disease began to subdue those brave spirits who had despaired death in every other form. After a siege of seven months, Columbo surrendered to the Dutch in 1656; and, by the fall of this place, a period was put to the dominion of the Portuguese in Ceylon, after it had subsisted for about a century and a half.

The joy of the natives at their deliverance from the yoke of the Portuguese, and the gratitude which they felt to the Dutch, seemed at first to have no bounds. The King of Candy, cheerfully paid the expenses of their armaments in cinnamon, and even conferred on his new allies the principal possessions, from which, by their assistance, he had lately expelled the Portuguese. On the other hand, they expressed the warmest gratitude to the monarch for these concessions; they began to fortify their new acquisitions under the profession of regard to his security; and so well were the natives convinced of their good intentions, that they afforded them every assistance in their power to complete their operations. The parts of the country assigned them were among the best adapted for cultivation on the island, and they also began to turn these to the best advantage. At the same time, they kept up a most friendly intercourse with the natives, so that the Ceylonese viewed their operations without jealousy, and were eager, by their good offices, to shew the gratitude which they felt to the guardians of their coasts. By means of these prudent measures, the colony was quietly brought into a flourishing state, and was even able to depend on its own internal resources. But, unhappily, the Dutch did not long pursue this wise and moderate system of policy. By degrees, they began to extend their posts into the interior of the country, and to seize on every spot which appeared advantageous for cultivation; they also increased their demands on the king for the protection they afforded him; and he quickly found that all the cinnamon which grew in his dominions would not be sufficient to gratify their insatiable desires. At length, enraged by their accumulated acts of injustice and extortion, he suddenly attacked their settlements, and committed the greatest devastations upon them. This breach between the natives and the Dutch was followed by a long course of hostilities, during which much blood was shed, and no permanent advantage gained by either party. The Dutch, however, were the greatest losers in the contest; for though they frequently routed the natives, overran their country, and laid waste their villages, yet the hardships which they encountered in forcing their way through a country covered with wood and full of defiles, destroyed so many of their troops, that all their successes were too dearly purchased, and, in the end, they were always obliged to abandon the conquests they had made. On the other hand, the incursions of the natives upon their cultivated grounds, though in general temporary, and easily repulsed, frequently destroyed the labours of many years.

These considerations induced several of the Dutch
governors to attempt the restoration of tranquillity, rather by conciliatory measures, than by their ineffectual struggles. For this purpose they sent ambassadors to the court of Candy with a variety of valuable presents, and with instructions to gratify the king by all those tokens of respect which have so powerful an effect on uncultivated minds. The letters to him were wrapped up in silks, embroidered with gold and silver, and the ambassador carried them all the way on his head, the highest token of respect known in that country: in these letters they also dignified the king with many of those high titles, which are usually conferred on eastern monarchs. These conciliatory measures never failed to produce a considerable effect. But few of the Dutch governors were either sufficiently enlightened or interested to persevere in them. The renewed oppressions of the Dutch was the constant signal for the renewal of hostilities between them and the natives; and in consequence of a long course of warfare, the Ceylonese became both brave and dexterous. The Dutch were frequently repulsed even in close combat; several of their forts were taken; and whenever they attempted to penetrate into the interior of the country, they commonly lost large parties of their men in attempting to force the woods and defiles, or by the ambushes which their active and vigilant enemy set to surround them. At length, indeed, they triumphed over all these obstacles. The King of Candy saw those woods burst through, which he looked upon as an impenetrable barrier, and he beheld the Dutch soldiers in those valleys which he supposed could never have been approached by a foe. He was twice driven from Candy; the capital of his dominions, and forced to seek for refuge in the mountains of Descleggy, the highest and most inaccessible in the kingdom. Here, however, he found himself secure from the pursuit of his enemies, and contented himself with surprising and cutting off the convoys of provisions and stores sent up from the coast, till they should of their own accord abandon his dominions. This, after all their victories, they were constantly obliged to do. The last great war between them was about the middle of the 18th century, and though the Dutch suffered many disasters during the contest, they at length, by depriving the Candians of salt at pleasure, compelled them to comply with all their demands. In 1769, the king agreed to a treaty, by which, among other articles, all those parts of the coast which had not formerly belonged to the Dutch were to be delivered to them; and they were also to enjoy a monopoly of all the valuable productions of the island, with a great variety of other advantages. On the other hand, the Dutch, agreed to supply the Candians, free of expense, with salt sufficient for their consumption. But the articles of this treaty were quickly infringed, and scarcely one of the stipulations was actually fulfilled. Frequent encounters continued to take place between the Dutch and the natives; but at last both parties became weary of their ineffectual struggles; and hostilities, as well as every kind of intercourse, were broken off as if by mutual consent.

Such was the situation of Ceylon when an attempt was made by the British, in 1782, to obtain possession of the European part of the island. The attack proved unsuccessful at that time, but was again renewed on the junction of the Dutch with the French in the last war. In 1795, a body of English troops landed in Ceylon, and in consequence of the cowardice and want of subordination among the Dutch forces, they found it an easy conquest; indeed, they scarcely met with the semblance of opposition. Since it fell into our possession, we have also been engaged in war with the Candians. In 1798, the king died; and Pelime Talawee, the chief adigar, or prime minister, raised to the throne a young Maabar, of inferior extraction, and of no talents, who was only a puppet to dazzle the eyes of the people, while he himself ruled with absolute sway. In 1799, the governor, Mr North, had repeated interviews with the adigar, who, in the last of them, requested our assistance in taking away the life of the king, and placing himself on the throne; and promised, on this condition, to make the British masters of the country. The proposal was rejected with indignation; and, in 1800, the governor sent an embassy to the Court of Candy, with the view of forming a treaty of alliance and commerce between the two nations; but the plan proved abortive, as neither party would accede to the proposals of the other.

After this the Candians appeared to be making preparations for war in all quarters, and as the government, notwithstanding its promises, delayed to make preparation for some small outrages committed on our subjects, the British determined to send troops into their territories, in order to enforce these claims, and to exact security against the repetition of any similar act. Having communicated this intention to the Candian government, and made new proposals of accommodation, without any effect, our forces entered the dominions of the enemy early in 1803, and meeting with little opposition, soon arrived in the capital. This they found had been evacuated on the preceding day by all the inhabitants, and set on fire in several places. Upon their arrival in Candy, the adigar made proposals of peace, and it was agreed that the king should be delivered over to the care of the British government, while Pelime Talawee should be invested with the supreme authority, under the title of Octoon Komarayen, the Great Prince. In consequence of this agreement, the city of Candy was evacuated by part of the British forces; but, after an unparalleled scene of duplicity and treachery on the part of the adigar, the natives attacked the town; and our troops, under the command of Major Davy, being overpowered by numbers, agreed to capitulate, on condition that they should all be allowed to march with their arms to our settlements on the coast. They were accordingly permitted to take their departure; but they were afterwards forced back to the capital; those of the Malays who refused to enter into the Candian service, were immediately put to death; all the British soldiers were likewise cruelly massacred, excepting three or four, who either made their escape, or were spared by the Candians. The report of these events filled our settlers on the coast with alarm and consternation; and soon after the Candians made various descents on our territories, and even meant to attack the capital, but they were happily driven back by our
In 1804, they again made preparations for a
general attack on our settlements; but this was
prevented by an attack made by us on their own country,
which proved on every side successful. In February
1805, they however ventured again to invade our ter-
ritories, but they were completely routed in every
quarter. See Percival's Account of Ceylon; Pennant's
View of Hindostan, vol. 1; Cordier's Description
of Ceylon, 2 vols.; and Asinum Register, vol. vi.

From the preceding account, it appears that the
island of Ceylon is at present separated into two
grand divisions. It originally contained a number of
distinct petty kingdoms, but after the arrival of the
Portuguese, the whole interior of the country was
reduced under the dominion of the king of Cey-
lon. The other part of the island, which is now subject to
the British, includes the whole of the sea coast, and
completely encircles the Ceylonese territories. In
some places it extends only about six miles, in others
thirty, and on the northern side of the island about
sixty miles into the interior.

In approaching this island from the sea, it presents
a most delightful prospect to the eye. The level
districts on the coast appear bounded by beautiful
groves of cocoa nut trees, while the intermediate
plains are covered with rich fields of rice, and the
prospect usually terminates in woods, which cover
the sides of the mountains, and display a verdant foliage
during every season of the year. The interior of the
island abounds in steep and lofty hills, covered with
thick forests, and full of impenetrable jungles. The
woods and mountains completely surround the do-
minions of the king of Ceylon, and seem destined by
nature to defend him against those foreign enemies,
whose superior power and skill have deprived him of
the coasts.

The highest and rudest tract is the kingdom of
Conde Uda; and at the western skirt of the district
soars Hamalle, or Adam's Peak, which rises above
all the other mountains in the form of a sugar loaf,
and is seen even at the distance of the sea. On the
summit of this mountain is a flat stone, with an im-
pression resembling a human foot, about twenty-four
inches in length, which is said by the Mahometans
to be that of our common progenitor; but the Cey-
lonese consider it as the footstep of Buddha, their
great deity, when he ascended into heaven.

From this mountain, and the adjacent hills, the
principal rivers in the island take their rise. These
are, the Mahavellagaua, the Walluwy, the Culla-
gaua, and the Mooshal. They are, in general, ra-
 pid but smooth streams; some of them are navigable
for a considerable distance up the country. There
are a variety of other rivers, which rise from the hils
in different parts of the island, and though they are
not navigable, they might be rendered of great ad-
 vantage in fertilizing the fields.

The internal communications by land through the
island have scarcely passed the first stage of im-
provement. Along the sea coast, indeed, there are roads
and stations for travellers; but these in many places
are exceedingly steep and rugged. In the other parts
of the country footpaths are sometimes discernible,
but never any broad beaten way regularly formed,
and bounded by walks or ditches. This want of
roads gives a striking peculiarity to the aspect of the
country, which cannot easily be represented to the
mind of a person who has never travelled over a wild
and woody region.

In general, the climate of Ceylon is much more
temperate than that of India. From Chilaw south-
ward, to Tengalle on the western coast, the air is
salubrious and delightful. The medium heat of the
thermometer, according to Mr Cordiner, is about 81°,
and in the most sultry weather it seldom exceeds 86°
in the shade. In the other parts of the coast where
the soil is arid and dry, it often indeed rises consider-
ably higher. In general, the heat during the day is near-
ly the same throughout the whole year; but the va-
riation of temperature between the day and the night
is often remarkably great, the thermometer sometimes
ranging, in the course of nine hours, from 69° to
99°. The temperate climate of the coast, is doubt-
less owing, in a considerable degree, to the regular
breezes which prevail for a certain number of hours
every day. The sea breeze usually sets in about
eleven o'clock in the forenoon, and continues to blow
till near six in the evening; the land breeze com-
ences about seven, prevails during the night, and gra-
dually dies away towards eight in the morning. In
the interior, where the influence of these breezes is
not felt, in consequence of the thick and close woods,
and the hills which crowd upon each other, the heat
is many degrees greater than upon the coast, and the
climate often extremely sultry and unhealthy. This
inconvenience, however, might be in a great degree
obviated, by cutting down the woods, and clearing the
jungles, which at present impede the circulation of
the cooling breeze.

The lofty range of mountains which runs through
the kingdom of Candy, divides the island nearly into
two equal parts, and so completely separates them
from each other, that the seasons on either side are
totally different. These mountains terminate com-
pletely the effect of the monsoons, which set in
periodically from the opposite sides of the island, so
that not only the opposite sea coasts, but the whole
country in the interior, suffers very little from these
storms. Accordingly, whilst torrents of rain descend
on the south and west sides, the north and east expe-
rience an unclouded sky, with all the fervid heat of
the torrid zone; and when the latter are obscured, the
former are again enlivened with uninterrupted sun-
shine. Indeed it has sometimes been a constant
drought on one side of these mountains for several
years together, while the other has been deluged with
perpetual rains. The monsoons in Ceylon are con-
nected with those on the Coromandel and Malabar
coasts, and correspond very nearly with them; but
they set in much sooner on the western than the east-
er side of the island. On the west side, the rains
prevail in the months of May, June, and July, the
season when they are felt on the Malabar coast. This
monsoon is usually far more violent than the other,
being accompanied with dreadful storms of thunder
and lightning, together with vast torrents of rain,
and violent south-west winds. During its continuance,
the variations of the climate are particularly remark-
able. The torrents of rain which fall chiefly during
the night, render the atmosphere at that time extreme-
ly chill and damp, while the excessive heat of the sun
by day is almost insupportable. In consequence of
the sudden transition from a warm clear day to a cold
and wet night, the climate is more unhealthy at this
season than during the prevalence of warm dry weather. It is remarkable, however, that these changes affect the negroes and the natives of the continent much more severely than the Europeans.

These monsoons pass slightly over the interior, and do not produce any considerable effect. The seasons in the mountains are regulated by different laws, and do not exactly correspond to either of the monsoons. But this part of the island is not entirely free from the dreadful storms which commit such terrible ravages in tropical climates. There it rains incessantly during the months of March and April, while at that period it is perfectly dry in the low parts of the country; the thunder and lightning are also awful to a degree beyond the conception of a stranger. See Percival’s Account of Ceylon; Cordiner’s Description of Ceylon, vol. i.; and Asiatic Annual Register.

On this island there are few towns of any considerable importance. In the province of Tallanour, is the city of Candy, the capital of the interior, and the chief residence of the prince. It is situated in the midst of lofty mountains, covered with thick jungle. The pass to it are narrow and difficult, and are intersected with thick hedges of thorn. Fences of a similar kind are also drawn round the hills in its vicinity, like so many lines of circumvallation; and through them, the only passage is by gates of the same thorny materials, which are so constructed as to draw up and to fall down by means of ropes connected with them. When the natives are forced to retreat within these barriers, they cut the ropes, and then it is impossible to force a passage unless by burning the gates, which is attended with considerable difficulty and danger, in consequence of the green state of the bushes, and the constant annoyance which the enemy from behind them give the assailants. These hedge-rows are the principal fortifications of Candy. The town itself is a poor miserable place, and is surrounded by a mud wall of no strength whatever. It is about two miles in length, and consists of one broad street, with a number of smaller streets, which at different places proceed from it as so many branches. These streets are in general dirty; the houses are poor and mean; they are built chiefly of mud, are thatched with straw and leaves, and have miserably small apertures instead of windows. They are all raised on terraces about five feet above the level of the ground, and there are some stone steps which lead up to every door. A few of the houses at the upper end of the principal street are tiled and white washed. The only buildings of consequence in Candy are some of the temples of Buddha, and the palace which is situated at the head of the great street. The latter is built of a kind of cement, which is perfectly white, and is adorned with stone gateways. It is a square of immense extent, but a considerable part of it is not yet completed. In it are a great number of rooms, the walls of which present a multitude of inscriptions, and are painted with the most grotesque figures. Among others, it contains two temples to Buddha, one Hindoo pagoda, the cemetery of the kings of Candy, and an immense variety of arsenals and storehouses. When the British army entered this city in 1803, they found part of the palace consumed by the flames, the inhabitants having set it on fire before they evacuated the town. However, many of the apartments were still entire, and contained some elegant sets of glass and china-ware, and a few golden cups adorned with filigree. The walls of one of the rooms were completely covered with fine glasses, about seven feet high and four feet broad. Another room, supposed to be the place of private devotion, contained a gigantic brass image of Buddha in a sitting posture, and two smaller figures of a similar form. Amongst some of the stores was found a profusion of soft paper made of the bark of trees; the sheets were rolled up, and some of them measured twenty feet in length. There was also a vast collection of bows, arrows, and walking sticks, exquisitely painted, displaying a richness of varnish, colouring, and ornament, which probably could not be equalled in Europe. The other principal towns in the interior are Digbyggy Neur, and Nilenby Neur, both of which are only a few miles distant from the capital. The ruins of some other cities, which appear to have been larger and better built than any of these, shew that the country was once in a more flourishing condition than it is at present.

Of the European part of the island, Columbo is the capital. It is a large and beautiful town, is built on a regular plan, and much in the European style, though few of the houses are above one story in height. That part of it called the fort, is about a mile and a quarter in circumference; it occupies a situation almost insulated, and is defended by 200 pieces of heavy cannon. This division of the town is inhabited chiefly by the British, the Pettab by the Dutch and Portuguese, and the suburbs by the native Ceylonese. Including all these different classes, Columbo, according to Mr. Cordiner, contains upwards of 50,000 inhabitants. There is probably no place in the world where so many different languages are spoken, and which displays such a variety of nations, manners, and religions. Besides the European inhabitants and the proper natives of the island, you find almost every race of Asia: Moors of every class; Malabars, Travancorians, Malays, Hindoos, Gentooos, Chinese, Persians, Arabians, Turks, Maldiveans, Javanese, and natives of all the Asiatic isles; Persians, or worshippers of fire, who would sooner allow their houses to be burnt to ashes, and themselves to perish in the flames, than employ any means to extinguish them; together with a number of Africans, Cafrics, Buganeans, besides the half casts, people of colour, and other races which proceed from a variety of the original ones. Columbo is a place of considerable trade: in 1802, the customs amounted to £19,100. The harbour, however, is difficult of access during a considerable part of the year, and is very insecure for large vessels. The other principal towns in the British territories, are Trincomalee and Point de Galles. The former is one of the most valuable acquisitions on the island, on account of its excellent harbour, which is of incalculable importance to our Indian possessions, as the whole of the Coromandel coast presents nothing but open roads, so that on the approach of the monsoons, all vessels were obliged to stand out to sea to prevent inevitable destruction; and there are also many parts of the coast which could be approached during only a few months of the year, whereas the harbour of Trincomalee now affords them, at all seasons, a near and safe retreat. See Percival; Cordiner, vol. i.; Asiatic Register, vol. vi.

The soil of Ceylon is, in general, of a sandy nature.
Ceylon is particularly abundant in fruits. Almost all those plants which are peculiar to tropical climates are found in Ceylon in great plenty, and of a superior quality. Most of those fruits which are natives of the island, grow spontaneously in the woods without culture or care; and the only labour necessary is to pluck and bring them to market, where they are of course sold at a very moderate price. Among them are most of those which constitute the greatest delicacies in the deserts of our European tables, such as pine apples, pomegranates, melons, citrons, limes, oranges, almonds, &c. Besides these, Ceylon produces a great variety of valuable and delicious fruits. Among the vegetable productions of this country, cinnamon is the most important. The principal woods or gardens of this tree lie in the neighbourhood of Colombo. They approach within half a mile of the fort, and fill the whole surrounding prospect. The grand garden near the town is so extensive, as to occupy a tract of country from ten to fifteen miles in length, and in this space nature has concentrated all the beauty and the riches of the island. The low cinnamon trees which cover the plain, allow the view to reach the groves of evergreens, which are interspersed with tall clumps, and bounded by extensive ranges of cocoa nuts and other trees. The whole is diversified with small lakes and green marshes, or skirted by fields of rice and pasture. One large road, which proceeds from the west gate of the fort, and returns by the gate on the south, makes a winding circuit of seven miles among the woods. It is here that the gentlemen belonging to the garrison of Colombo take their morning ride, and enjoy one of the finest scenes in nature. The quantity of cinnamon raised on other parts of the island is now very small, unless around Negumbo Calcuta, Point de Galle, and Matura. Of late years, little is procured from the interior, and what is brought thence is coarser and thicker in appearance, and of a hot and pungent taste. The internal parts of the country are not so well adapted for the production of this plant; and the exactions and avarice of the Dutch, at length reduced the king of Candy to such desperation, that he resolved to secure himself against their future attacks, by leaving nothing in his dominions which could excite their covetousness. With this view he has, since the conclusion of the treaty with them in 1706, employed every means to prevent the growth and propagation of the cinnamon tree. In other respects, however, the state of husbandry in Candy does not appear to be despicable. Mr Cordiner informs us, that all the way from Geerigamme to the capital, the country is extremely beautiful, and probably in a higher state of cultivation than any part of India. Many of the hills are cleared to the summit, formed into ridges, and sown with grain. The fields below are terraced in the most regular manner on different levels, so that not a drop of water can be lost. The valleys are ornamented with groves of cocoa nut, areka, orange, lime, pimplemose, and plantain tree. See Percival. Cordiner, vol. i. Asiatic Register, vol. vi. For a more particular account of the vegetable productions of Ceylon, see Pennant, vol. i. p. 215—252; Percival, p. 312—351; Cordiner, vol. i. p. 348—122; and Thunberg's Travels, vol. iv.

Ceylon is much celebrated on account of its mineralogy, and particularly for the number and variety.
CEYLON.

of the precious stones which are found upon it. To the class of minerals we may refer the diamond, the ruby, the hyacinth, the agate, the amethyst, the sardonyx, the emerald, the Jasper, the tournaline, red, green, blue, and yellow; the topaz; the sapphire, green and blue; the sulphur, white, yellow, brown, and black; crystals; cat's eye; and cornelian. All these precious stones occur, particularly in the region round Matura, in the vallies, and at the foot of the mountains, in a compound of earth and fat clay. Several different kinds are found in the same soil, and in the same place. Sometimes they are found likewise on the surface of the earth, where they have been brought down from the mountains by the violence of the currents or rains. The ruby, the topaz, and the diamond of this island, are not, however, so valuable as those of Golconda or the Brazils. The sapphire, aquamarina, and tournaline, are, on the contrary, equal to those of any other country. Formerly the precious stones were an article of revenue, and were collected by farmers, who contracted for a particular range with government. This plan, however, was for some years given up, as the stones found in the king of Candy's dominions were superior to those of the coast; and the Dutch found it the easiest method of procuring them, to demand from him a certain quantity in the way of tribute. For some time that prince was obliged to comply with the mandates of his imperious neighbours, and sent them a certain proportion of stones every year. Of late, however, he has shaken off this servitude; and, in order to tempt the avarice of Europeans as little as possible, he has prohibited any more from being collected in his dominions. He does not now allow his subjects, on any account, to barter precious stones with Europeans, or to carry any above a certain value out of his territories, under pain of death. It is even dangerous for a Can- dian to retain any, above a certain value, in his possession, as, by a royal decree, they all belong to the king. Lead and tin are found in the interior; but they are not applied to any useful purpose. There is also abundance of iron stone, the preparation of which constitutes one of the principal manufactures of the natives. They melt it in crucibles over a fire, which is blown with two pair of bellows. They separate the scorze with tongs made for the purpose: the melted mass is then poured into a mould of clay; after which it is purified further, and forged for a variety of purposes. There were also several mines of quicksilver wrought by the Dutch; and they have again been opened since the island fell into the hands of the British. See Thunberg, vol. iv. Percival. Knox.

Animals.

Among the quadrupeds of this island, the elephant justly holds the highest place. This animal is produced in great numbers in Ceylon, and is superior to those of every other part of the world, with regard to shape, appearance, and docility. In 1797, no fewer than 176 were sent over from this country by Adam's Bridge to the continent of India. Of animals employed for domestic purposes, Ceylon produces but few. The horse and sheep are not natives of this island, and can scarcely be made to thrive even when imported. The former are never employed in servile work, but are chiefly used for drawing gigs, and other light pleasure vehicles of the Europeans. The Indian horses are extremely spirited, and often defend their riders from the attacks of other animals. Captain Percival mentions, that, on one occasion, he was indebted to the prowess of his preservation from the fury of a buffalo. It is only when so vicious as to be perfectly unmanageable, that these animals are ever castrated in this quarter of the world; and in this mutilated state they decrease greatly in value, as they are then by no means so capable of enduring the heat of the climate, and the violent fatigue occasioned by exertion in a warm country. The oxen of Ceylon have a hump on their back, and in size scarcely exceed our calves of a year old. The beef, however, is sometimes tolerably good, and forms the principal food of our European soldiers; and, though these animals are so remarkably small, they are very useful as beasts of burden. The buffalo is also found in great numbers on this island; and, being much larger and stronger than the ox, it is more frequently employed for the latter purpose. Few parts of India produce a greater variety of wild animals than Ceylon; indeed, the forests are extremely dangerous, in consequence of the number of beasts of prey and noxious reptiles which infest them. Many wild animals are also offered to the use of man; and afford subsistence to the tribes who, like them, range the forests. Among these we may mention tygers, leopards, jackals, monkies, porcupines, racoons, armadilloses, the ichneumon, the flying fox, the cobra de capillo, the alligator, deer, hares, wild hogs, and a variety of others. The birds of Ceylon are also a numerous class. The different species of our domestic poultry are natives of this island; and there are few birds found in our woods which do not abound here. The more remarkable birds of Ceylon, are peacocks, parrots, pheasants, the honey bird, the Indian roller, the tailor bird, some of which are found both wild and tame. Many excellent kinds of fish are caught all around the coasts of Ceylon, and form a principal article both of the traffic and of the food of the natives. See Percival.

For a more particular account of the zoology of Ceylon, see Pennant, vol. i.; Percival, p. 278—313; Cordiner, vol. i. p. 219—248, 422—445; Knox, p. 20—32; and Thunberg, vol. iv.

In this place we shall introduce some account of Pearl fish. in the bay of Condatchy, which is ery one of the most important and valuable acquisitions which the British have made on the island. The banks where it is carried on extend several miles along the coast, from Manar southward of Aripipo, Condatchy, and Pomparippo. There are fourteen beds, but they are not all productive; and only two or three of them are fished in one season. The principal bank is opposite Condatchy, and lies out at sea about twenty miles; it is about ten miles in length, and two in breadth: the others are much smaller. The depth of water over the different banks varies from three to fifteen fathoms; but the best is in about six or eight fathoms. The pearl oysters on these banks are all of one species, and of the same regular form; but they are of different qualities and denominations, according to the nature of the ground to which they are attached, and the appearance of the zoophytes which adhere to the outside of the shells. The shape of the oyster is an imperfect oval, pretty nearly the same as that of a cockle, and is about nine inches and a half in circumference. The outside of the shell is smooth,
CEYLON.

unless when covered with corals, sponges, and other marine productions; the inside is brighter and more beautiful than the pearl itself; the body of the animal is white, fleshy, and glutinous. The pearls are commonly contained in the thickest and most fleshy part of the oyster; they are composed of successive layers, of a substance similar to the shell, and are supposed to be the effect of a disease to which the animal is subject. In general, they are of a bright shining white; but some are occasionally found of a beautiful pink, others of the colour of gold, and a few of a jet black. An oyster commonly contains several pearls; and one has been known to produce 150, including the seed or dust pearls: but, on the contrary, an hundred oysters have been opened without yielding a single pearl which was discernable. The oysters are supposed to attain a complete state of maturity in seven years; after which, it is said, the pearl becomes so large and inconvenient to the fish, that it throws it out of the shell.

Owing to certain disputes in which the Dutch were engaged, this fishery was neglected by them from 1768; but it was resumed by the British government in 1796, after they obtained possession of the coast. The produce of it has varied in different seasons. In 1797, the net proceeds amounted to about L 144,000, and in 1798 it produced a clear revenue of no less than L 192,000; but the banks having been exhausted by the three preceding fisheries, it yielded only L 30,000 the following season. The fishery for 1804 was let by government to a native of Jaffananapam, who, for thirty days fishing with 150 boats, came under an obligation to pay L 120,000; but, as the fishery was very unsuccessful that season, about one-third of the rent was afterwards remitted.

The fishing season commences in February, and, allowing for interruptions of various kinds, commonly lasts about 30 days. During this time, all the boats regularly sail and return together, with the land and the sea breeze. In each of the boats there are ten divers, who go down into the sea by five at a time, and by their diving alternately, they have time to recruit in the interval. These people are accustomed to dive from their infancy. When one is about to descend, he seizes a rope, to which a large stone is attached, with the toes of his right foot, while he takes hold of a bag of net-work with those of his left. Having done this, he seizes another rope with his right hand, and holding his nostrils shut with his left, plunges into the water, and speedily reaches the bottom of the sea, where he collects as many oysters as he can, while he is able to remain under water, which is usually about two minutes. He then makes a signal to the rowers in the boat, by pulling the rope in his right hand, and is immediately drawn up, leaving the stone to be afterwards pulled up by the rope attached to it. The exertion of the divers in this pursuit is so violent, that, on getting into the boat, they discharge water from their mouths, ears, and nostrils, and frequently even blood. But this does not prevent them from diving again in their turn. In the course of one day, they often make from 40 to 50 plunges, and at each time bring up about a hundred oysters. Some rub their bodies over with oil, and stuff their ears and noses to prevent the water from entering them, while others use no precaution whatever. They are in general, indeed, under dreadful apprehensions of the sharks, and in order to quiet their fears, the employment of conjurers is a necessary part of the establishment. Two of them are regularly engaged by government. The one goes out in the head pilot's boat, while the other performs certain ceremonies on shore. In these the divers place unlimited confidence; and indeed accidents from sharks rarely occur. Although the usual time of remaining under water does not much exceed two minutes, yet there are instances of some who could remain four and even five minutes: and Mr Beck informs us, in the Asiatic Researches, that he saw a Caffir boy remain no less than seven minutes.

Though every precaution is taken to prevent any of the pearls being secreted, the Indians are exceedingly dextrous in making depredations on them. As the boats return to the bay, the oysters frequently open their shells of their own accord; a pearl may thus be easily discovered, and the animal prevented, by the interposition of some small substance, from closing the shell, until a favourable opportunity occurs of secreting the prize. Those fellows who are employed in searching the fish also commit many depredations, and even swallow the pearls to conceal them. When this is suspected, the merchants lock up the roguers, and give them strong emetics or purgatives, which have frequently the effect of discovering the stolen goods. Sometimes also those employed in collecting the pearls agree that one of their number shall act the part of a thief, and bear the punishment of his crime, in order to afford his comrades an opportunity of pilfering. If one of them happens to meet with a large pearl, he makes a sign to his accomplice, who instantly conveys away one of small value, in such a manner as to attract notice. On this the pearl is taken from him, and he is punished for his crime. In the mean time, while he is making a dreadful uproar, his accomplice secures the valuable pearl, and they afterwards share the booty between them.

The pearls found at this fishery are of a whiter colour than those from the Gulf of Ormus, on the Arabian coast; but in other respects they are not accounted of so excellent a quality. The various kinds are sent to different markets. Those of the largest dimensions being most costly, and esteemed emblems of greatness, find a ready sale among the rich natives of the Nizam's dominions, the country of Guzerat, and other parts of India. Those of smaller size are chiefly in demand in England, France, Germany, and Russia, while the refuse find a ready market in China.

The variety of characters, and the display of curious manners, which are seen at this fishery, furnish one of the most interesting scenes which Ceylon presents. Parties of strolling jugglers, tumblers, dancers, mendicants, mechanics of every description, retailers in every branch, come on shore, even from the remotest parts of India; resort to Cafferty, during the season of the pearl fishery, in the hope of acquiring some share of the transient stream of wealth which flows periodically through its barren plains. See Asiatic Researches, vol. v. 393—411. Corriner, vol. ii. Pethoul.

With regard to the population of this country, we Inhabitians do not possess any authentic accounts, but as it is so vast.
CEYLON.

much in a state of nature, we may conclude that the inhabitants are not very numerous. Mr Cordiner estimates them at 1,500,000; but this calculation rests on no certain data. Besides the Dutch and British inhabitants, there is a numerous race, known by the name of Portuguese, who are the spurious descendants of that people by native women. We also find a vast number of Malays, who, indeed, are scattered over most of the islands in the Indian Ocean, and are a remarkably ferocious race, and very peculiar in their manners. These various classes have settled on the coasts of Ceylon, for the purposes of conquest or of commerce; but by far the greater proportion of the inhabitants consist of Ceylonese, which is the general name of the natives of the island. To distinguish them more particularly, those under the dominion of the British government retain the original appellation. Cingalese; while the inhabitants of the interior, who are subject to the authority of the native prince, receive the name of Candians. The constant intercourse of the Cingalese with Europeans, and the aversion which the Candians have always expressed for their invaders, have introduced considerable shades of difference into the character and manners of these two branches of the same people. In most parts, however, they still continue to resemble each other, so that one description may, in general, apply to both.

The following character is drawn of them by Mr Knox, who was a Captain among them for nearly twenty years: “In short,” says he, “in carriage and behaviour, they are very grave and stately; in understanding, quick and apprehensive; in danger, subtle and crafty; in discourse, courteous but full of flatteries; naturally inclined to temperance, both in meat and drink, but not to chastity; near and provident in their families; commending good husbandry. In their dispositions not passionate, neither hard to be reconciled again when angry. In their promises very unfaithful, approving lying in themselves, but misliking it in others; delighting in sloth, deferring labour till urgent necessity constrains them; neat in apparel, nice in eating, and not given to much sleep.” The Ceylonese, in general, are of a middling stature, and fairer in complexion than the natives of India. According to Mr Cordiner, the Cingalese are indolent, harmless, and unwarlike, remarkable for equanimity, mildness, bashfulness, and simplicity; the Candians are a bold, active, and hardy race. This diversity of character naturally arises from the difference of circumstances in which they have been placed.

The Ceylonese, like the Hindoos, are divided into a number of casts. Captain Percival mentions nineteen, according to the several occupations of the people. The highest comprises the nobles, and next to them are the superior classes of artificers, as painters, goldsmiths, smiths, and carpenters. All the different casts, according to the Indian custom, are careful not to intermingle together. The son pursues the profession of his father from generation to generation, nor is one cast allowed to interfere with another. The principal external distinctions of the higher and lower casts consist in wearing doublets, or going barebacked without them; the length of the cloth below their knees; their sitting on stools, or on mats spread upon the ground, and in the caps which they wear. But besides the regular casts, there is a wretched class of mortals, the martyrs from age to age of this unnatural and barbarous institution. Those who by any crime or act of negligence forfeit their cast, are not only condemned to infamy themselves, but their descendants are involved in the awful consequences of their guilt. They are not allowed to exercise any trade or profession, but are obliged to beg for daily sustenance; and thus, age after age, become a dead weight upon society. At the same time, they have to pay the lowest of the other natives as much respect and reverence as the latter shew to the king.

The houses of the Ceylonese are small and low, consisting only of one story. They are constructed of slender pieces of wood or bamboo, daubed over with clay, and covered with rice straw, or the leaves of the cocoa tree. Round the walls of these huts are small banks of clay, on which they sit or sleep. These benches, as well as the floors of their houses, they overlay with cow-dung, in order to preserve them from vermin, and to keep them smooth and clean. The furniture of their cottages is of the most simple kind, and consists merely of a few instruments, indispensably necessary for the preparation of their victuals. The Ceylonese use neither tables, chairs, nor spoons; but, like other Indians, place themselves on the ground, and eat their food with their hands. The houses of the Candians are much superior to those of the Cingalese; for although the latter are accustomed to see better models, yet the abject state to which they have been reduced under the tyranny of the Portuguese and Dutch, has retarded their progress in improvement. Their villages, instead of presenting the regular compact appearance of a town, look like a number of miserable huts scattered through the midst of a thick forest. There is not the smallest regularity observable among them; but every individual places his cottage near the centre of a cocoa tree tope, in the most convenient spot he can find. In the mountainous parts of the country, where the natives live in continual danger of attack from wild beasts, of being annoyed by serpents, or suddenly overtaken by inundations, it is usual for them to build their huts on the summit of rocks, or even on the top of lofty trees. Some of them also fix a number of high posts in the ground, and place on these a kind of hurdle, which serves them for a nocturnal habitation.

In their dress, the Ceylonese are remarkably simple. That of the lower ranks of men consists merely of a piece of coarse cloth wrapped round their loins, and covering their thighs, or frequently only the parts which decency requires to be concealed; that of the women is similar, but only longer, and they also wear a short jacket, which usually covers their breasts and shoulders, leaving the middle of the back bare. The higher ranks cover the whole of their bodies; they are fond of ornaments, and the dress of many of them bears some general resemblance to that of Europeans.

In their diet the Ceylonese are remarkably temperate. The principal part of their food consists of fruits and rice. Flesh is seldom used by them; but in some places where fish abounds, they employ
them as a portion of their meals. In dressing their victuals, the Ceylonese are scrupulously nice; and, in drinking, they are careful not to touch the vessel with their lips, but hold it at some distance over their head, and pour the liquor down their throat. All ranks among them chew the betel leaf; this is the desert at all their entertainments, and the usual supplement to all their conversation. Along with it they mix tobacco, areka nut, and the lime of burnt shells, in order to render it more pungent. When chewed, this mixture becomes red as blood, and stains the mouth, lips, and teeth, of an indelible black colour. This they think a beautiful effect, for they consider white teeth as only fit for dogs, and a disgrace to the human species. This hot mixture, however, soon destroys their teeth, and often renders them toothless at an early age. There is a wonderful degree of gravity observed among the Ceylonese in company, even among relatives and intimate friends. At meals they seldom converse with each other; and it is not unusual to see a party sit perfectly mute for a long time, and during all the while chewing the betel leaf.

Politeness.

The Ceylonese are courteous and polite in their manners, to a degree far exceeding their civilization, and greatly superior to other classes of Indians. In their salutations they are particularly punctilious. The form which they use is that common in the East, of bringing the palm of the hand to the forehead, and then making a low bow. However, though in general courteous and polite, if their anger is once roused, it is proportionally furious and lasting. Their hatred is so violent, that they often destroy themselves to obtain the destruction of the detested object. A Ceylonese has been known to kill himself in the company of his enemy, that the latter might suffer for it.

Disobedience.

The Ceylonese are of a remarkable dissolute character. It is common for the men to indulge in promiscuous intercourse with the female sex; while the infringement of the laws of chastity on the part of a woman, scarcely subjects her, even though married, to the slightest reproach, unless, indeed, it happens to be with one of an inferior cast; an act which is considered as the very excess of infamy. Among people of the same rank, the most unhonoured commerce is carried on in private; and it is by no means uncommon, nor attended with any disgrace, for the nearest relations to have connection with each other. The Ceylonese are particularly fond of forming a correspondence with Europeans; and, instead of accounting it any reproach, a mother, in quarrelling with any of her neighbours, will silence them at once with regard to her superior dignity, by telling them, that her daughter has had the honour to receive the favours of a European.

Marriage.

Though in Ceylon the men are not limited to one wife, yet in consequence of the ease with which promiscuous intercourse is carried on, and the facility with which marriages are dissolved, together with the poverty of the natives, polygamy is not general among them. Indeed this is so far from being the case, that it is not unusual, particularly for brothers, to have one woman in common. In general, the contract of marriage is originally made by the parents while the parties are in a state of childhood; and it is often dissolved by mutual consent, almost as soon as it is consummated. It is also customary for those who intend to marry, previously to cohabit together, and to make trial of each other's temper, and if they do not agree, they break off the connection without any further ceremony. In this case, no disgrace attaches to either party, but the woman is held in as high esteem by her next lover as if he had found her in a state of virginity. If, however, the parties agree to marry, the man presents the bride with the wedding clothes, which consist only of a piece of cloth about six, or seven yards in length, and with another cloth which is placed on the bed. On the following night he is entitled to sleep with her; and on this occasion they fix the time for the celebration of their nuptials. When the day arrives, the bridegroom and his relations repair to the house of the bride, carrying along with them what they are able to contribute for the marriage feast. The parties then eat out of one dish, to denote that they are of the same cast; after this their thumbs are tied together; and the ceremony concludes by the nearest relations, or the priest when present, cutting them asunder. This form, however, is scarcely considered as obligatory. When the Ceylonese wish to render a marriage as firm and indissoluble as the nature of their manners will admit of, the parties are joined together with a long piece of cloth, folded several times round both their bodies, and water is then poured on them by the priest, who always officiates at this ceremony. After the marriage, the young couple pass the night at the bride's house, and in the morning the husband takes her home, accompanied by her friends, who carry with them provisions for another feast. The dowry of the wife is in proportion to the ability of the parents; but if they afterwards separate, it returns with her, that she may be as good a match for her next husband. Both men and women often divorce several times before they find a partner with whom they can reconcile themselves to spend their days. If they have children when they separate, the common law is, that the sons remain with their father, and the daughters go with their mother. Indeed, they often infanticide have no family, as the practice of infanticide is common in Ceylon. As soon as an infant is born, the father applies to an astrologer to know whether it is in a good or an evil hour. If it is found to be the latter, they immediately destroy it, either by starvation it to death, by drowning it, or by burying it alive; or else they give it to some person of the same rank with themselves, for they say the child will be unhappy only to the parents. In general, the women of Ceylon are much more pleasant and agreeable than those in the other parts of India; but owing to their early intercourse with the other sex, (for they are regularly married when about twelve,) they soon lose the appearance of youth, and become old and haggard in their looks immediately after they pass twenty.

The Ceylonese, according to Mr Knox, are of a disease, healthy constitution, and many of them live to the age of fourscore and upwards. During the wet season, however, they are subject to a variety of diseases, particularly fevers and fluxes. Leprosy appears to be very prevalent among them; and the streets of Colombo swarm with Cingalese beggars labouring under this dreadful disorder. But the disease which particularly excites their apprehensions is the smallpox. It is looked upon as the immediate instrument
of divine vengeance, and therefore they employ no charms or incantations for the recovery of those who are so unhappy as to labour under it. If any one dies of this disorder, he is thought to be accursed by God, and therefore they deny his body the common rites of burial.

The reports of the progress of vaccination in Ceylon are peculiarly interesting; as they place in the strongest light the success of that practice. The ravages which the small pox formerly made in this island were dreadful; but in 1802, the progress of that destructive malady was happily checked, by the introduction of the cow-pox; and from that period till the beginning of 1810, the number of persons vaccinated, amounted to 128,732, of whom there were no fewer than 25,607 in the course of the preceding year, besides some others inoculated by private individuals. Indeed, so completely effectual had the practice proved, that, according to the best information, the small-pox had not appeared in any part of the island from February 1808 to October 1809, a period of not less than 20 months. It was then, indeed, introduced at Jaffanapatam, by a country boat from Quilon on the Malabar coast; but it attacked only a few individuals who happened not to have been inoculated. We have here, therefore, a striking proof of the beneficial effects of general vaccination. Contagion may be introduced into a country, but it dies for want of susceptible subjects: a fire-brand may be applied, but there is no fuel to produce a conflagration.

In ordinary cases, the higher ranks burn the dead; but the inferior castes bury them without any particular ceremony. The house in which a person dies is always deserted for some months, or even for ever. The water of the sea is considered as the best for purifying such a place; but when this cannot be had, they use the water of a stream, cowdung, and curcuma. In order, however, to avoid this inconvenience and trouble, they sometimes have recourse to the following cruel practice. When the relations of a sick person despair of his recovery, they take him into a wood in spite of his cries and groans, and there leave him perhaps in the agonies of death. It sometimes happens that people thus left recover and return to their families, without, it is said, entertaining the smallest resentment against their unfeeling relations. This atrocious practice is particularly common in the poorer provinces of the kingdom of Candy. See Percinal. Knox. Cordiner, vol. i. Asiatic Researches, vol. vii.

But besides the Ceylonese, there is a singular class of people in this country called Bedahs, who inhabit the deepest recesses of the forests, and whose origin has never yet been traced. They are scattered over the woods in different parts of the island; but are most numerous in the province of Bintang, which lies to the north-east of Candy, in the direction of Trincomalee and Batacolo. This singular people subsist entirely by hunting deer and other animals, with which the forests supply them, and on the fruits which spontaneously grow around them. They seem to have no houses, for they usually sleep either on the branches or at the foot of trees. In the latter case, they surround them with thorns and other bushes, to keep off wild beasts, or by their rustling to give warning of their approach; and if the smallest noise rouses the apprehensions of the Bedah, he climbs up the tree with the utmost expertness and celerity. Though they do not acknowledge the sovereignty of the king, yet once a-year they send two deputies with honey and other little presents to him. On their arrival at the gate of the palace, they send word to his majesty, that his cousins wish to see him. They are immediately introduced, kneel before him, then get up, and enquire familiarly about his health. The king receives them well, accepts of their presents, gives them others, and orders that certain marks of respect be shewn to them on their return from the palace. Those of the Bedahs who skirt the European territories, barter the natural productions of the forests with the Cingalese for the few articles which their simple mode of life requires; but in order to prevent themselves from being surprised or made prisoners while carrying on this traffic, they employ a curious method. When they are in want of cloth, iron, knives, or any articles of smith-work, they approach some village during the night, and deposit, in a place where it is likely to be immediately discovered, a certain quantity of their goods, along with a talipot leaf, expressive of what they wish in return. On a following night they repair again to the same place, and generally find the expected reward awaiting them; for although they are easily satisfied, and readily allow the advantage to the person with whom they deal, yet if their request is treated with neglect, they do not fail to watch an opportunity of doing him mischief. The Cingalese, as they can afterwards dispose of the articles afforded by the Bedahs, find the traffic profitable; and in some places they even go into the woods, carrying with them articles of barter. The dogs of the Bedahs are remarkable for their sagacity, and not only readily trace out game, but also distinguish one species of animal from another. On the approach of any carnivorous animal, or of a stranger, they immediately put their masters upon their guard. These faithful creatures are, indeed, invaluable to them, and constitute their chief riches. When their daughters are married, hunting dogs form their chief portion; and a Bedah is as unwilling to part with his dog, as an Arabian with his horse. See Percival. Asiatic Researches, vol. vii.

The learning of the Ceylonese consists chiefly in Literature; some pretensions to skill in astrology. It appears, however, that they were formerly possessed of some literature, and had attained some refinement in the arts. Their language consists of two dialects, which differ considerably from each other, and have separate grammars. To read and write are no ordinary accomplishments among the natives of Ceylon. In Candy, they are chiefly confined to the learned men of the sect called Goories, who are retained by the king to execute all the writings of state, and those which relate to matters of religion. The Arabic is the character which they employ on these occasions. In writing, they commonly employ, instead of paper, the leaf of the talipot tree. From these leaves, which are of an immense size, they cut out slips from a foot to a foot and a half long, and about a couple of inches broad. Having smoothed the slips, and taken off any excrescences with a knife, they are ready for use; without
of the religion of the Ceylonese we have very imperfect and contradictory accounts. They acknowledge the existence of one Supreme Being, the Creator and Governor of the world, but they have also a number of inferior deities and evil demons. Of the former, the most exalted is Buddhū, whom some represent as originally a divine person, and others as the spirit of a good man crowned with divine honours. He is said to have appeared in the world in the form of a man, and after having performed a vast number of virtuous actions, and been transformed into a great variety of shapes, he ascended again into heaven, where he acts as a mediator with the Supreme Being, and procures the pardon of his worshippers. The Ceylonese dedicate no temple to the Supreme Being; but those of Buddhū are superior to those of all the other deities. They have no certain form, as they are generally built in the caves of rocks, and it depends on the particular nature of the cave, whether the statue of Buddhū is standing, or sitting with its legs across, or lying upon its right side. This figure is invariably yellow from the head to the feet, and a large garment of the same colour covers the whole body except the right breast. On one side of the temple there is always a monument in the form of a cupola, placed on a mounded pedestal, which is said to contain a particle of the bones of Buddhū. Captain Pervical mentions, that the ruins of the temples and pagodas, which he saw in the interior of the country were all of hewn stone, and of much superior workmanship to those on the coast. Several of them were in a state of perfect preservation, and, on comparison with the modern structures, afford the strongest proof that the inhabitants of this country had formerly attained a much higher degree of improvement than at present appears among them. As the temples of Buddhū are superior to those of the other deities, so the priests of that god are held in the highest estimation, and are endowed with a variety of peculiar privileges. They are chosen by the king from the body of nobles, and in consequence of their birth, they are generally men possessed of power and influence independent of their sacred character. Though they are chosen by the sovereign, he retains no authority over them, but endeavours to cultivate their regard, by respecting their privileges, and loading them with favours. They choose their own superiors, and the chief priest is invested with the power of settling all religious disputes. They have also the chief management of public affairs, and are exempted from the payment of all taxes. The highest honours are paid them by the rest of the nation. All ranks bow down before them; when they sit, their seats are covered with a white cloth, and when they walk, the broad end of the talipot leaf is borne before them;—privileges which, in Ceylon, are of the highest kind, and shared with them only by the monarch. But while the priests enjoy these and other honours, they are also placed under certain restrictions. They are not allowed to marry, and they are also prohibited the use of wine and animal food. They have an opportunity, however, of escaping from these restraints, as they are allowed to lay aside their order whenever it suits their inclination. The temples dedicated to the other deities are much inferior to those of Buddhū. In general, they are poor, mean, contemptible huts of one story high, without windows, constructed of clay and wood, and covered with cocoa-nut leaves. There is no figure too ridiculous to find a place in them; besides swammics of all descriptions, there are representations of wild beasts, birds, pieces of consecrated armour, and some very indelicate figures of men and women. The priests of the inferior deities, though dressed like those of Buddhū, may easily be distinguished by the smaller degree of respect which is paid to them. They are continually met in their wandering excursions over the island, and like all those of the same class in India, are a set of lazy, impudent vagabonds, who, without any exertion or industry, are enabled to live comfortably by the extortions which they practise upon the people. But though the Ceylonese worship these various deities, the chief object of their fear are the subordinate demons, whom they consider as the spirits of wicked men. These impress their mind with much greater awe than the more powerful divinities who dispense blessings among them. They, indeed, think that their country is in a particular manner delivered over to the dominion of evil spirits. There is no people who labour so much under the influence of superstitious fear as the Ceylonese. Omens regulate the whole of their conduct, and even decide upon their destiny from their birth. The Mahavellaganga is said, by Mr Cordiner, to be held in the same religious veneration by the Ceylonese as the Ganges by the inhabitants of Bengal. The water of this river is considered as effectual in washing away sin; but dead bodies are never thrown into it. The immortality of the soul, and the resurrection of the body, are doctrines generally believed among the Ceylonese. They suppose that the souls of the just are immediately after death admitted into the rank of gods, and that their ancient prophets and good kings are long since employed in exercising the power of deities: while, on the other hand, the
souls of the wicked, particularly of unjust tyrants and impious priests, are supposed to have passed into wild beasts and reptiles. The Ceylonese are very liberal in the distribution of charity. It is customary for them even to appropriate a certain portion of their food for distribution among the poor; and although among the Hindoos, strangers in distress are accounted objects of very little compassion, yet a Cingalese will not shut his house against a Malabar or Moor who asks him for relief.

Such is a slight sketch of the system of Paganism professed in Ceylon. Christianity, however, has been established on the island for three centuries past. The Portuguese, when they first settled on the coast, introduced the Catholic religion among the Cingalese, and subjected them to the yoke of the church of Rome. Afterwards, the Dutch introduced the doctrine of the Reformation, and propagated the profession of them among the natives. Indeed, if the number of converts be any proof of success, in no country has Christianity been so successful, in modern times, as in Ceylon. Both the Catholics and the Protestants, boast of hundreds of thousands among the natives whom they called Christians; but we regret to add, that most of them had no claim to the title, for though they had been baptized in the name of Christ, they were still worshippers of the idol Buddha. So late as 1801, we are informed that the number of native Protestant Christians on the island was upwards of 342,000; and that it was supposed the Roman Catholics were still more numerous. At the same period, the number of native schools amounted to about 170; but shortly after, the most of them were suppressed by the ill-judged parsimony of the Court of St James's, though the whole saving to government scarcely amounted to the paltry sum of £1800!

The government of Candy is an absolute despotism; but notwithstanding this, the natives look upon certain fundamental laws and regulations existing among them from time immemorial, as the real depository of power; and they maintain, that if the king encroach upon these, he is amenable to the justice of his country as well as the meanest subject. It is evident, however, that while there is no power to balance that of the sovereign, it is only a successful rebellion that can bring him to justice. The monarchy of Ceylon is completely elective, according to the fundamental laws of the kingdom; and when a deposition takes place, this principle is usually acted upon. It is in the power of the people to put aside the next branch of the royal family, and to elect a distant relation, or even a perfect stranger. If the last king has no immediate descendants, and the hereditary right lies equally between males and females, the preference, according to the Candian laws, is given to the female branch of the family.

The king of Candy yields to no eastern prince in the number and extravagance of his titles, and in the reverence which is shown him by his subjects. No one dare approach him without prostrating himself three several times before the throne, and each time repeating a long string of his majesty's titles. No one, even of the highest rank, is allowed to cough or spit in his presence; every one is silent before him, nor does any one, even in a whisper, venture to address one another. The prime minister is the only person who is allowed to stand in the royal presence, and even he is obliged to be some steps lower than his majesty, as no one must appear on a level with him who is supposed to be descended from the sun. The business of state is transacted between the king and the prime minister in low whispers; and any message from his majesty to those present, is conveyed in the same manner by the adigars.

The highest officers of state are the adigars or prime ministers. They are two in number, and actually share all the power of the court between them. The officers next in rank are the dessauvas, who are the governors of the corles, or districts, into which the kingdom is divided, and they are also the principal military commanders. The whole plans of government form a regular system of oppression, which fall with peculiar severity on the lower orders of the people. Few have the courage to appeal against the unjust extortions of the higher ranks, and fewer still meet with any redress. They have long since been strict of every thing valuable, and many of them trust for subsistence to the spontaneous productions of their forests, rather than cultivate fields, whose produce must be shared with their oppressors. Revenues.

The principal revenues of the king consist of presents or contributions brought him by the people, or rather forced from them by his officers. They consist of money, precious stones, ivory, cloth, corn, fruit, honey, wax, arms, and other articles of their own manufacture, such as spears, arrows, pikes, targets, &c. The lower classes, however, are not the only persons who feel the burden of supplying the royal treasury. On certain festivals, which the king observes in great state, all the nobles and principal people are obliged to appear before him, and none of them must come without a present. It is dangerous for them to keep back on these occasions, and a liberal gift is necessary for the preservation both of their persons and their property. But these stated contributions are not the only kind of extortions practised in Candy to fill the royal treasury. The moment that the king's officers understand that any one is possessed of valuable articles, he demands a share of them for the sovereign. Artists are likewise frequently employed by the prince to make him arms and different works in gold and silver at their own expense.

As the government of Candy is completely despotic, every subject, without distinction, must be ready at the call of the sovereign. His regular troops, Captain Percival estimates at about 20,000; but these, though called regulars, have neither arms nor clothes to entitle them to that appellation. They wear whatever dress they choose, and arm themselves with any kind of weapons they can procure, as spears, pikes, swords, targets, bows and arrows, muskets and bayonets, so that altogether they have a very motley appearance. Besides those that are considered as regular troops, the king has a numerous militia scattered over the country, and his guard, like that of despots in general, is composed entirely of foreigners.

A few years before this island fell into the hands of the British, the Dutch introduced new regulations in the management of the finances of the settle-
ment, in consequence of which its income was greatly augmented, while the expenses were diminished, as appears from the following statement:

</table>

For some years after the Dutch possessions on this island fell into the hands of the British, they were placed under the management of the East India Company; but from the beginning of 1802, they became a royal government, and were placed under the immediate direction of his majesty's ministers, who now regulate the affairs of the settlement. The Cingalese, who live under the British government, are now subjected to our laws, and to our form of administering justice, except in a few points in which their ancient customs are retained. They are governed by their native magistrates, but the supreme controlling power always reside in the servants of his majesty. According to the report of the Dutch board of trade, the revenue of Ceylon was formerly able to defray their expenditure on account of the island; but of late years the expenditure had far exceeded the produce of the revenue. In 1795 it amounted only to 611,704 livres, while the charges of the established government were upwards of double that sum, amounting to 1,243,338 livres, or £57,934 sterling. Though the revenues of Ceylon are now much greater than under the Dutch administration, they are not sufficient to defray the expense of our various establishments on the island. Captain Percival, indeed, estimates them at £1,200,000; but Mr Corriner informs us that this must be a great mistake, and that at present they do not exceed £226,600, while the ordinary expenditure of the island amounts to £330,000, so that the loss to government amounts to no less than £103,400. In this state of the revenue, he says, every source is included, allowing £60,000 from the East India Company on account of cinnamon, and £40,000 as the average produce of the pearl fisheries, though we apprehend the estimate of the latter is too low. See Percival, Corriner, Edinburgh Medical and Surgical Journal, vol. vii. p. 259, Fabriciit lux Evangelii per totam orbem exerc. cens. Transactions of the Missionary Society, vol. ii. and iii. Martyn's Christian India, a sermon preached at Calcutta, January 1. 1811. (w. n.)

CHAFF-CUTTER, is a machine for cutting hay and straw into short lengths for cattle. The machine for cutting chaff, which has been long in use, consists of a plane box or trough, mounted on four legs to support it, and across the end of the box, a large knife or blade is worked by means of a handle fixed to one end of it. The other end of the knife is jointed to a lever, which moves on a centre at the bottom of one of the legs, so that when the knife is worked, one end describes the arch of a circle, while the other is applied by the handle to the end of the trough or box, and the straw being placed in it, the end of the straw which projects beyond the extremity of the box, is cut off by the knife when worked in an inclined position, and with a drawing or thrusting stroke, which causes it to cut very clean. The workman depresses the knife with his right hand, whilst his left is employed in making the straw advance in the box, every time a cut has been made. This he does by a fork with a wooden handle, and four or five prongs, which are stuck into the straw. At the time when the cut is made, a treadle is pressed down by the foot, which draws a piece of wood down upon the straw in the box, and thus compresses it so closely, that the knife cuts much better than if it had been loose.

From the difficulty of using this implement with any rapidity, the farmer employs a man who makes a business of cutting straw, and travels from one farm to the next with his chaff-box at his back.

Mr R. Salmon of Woburn, Bedfordshire, has invented the most complete chaff machine which has yet been produced: it is represented in Plate CXXXV, CXXXV, Fig. 1. in which AA, BB are two cast-iron wheels, connected together by bolts a, a, extending from the rim of one wheel to that of the other. The wheels are mounted on an axis C, which is supported on bearings in a proper framing, as is evident from the figure. The straw is put into a box or trough GF, and what projects beyond the end thereof is cut off by two knives b, b, attached to the sides of the rims of the two wheels AA, BB, which are turned round by the winch handle E; or where there is a thrashing or flour-mill, an endless rope may be conducted round the pulley or rigger D, and thus give it motion without any trouble. The knives b, b are placed at an angle of 45 degrees to the direction of the wheels' motion. They are attached to the wheels by iron rods or levers C, moveable on a centre-pin, and capable of being forced forwards towards the chaff-box by springs, which are formed to adjust by screws h, and act more or less as occasion may require, so as to give the knife as much pressure against the end of the box as may be requisite to cut the straw. The knives are prevented from coming too far forward, and occasion unnecessary friction, by the wedges under the staples near C; which wedges, as the knives wear, must be drawn out so as to permit the knives to come more forward. With the provision before-mentioned, it will be found very easy at any time to put in new knives, as the springs and levers will always adjust them to their work.

On one side of the wheel is fixed a round block of wood f, in which there are four holes and a moveable screw, acting as a crank, upon one end of the feeding arm g, extending nearly horizontal to the cross lever LM, Fig. 2, to which the end of g is attached by a pin. The straw is brought forward by a pair of rollers in the box E, the form of which is shown at m m, in Figs. 2, 4, and 5, which rollers are turned from the outside by ratchet wheels H, on each side of the box F. The ratchet wheels are provided with clicks, as shown in Fig. 2, which are actuated by means of small rods r r, Fig. 3, extending from each click, and jointed to the cross lever L M, which moves upon a centre-pin e, fixed beneath in the bottom of the box F; by this means, the rods r, in moving either way, by actuating one or other of the clicks, turn the ratchet wheels and rollers round a proper quantity, to advance the straw forwards; but this quantity can be regulated at pleasure, according to the stroke given to the cross lever L M, by the feeding arm g, and crank. The pin which attaches the end g of the feeding arm to the cross lever L, is moveable to five different holes in L; by means of which, and the four holes in the block f, before-described, for the crank-pin, twenty changes in the length
of the chaff may be obtained. By this mode of 
feeding, the straw is perfectly at rest, and does not 
press forward at the time of the cutting ; at 
the same time, lifting up the feeding arm, its end is 
dis-engaged from the pin fixed at the end of the 
cross-lever, and the feeding motion is instantly thrown off, 
although the wheel and knives may continue their 
motions.

Beneath the box is suspended the pressing-weight R, 
which may be made more or less powerful, by shifting 
the weight on the lever from which it hangs; 
and it also may be thrown on either side, more or less, 
as occasion may require; which will be found useful, 
in forcing the straw towards the knife, and counter-
balancing the ratchet-wheel of the upper roller. 

The arbor of this lever carries two short levers, one of 
which is shewn at r, Fig. 1. From these, iron rods 
proceed to the pivots at the ends of the upper spiked 
rollers, by which means the straw is always equally 
pressed in passing the two spiked rollers. Great 
advantage is obtained in this machine, from its cut-
ting various lengths—from its resting during the cut 
—from the knives being adjusted to work by their 
regulating springs—from the feeding being readily 
thrown off—and from the pressure being moveable 
to either side of the box. In consequence of the knives 
acting against the end of the box, which is covered 
with steel-plate, they are constantly kept sharp.

Figs. 6, 7, and 8, are figures of a chaff-cutting 
machine, which, under a variety of forms, has 
come into very general use. The original was con-
structed by Mr James Pike, who presented one 
to the Society of Arts many years ago. It has 
received successive improvements from Messrs Cook, 
Nailer, Winlaw, Macdougal, and other implement 
makers, till it obtained the form given in Plate 
CXXXV. Fig. 6 is a front, and Fig. 7 a side 
elevation; in which A A A is a cast-iron 4 5-y-wheel, with 
three curved arms, extending from its centre to the 
circumference; and against these, 3 knives b b b are 
screwed and adjusted by wedges behind, to apply 
fairly against the end of the box D, in which the 
straw or hay is spread evenly and regularly. The 
spindle a, Fig. 7, of the wheel is supported in bear-
ings at each end, one being screwed to the side of the 
chaff-box, and the other fixed upon a post H, which 
is attached to the frame K by blocks, and secured 
to it by braces I ; so that it is very firm and 
secure at a proper distance from the frame K. The 
axis a has a worm, or endless screw, formed upon it, 
which actuates the teeth of a wheel F, fastened upon 
the end of the spindle of the lower roller in the 
chaff-box. The upper roller is supported in a frame 
of iron e f, shewn separately in Fig. 8. This is at-
tached to the box by centre pins at e e, and the arms 
e f, e f proceed to the branches which carry the pivots 
of the roller g. A bar j j unites the two sides of the 
frame; and upon this a short lever operates 
to press down the whole frame, and thus hold the 
roller down forcibly upon the straw, and press it be-
tween it and the lower roller, so that it will be 
moved forward when the rollers are turned round by 
the motion communicated to the worm-wheel of the 
lower roller. The upper roller is moved by a con-
trate wheel h, on the extremity of its spindle, which 
is turned round by a long upright pinion m; and this 
receives its motion by means of a similar contrate 
wheel l from the lower roller. By this means the 
upper roller is always kept in motion, let it rise as 
high as it will, in consequence of a great feed of 
straw being introduced between the two. The short 
lever, which, as before stated, depresses the upper 
roller and frame e f, is fixed upon an axis d; on the 
end of which, a lever d c is fastened, and loaded at 
pleasure by a moveable weight e, which, like a steel-
yard, can be shifted at pleasure, to increase the pres-
sure upon the straw. A piece of wood h, Fig. 8, is 
attached to the iron frame e f, and pressed down 
upon the straw, just before the place where 
the knife cuts the straw. The whole is turned round by 
one man working a handle B, fastened on the end of 
the main axis; and it is stated by the inventor, that 
twenty-two bushels can be cut in an hour by this 
machine with one man. The rollers which advance 
the straw, have diagonal ribs of iron projecting from 
them, as shewn at g, Fig. 8, which hold the straw 
fast; and the lower roller has the same.

This machine is of small size, and being sold at 
a low price, is very generally adopted; but the action 
is not by any means so good as that of the machine of Mr 
Salmon; and the rollers acting to advance the straw 
forwards all the time during the cut, causes a great 
friction on the back of the knives. Mr Pasmore of 
Doncaster makes machines on Mr Salmon’s plan, of 
a small size, in cast iron, which are cheap and effec-
tive: And Mr Braby of London has produced a 
simple machine, which is the old chaff-box provided 
with rollers to advance the straw; and these are 
turned round by a ratchet-wheel, which is moved 
every time the knife is raised up to make a fresh 
stroke, and thus the straw stands still during the cut.

CHAIN. See Surveying.
CHAINWORK.

Under this head may very properly be ranged some of the most extensive and useful manufactures of this country. The term Chainwork is used for those substances, whether lineal or superficial, in which any kind of cordage or thread is linked together in the form of a chain, for any purpose of useful or ornamental manufacture. The variety of these is considerable, and their utility renders all of the branches very extensive.

Of the lineal kind, the ornamental manufacture known by the name of Tambouring, and now very extensively practised in this part of Great Britain, is the principal.

Under the superficial, every class or branch of hosiery may be included, whether plain or ornamental; and all the varieties of the lace manufacture, as practised both upon the continent and in Great Britain. It also may be considered as including every species of net-work, whether of that flimsy and light kind, which is manufactured either in the weaving loom or stocking-frame; or the more substantial kinds, employed in the various fisheries, for lining the sides of ships of war, and many other purposes. These manufactures, being strictly little more than varieties of the same class, it is proposed, in the present article, to give some account of them, in the following order.

1st, Lineal chaining, or tambour work, as executed both by the hand and by the recently invented machinery.

2d, The various leading branches of the hosiery or stocking manufacture.

3d, Reticulation, or net-work of various kinds, especially that which, by promoting and extending the British fisheries, is of the most essential importance to every branch of the community.

It can hardly be expected, that, in a field so unboundedly extensive, every detail should be included; but if a general view of the whole, combined into one focus, can be effected, the object will be in a great degree attained. The first, then, to which attention is to be paid, is the principles and practice of tambour or chainwork on cloth.

CHAP. I.

Application of the principle of Chainwork to Tambouring, or the production of ornamental Flowers and Figures upon Cloth.

The close and compact form which the linking of any kind of thread or yarn, into the form of a chain, assumes when tacked upon the superficies of the lighter fabrics of cloth, has been very successfully and extensively applied to many species of ornamental manufactures of this description. Of the origin of these manufactures, if any record has at all been preserved, it has never reached the public view; and as it seems highly probable that most of them either originated, or were first noticed, in those recesses of monastic seclusion, to which it became the policy of the Roman Catholic priesthood, during the plenitude of the papal power, to devote even a very great proportion of the female population of Europe, it was hardly to be expected that arts, which were deemed at least childish and nugatory by the men, whose chief trade was war, and whose ambition and interest alike were gratified by the profession of arms, should form objects of curiosity or attention. The priesthood alone, unenured, and probably but little inclined to exercise in their own persons those military talents to which they were too often sufficiently anxious to prompt the laity, were almost the only depositories of every art, as well as every science; and their obvious policy dictated the concealment, more than the propagation, of every art and science, by the knowledge of which either celebrity or wealth might be attained. If this general principle be studied with candour and patience, we shall be at very little loss to account for the almost universal ignorance of what are termed the dark ages; and it is at least a matter of some curiosity to trace the same principle which directed the most powerful empires and monarchies, even so low as to regulate the casual employment of the meanest female. In the exercise of most of those manufactures which we have derived from our intercourse with our continental neighbours, we have, very naturally and very wisely, been at more pains to adapt them to suit our own purposes, than to conceal their origin; and the original names remaining, generally serve us to trace their origin.

The original frame upon which cloth is stretched to undergo the operation of the hook, which forms the chainwork upon its surface, consists of two circular hoops; the outer ring being coated round with lists of cloth, or any other soft and compressible substance. The cloth being stretched over the inner ring, the outer is applied, and the friction of the two gives the whole means of tension. These frames, or hoops, in their most simple form, are merely held between the knee and the chin of the operator, while working. As this is a clumsy and inconvenient posture, the first improvement seems to have been confined to the addition of a pedestal, upon which the hoops might rest, and the female, who performed the work, might sit in a more easy posture while at her employment, or leave it with ease and security for the purpose of attending to any other domestic occupation.

Such has been, and probably still is, the state of this art upon the continent, excepting in Switzerland, where it has been long a source of marketable profit, rather than domestic ornament.

As an ornamental branch of what is termed ladies' work, it has been long known and practised in Britain; but its introduction, as an article of general manufacture, is much more recent than the first practice. The introduction of it into the western part of Scotland, where it is chiefly exercised, hardly ex-
A CHAINWORK.

ceeds the period of thirty years; and in the early instances, it was chiefly under the direction of foreigners. As the art, which is very simple in its principle, but requires a great degree of manual dexterity and practice, became more extensively used, means to obviate two inconveniences attending the tambour, or drum tent, were first employed.

It was found convenient, where a piece of cloth was broad, and a pattern close and tedious, to employ a number of hands upon the same piece; in order that it might be quickly finished and brought to market. Hence the invention of the common tambour frame, now universally used in those districts of Britain where the manufacture is practised, took its rise. This tent, or frame, is excessively simple, consisting merely of two parallel rollers placed horizontally in a wooden standard, and furnished with ratchet wheels and catches, to preserve or augment, when necessary, the tension of the cloth. When the cloth is 2 or 3 inches broad, six girls may be employed upon the same piece without impeding each other while at work, and by dividing the cloth, which is stretched between the rollers, at one time, either into equal portions, or according to the capability of the respective workers, it must be evident that a very powerful spirit of emulation will be excited, which will very far overbalance any disadvantage arising from delay, in any of them detaining the others while finishing her particular portion.

The operation consists in drawing the loop of a thread successively through the other loop, so long as the work is continued, and as all those loops would be undone in a moment, merely by pulling the end of the thread which has been used, it becomes necessary to make the end fast, either when a thread is exhausted, or a figure finished. The appearance of the chain will be found by inspecting Fig. 5, Plate CXXXVII.

To apply tambouring to ornamental purposes, the variegation of these chains is all that is necessary; but the judicious application of this to actual practice, is the great excellence of those who are esteemed most dextrous at their business. From this the whole art may evidently reduce itself to two heads, viz. chaining, and directing the chain. The first of these is that property which brings the art of tambouring within the general scope of this article. The second is that particular application of chaining, which fits it for the special purpose to which it is to be peculiarly applied. The chaining part of the operation is in every particular analogous to the principle of the stocking manufacture, excepting that we may fairly consider hosiery as a superficies, and tambouring as a succession of lines, drawn in such directions as to constitute a superficies of that form which we require, and that this latter superficies only partially covers another, which forms the plane upon which it is placed, for the purpose of ornament.

As an article of manufacture, considered as a source of national or individual wealth, the tambour manufacture may be regarded in three points of view.

1st. As it becomes a source of employment to the poor and laborious classes of the community, and how far either general or individual comfort may be promoted by the cultivation of the art; and, consequent", how far, in a moral point of view, it may have been either beneficial or injurious to society.

2dly. If considered merely as an article of innocent luxury, what proportion of the population of Britain may be fairly directed to it, without prejudice to the exercise of relative duties more important and indispensable?

It has been computed that the tambouring of muslins, when at its greatest extension, employed at least 20,000 females, either wholly or partially. Of these females, many lived in the vicinity of Glasgow, the chief seat of the manufacture, and others were scattered through almost every part of Scotland, and supplied with work and money by agents employed by those manufacturers who found it their interest to embark extensively in the business. Whether the diversion of even the occasional industry of 20,000 females from all the common duties of life, for the purpose of ornamenting a few rags, which would hardly bear the alkaline deterioration produced by half a dozen of washings, was a proper direction of the energies of a country, may be very fairly questioned. Even in the most remote parts of Scotland, while the business was general, the effects were prejudicial both to the morals and the comforts of the people. In Glasgow, they were to the last degree deplorable; a tambourer of ordinary dexterity could, in general, earn five or six shillings a week, by constant application. By those vicissitudes of price which the almost constant fluctuations of the mercantile system produce, much less could sometimes be obtained. To the labouring artisan, who could with difficulty procure the necessaries, and but seldom the comforts, of life, the possession of a few daughters became really a source of wealth; every thing therefore was, in most instances, sacrificed to the tambouring. At five years of age when it was found that a child could handle a needle, and perhaps earn a shilling or two in a week, every idea of education was instantly abandoned. A female child was rendered incompetent to the performance of any one social duty, that she might bring a shilling or two more home upon Saturday. The children finding their pecuniary value, soon began to think that the application, as well as the earning, of money, came immediately within their proper cognizance. The consequence was natural; theft and prostitution followed so closely upon the heels of misdirected industry, that many never saw the age of 20 years! The picture could be much more highly coloured, but it would become nauseous and disgusting. The outline is faithfully drawn from long observation, and could be confirmed by viewing the untimely graves of many thousands! Were the picture coloured, it would be unfit for human view!

It would be a ridiculous affectation of morality, which could hardly gain credit, to say, that these were the chief objects which directed the attention of the author of this article to the invention of the machinery, by which this direction, or mis-direction, of human labour might be at least in a great degree superseded. But although this might have, in some degree, resulted, or may still perhaps result, from the use of the machinery, if the demand for tambour work continues, the immediate stimulus, as in all commercial pursuits, was directed by personal interest. By restoring a number of efficient
beings to the exercise of fair industry, in objects which promised to be of great benefit, both to themselves and to the public in general, he might indeed have done some good to society. The immediate use of the machine, it is his present object to describe, and this may perhaps prove more likely to attract the attention of his reader.

The first idea of this machine arose from a casual conversation with a gentleman, at that period extensively engaged in the muslin manufacture, and fond of mechanical pursuits. Some study convinced the inventor, that the construction of a machine, which, by bringing into action a great number of needles at the same time, would shorten the process by manual labour, and might be rendered actually efficient, was perfectly practicable. The diversification of pattern seemed to constitute the whole difficulty, and the application of Sir Isaac Newton's principle of two forces acting at right angles to each other, presented a facility of overcoming this obstacle, which encouraged him to proceed. To apply this principle in the various ways which might effect his purpose, did not occur for a long time afterwards, and his first idea was confined to the construction of a machine, which might be put in motion by a person who should exercise his discretion in shaping the pattern, whilst he should be enabled to perform all the other operations by the pressure of his feet. It seemed more easy to move the cloth than the needles, and for this reason the cloth frame was made to shift in both directions; at the same time he received a suggestion, that a perpendicular position might admit of many conveniences of which a horizontal one could not be made susceptible; and satisfied of the justice of the remark, he immediately adopted it. After some consideration, a machine was constructed under his direction, and afterwards a second, which he casually superintended, being at that time engaged in other pursuits. After two years, he formed a connection, by which his whole study and time were to be devoted to the completion and practical application of his invention. Six of the machines were set to work in this way, after which he went to London by the company, in order to procure the patent, and comply with that proviso common to all patents, which requires a specification of the invention to be enrolled in the Court of Chancery within thirty days of the sealing of the patent. At this period, the idea of rendering the machine automatic had barely presented itself to him, and consequently the last part of the specification which describes the possibility of applying mechanical power, is stated as merely prospective. Upon his return, he extended and applied this principle so long as the work was under his direction. The results of that experience, and what has since occurred to him, will be found in the description which follows.

In Plate CXXXVI, are represented four elevations of this machine, according to the latest improvements made upon it. Fig. 1. is a transverse elevation, viewed in front, or at that part where the person who has the care and superintendence of it is supposed to be placed. At A A A, are three up right posts, being exactly one half of what are used, those behind corresponding in every respect with those in front. At B is a horizontal cross rail, of tambouring. The frame in which the cloth is stretched appears at C, the lower beam and under part being concealed by the beam D, but correspondent in every particular with the upper part, which is visible. At E is the middle frame, which in that work contained 54 needles, each being placed at the distance of one inch asunder, and designed to tambour a piece of muslin 6-4ths wide, one whole row being wrought at the same time. The cloth frame is suspended, so that it will move freely, and without the exertion of much power, either upwards or downwards; and with equal facility from right to left, and vice versa. To ensure this, the roller G is placed above; and in order that both sides of the cloth frame may rise and sink equally, cords are attached to each end, which, after passing a sufficient number of times round the roller G, descend upon the opposite side, where the weight of the frame is nearly, but not quite, counterpoised by the weights L L.

The tension of the cloth is preserved by ratchet wheels and catches to either roller, precisely as in a common tambouring tent; and in order that it may be stretched laterally as well as vertically, at each side was a piece of iron filled with wire hooks, which took hold of the selvage of the cloth, and which operated exactly like those frames for drying cloth, used at bleachfields, and called by the name of stenters. In the double framing at the right hand, that part of the machinery which forms the pattern is contained, and this consists of four wheels fixed upon the same axis, which was a bar of iron one inch square. Of these wheels, three were 18 inches in diameter, and one 26 inches. The wheel nearest to the front of the machine is a ratchet, and merely regulates the motion of the others. It was customary to form two flowers by one revolution of the axis, because when the flowers were similar, every second row was reversed, and when dissimilar, every alternate row was of the same form. In the first case, the ratchet-wheel formed a flower by half a revolution; in the second, the number of teeth corresponded to the number of loops or stitches in the respective flowers. The next wheel in order communicated the horizontal motion to the frame, in which the cloth was suspended; the third wheel gave the perpendicular motion; and the fourth, or 26 inch wheel, gave a rotary motion to the needles upon their own axes. The second and third wheels, of course, were those immediately employed in the formation of patterns; and it may be proper in this place to give some account of the principle by which they were fitted for this purpose, as it is by far the most curious and least understood part of the whole machinery.

The principle upon which this motion is constructed, and which is susceptible of infinite variety, depends upon the two following corollaries to the third law of motion, as given in Sir Isaac Newton's Principia, and extracted from Mr Motte's translation, edition 1803, pages 15, 16.

"Cor. 1. A body by two forces conjoined will describe the diagonal of a parallelogram in the same time that it would describe the sides of these forces apart.

"Cor. 2. And hence is explained the composition of any one direct force out of any two oblique forces;
and, on the contrary, the resolution of any one direct force into any two oblique forces; which composition and resolution are abundantly confirmed from mechanics."

Upon the application of this theorem, that profound and illustrious philosopher founded the first rational and satisfactory explanation of the causes of the elliptical orbits of the planets, and accounted for the causes by which the whole system of the universe is regulated; and the recent discoveries of La Place, and other eminent philosophers of the French school, are merely extensions of the same general law, involving the effects produced by the gravitation of the planets towards each other, as well as towards the sun.

To apply this principle to the construction of the tambour machine, or any other requiring extensively varied motion, it was only necessary to produce two direct motions, which, as being the most simple and efficient mode of construction, were placed at right angles to each other, one being in a vertical, and the other in a horizontal direction; and as it is easier to communicate motion to one body than to many, it was found better that the motions which produced a relative change of position between the cloth and the needles, so as to regulate the successive points of perforation, should be given to the former rather than to the latter. In the first construction of the machine, the motion given to the cloth frame was effected by two screws, one placed vertically, and the other horizontally. As the machine in this state was wrought by the operator's hands and feet, and entirely under the guidance of his discretion, the screws were turned by his hands, by two small winches, so calculated, that when either winch was turned to the extent of a quarter or quadrant of one revolution, a shift of the cloth, equal to \( \frac{1}{4} \) part of an inch, was produced. This was found a proper length when the motion was directly given by one screw, either vertically or horizontally. But when any intermediate angle was to be formed, it required that the shift should be less in both screws, as the oblique line produced by the combined action of both screws was always greater than either side apart, in the same ratio that the hypothenuse of a right angled triangle exceeds that of either of the sides. When the screws were judiciously turned, this operation succeeded very well; but as the ratio of the one to the other constantly varied, even the most careful operators, totally ignorant of the most simple elementary principles of trigonometry, were in constant danger of error; and when entrusted to women or boys, which considerations of economy rendered peculiarly desirable, it was found impossible to place much reliance upon the quality and regularity of the work. These reasons, therefore, induced the inventor seriously to endeavour to find some remedy, which, by fixing the motions of the machine under regular mechanical laws, should entirely remove both the blunders and inaccuracies of human agency, and this lie was enabled to effect by removing the screws, and substituting the traverse wheels. When this point was gained, very little more was necessary to render the machine entirely automatic, and this was speedily effected.

In order to form a rule by which a pair of wheels may be formed, to produce a straight line at any angle of obliquity, nothing more was necessary than to construct a table of trigonometrical calculations from \( 1^\circ \) to \( 89^\circ \) inclusive, the measure of the hypothenuse being always the side given \( = \frac{1}{12} \) of an inch; but to execute such minute measures with accuracy, it became necessary to invent a machine for the regulation of those divisions. In order to effect this, he availed himself partly of the principle of the common clock-makers' cutting engine, and partly of the best description which he could find of Mr. Rainsden's celebrated machine for dividing astronomical instruments. Combining these with such variations as suited his particular object, he contrived a cutting engine, by which he was enabled to cut with considerable precision and accuracy to divisions so minute as the 1200th part of an inch, and this was found quite competent for every practical purpose.

When the cutting machine was completed, the given measure of \( \frac{1}{12} \) was effected by turning a handle or winch 18 revolutions, consequently 18 became the constant measure of the hypothenuse; and from these the vertical shift was equal to the perpendicular of the triangle; the horizontal shift to the base; the angle of obliquity contained between the base and hypothenuse, constituted the deviation from the horizontal line, and its complement the deviation from the perpendicular. If this table be geometrically examined, it will not be found absolutely correct; but taken as an approximation for a practical purpose, its greatest deviation will not exceed \( \frac{1}{1200} \) part of an inch, which was deemed sufficiently near.

From this table a very correct practical rule was found for straight lines in every direction of obliquity, and the curved lines were constructed in a similar manner, by supposing every curve to be the arc of a circle of some specified dimension. That none of them could be geometrically circular, will be obvious from the simple consideration, that being a succession of loop or chainwork, the tendency of the thread or yarn was always in a direct straight line when stretched, and consequently all circular curves were treated as inscribed polygons, the number of whose sides was so great, and the measure of each so minute, as to render the deviation from an actual circle imperceptible to the eye.

The Polygonic Tables, a few of which are annexed as specimens, were then calculated, to show by inspection the angle which each would form with a horizontal straight line, and these were instantly found merely by referring to the tables. In order to apply these tables to the formation of any pattern required, the usual and perhaps the easiest way, was generally to draw the pattern upon a very enlarged sheet. To calculate the number of loops required was the next object, and this in straight lines was easy from actual measurement, 52 loops being always allowed for an inch. The curves being always supposed to be arcs of some circle, were found by the common analogy which the circumference of a circle bears to the diameter, the medium proportion as 115 to 555 being generally used. Were more minute calculation necessary, elliptical, parabolic, and hyperbolic curves, might have been very minutely found; but it never appeared necessary in a business which only required a sufficient portion of accuracy to please the eye, to expend time upon such extreme nicety.
These were the general rules observed in this business; and the Tables, with short explanations of each, will be found at the conclusion of the article.

The cloth frame being loosely suspended, and its motion regulated by the cylinder above, it was further suspended by the centre from one end of the lever H, the other end of which was connected by means of two stout iron wires, with a piece of iron furnished with a small friction-wheel, and acting on the rim of the perpendicular traverse wheel directly under its centre. The tendency of the frame to descend, produced a gentle pressure of the friction-wheel against the rim of the traverse, and according to its shape the frame was either lowered or raised at every shift of the wheel.

The communication between the cloth frame and the horizontal traverse, was effected merely by a small connecting bar of iron between the edge of the cloth frame and the wheel, the rod being placed directly level with the centre of the wheel. The pressure against the wheel was very simply effected, merely by tying a piece of whip cord to the frame, and after passing it over a pulley, suspending a small weight to the other extremity of the cord. A screw was also attached to the breast-beam, by which the cloth frame could be raised at pleasure, to present fresh cloth, by shifting a notch in the suspending rod C. Thus ten or twelve rows could be wrought without shifting the beams upon which the cloth was stretched. The general motion was communicated by a leather belt passing over the pulley at N, and the machine could be engaged or disengaged at pleasure, by means very similar to those used for other machinery. When a flower was finished, the ratchet wheel moved a small lever, which instantly stopped the machine, in order to prevent accidents. There were three treddles below, moved by wipers upon the cross shaft, by which all the motions were given. The first, P 1, served to set forward the needle frame, so as to produce the perforation of the cloth by the needles; the second, P 2, set in motion that part of the machinery which supplied the needles with thread, and which is afterwards to be described; and the third, P 3, moved the ratchet-wheel one tooth between every perforation. These were the chief motions in front of the machine. Some idea of those behind may be formed by inspecting Fig. 2, which is a view taken directly behind the machine.

Of the parts here visible, those which can be seen in Fig. 1, are distinguished by the same letters. The remaining parts are as follow: At Q is a roller or cylinder of wood, which gives motion to the needle frame; it is operated upon by a chain or wire, communicating with the treddle, which produces the perforating motion, and returns by the gravitation of a weight suspended from a stud in the opposite side of the cylinder, as soon as the pressure is removed. At R appears that part of the machinery which, by the operation of the treddle P 2, gives the rotatory motion which supplies the needles with the yarn, and which will be better understood by referring to Fig. 2, in Plate CXXXVI. At T, Fig. 2, Plate CXXXVI, is a lever suspending a weight which elevates the ratchet R, as soon as the pressure of the wiper is removed from the treddle. At S is a guide by which the motion of the ratchet is regulated. At U is the weight which produces the returning motion of the needles to the front, after being supplied with the thread. At V, V are two studs driven or screwed into the roller Q, with joints, by which the connection is formed with the back part of the needle carriage, to produce its reciprocating motion. In Fig. 3, is a profile elevation of the left hand part of the machine, or that most remote from the CXXXVI. traverse wheels, and contiguous to the part where the moving power is applied. In this figure the upper part of the cloth frame appears at C, with one of the ratchets for distending the cloth. The upper roller is at G, and the balance weights guided by the pulleys at C, appear at L. At O is the centre of the shaft which carries the wipers, and at Q the back roller, as in the preceding figures. At d is a piece of iron by which is suspended an iron bar, which opens and shuts the bars or hooks of the needles. At b is a profile of the needle carriage. At E is the needle frame, the form of which is now more apparent. At d is a screw which serves as a stop for the carriage, and which may be tempered at pleasure.

In Fig. 4, the forms of the traverse wheels become more apparent: 1 being the rachet, 2 the horizontal, 3 the perpendicular, and 4 the needle traverses. At 5 and 6 are the centre screws, in which the axis revolves.

In Fig. 5, Plate CXXXVI, is a horizontal section of the machine immediately above the needle-frame. In this figure, many parts, partially or wholly concealed in the former, may be seen in their proper forms. The letters of reference denoting the particular parts are preserved the same as in the former figures, and a short recapitulation, with such occasional remarks as may occur, will probably be sufficient for the purpose of further illustration. Let the frame work be supposed to be cut asunder immediately above the level of the needle frame, and the six posts which support and connect the framework, will be represented by the letter A, six times repeated. Of this frame-work, the larger department at the left hand contains the general part of the machinery, whilst the smaller part to the right is exclusively appropriated for that portion which is peculiarly constructed for the formation of the patterns. At C appears a horizontal section of the cloth-frame, the top rail and upper roller being cut away. Immediately below the upper roller is a cross bar placed with its edge towards the cloth, and another bar exactly similar is placed below. These serve to keep the superficies of the cloth always at an equal distance from the points of the needles; as the diameters of the rollers are constantly varying by the cloth being unwound from one and rolled upon the other. At E is the horizontal view of the needle-frame, consisting of two strong iron bars, placed parallel to each other, at the distance of about four inches, with their edges upwards. Of these, the bar nearest to the front of the machine is perforated with small round holes at equal distances, the centres of the whole being exactly in the same straight line. The front bar, or that nearest to the cloth, is cut into triangular notches, also at equal distances, and which serve for the second support of the needle-handle. The triangular form was found superior to
any other, because the handle, always pressing by its own gravity towards the acute angle below, touched both sides, and consequently left no room for the handle to shake, which would soon have been the case, by mere friction, even in the most accurately fitted bow. Besides this, it afforded a great facility for changing any needle which might accidentally be injured, and substituting another with little delay or loss of time. The bar next to E, after being bored, had another thin bar of malleable iron screwed to it, through which a number of small holes were drilled, and tapped to receive small screws, the centre of each small hole corresponding, as nearly as possible, with that which received the extreme pivot of the needle handle. These screws, the heads of which appear nearest to E, were found of very great practical utility; for if any small variation took place in the length of a needle when placed in the handle, it could be instantly corrected by turning the screw behind, either backwards or forward, as the case required; and thus all the points of the needles were preserved in the same straight line, and at equal distances from the cloth, notwithstanding any trivial inaccuracy in the setting. Contiguous to the bar furthest from the cloth was a slip of brass cut into the form of a rack, and extending somewhat more than the whole length of the frame. It was hung to the bar so as to move freely from side to side, and by means of a small pinion of 16 leaves upon each handle, communicated a rotatory motion to the needles upon their own axes, either from right to left, or vice versa. The teeth being below, neither the pin nor the pinion can be seen in Fig. 5; but the mode of operation is distinctly visible in Plate CXXXVII. Fig. 1. Behind the cloth frame, at a few inches distance, is a cross rail or beam of wood, which carries all that part of the machinery which was appropriated to the purpose of supplying the needles with the thread, or as it is used to be called by the work people, the feeding machinery. On the centre of this beam, at R, was a small frame of cast iron, in which was the wheel work necessary for the rotatory part of the motion. The other motion was a reciprocating one, alternately approaching to and receding from the cloth, which was effected by an apparatus below, part only of which is visible. The use of both motions was as follows: 

1st. In order to throw a loop into the hook of the needle, it was necessary that the thread should pass round the stem of the needle in the interval between the time when the perforation was completed, and that when the needle returned after receiving the loop. This was performed by a separate set of brass needles similar to those used by weavers for the weaving of lappets, and which are described under the article Cloth Manufacture. The motion of all these needles being entirely the same, they were driven into a bar of hard wood at distances equal to those of what were termed the working needles, in the needle frame, so that they might correspond with each other respectively. Consequently a single rotatory or circular motion communicated to this bar, gave a corresponding motion to every needle which it contained. By these means, after the perforation had taken place, the first motion was a circular one of the feeding needle round the working one, which lodged the loop upon the stem of the latter. But as it was necessary that the working needle should be shut by a slider, to prevent the bar from injuring the fabric of the cloth when returning, it was also necessary, that before this operation took place, the thread should not only be thrown round the stem, but drawn backwards into the hook. This second operation was effected by the additional apparatus below.

A third motion was also necessary to insure the certainty of the hook always catching the loop when drawn back; and as the working needle required a rotatory motion on its axis, it became necessary that a corresponding motion should be given to the feeding needle, so that one should be always as nearly as possible in the directly opposite part of the circle to the other. The means by which all these different motions were effected, will be best understood by describing the particular construction of the machinery behind; and this is more clearly represented in Figure 6. than in any other part of the Plate. The frame which contains all this part of the machinery, is represented at A, and a small additional frame is placed behind at P, for a certain portion of the wheels. The whole of this frame is to be fixed firmly upon the centre of the cross-rail behind, and at right angles to the rail, so that the oblique point O may project towards the back part of the cloth, at a few inches distance. The oblique projecting part of the spindle, or axis at O, is designed to answer the purpose of any common revolving crank, by moving round a given point, and carrying with it the bar in which the feeding needles are driven; and this motion is very simply effected by the perpendicular rack D working into the wheel C, which is loose upon the axis. The rack D is fixed to an upright or vertical rod of polished iron, sliding freely in two guides fixed to the rail or beam which carries the whole apparatus. The lower part of this polished rod is worked by the middle treddle, so that when the treddle is forced down by the wiper, the rack descending gives rather more than a full revolution to the wheel C. Attached to this wheel is a circle of brass E, larger in diameter than the wheel C, and furnished with a spring catch G, which rests in the wheel F, which is a ratchet. This, when C is pulled down the spring G, acting upon the ratchet F, which is fast upon its axis, carries it round, and as the spring does not work in the contrary direction, the rack returns for the next stroke, without bringing back the spindle; which would undo what had been done. Thus the whole revolution of the spindle is uniformly one way without returning. This is all that is necessary for the rotatory motion.

That motion, by which the feeding needle is always placed in the opposite part of the circle to the working needle, is effected as follows, by the wheels in the small frame behind. On the extremity of the spindle is fixed the pinion I, which revolves along with it, giving motion to the wheel with which it is connected, and which is loose upon its axis. To this wheel is fixed the ratchet K, containing only two notches which bisect the wheel, one being at each extremity of its diameter. The spring catch L pressing on the circumference of the wheel, catches each of these notches in succession; the effect of which will be immediately seen. The wheel L is fast upon the axis, and is wrought by the rack M, which is screwed to a cross bar deriving its motion from the
largest traverse wheel. Upon the large spindle the pulley at H carries a small band passing two or three times round it, and from each end of which is suspended a weight. That represented at N is much heavier than the one suspended from the opposite side, as its intention is to pull in a direction contrary to that of the impelling power. This excess of weight must be sufficient to pull back the band by friction, after the pulley has been stopped by the spring-catch I, laying hold of one of the notches in the ratchet K. The effect of this apparatus is as follows. When the main spindle O has performed a revolution, or somewhat more, by the descent of the rack D, any excess is instantly cured by the joint operation of the balance-weight N, and the friction of the rack D in reascending; and the position of the tooth in the ratchet K becomes the stop by which the relative positions of the feeding and working needles are preserved. Merely for the sake of convenience, the calculation between the front rack for the needles and the back rack for moving the regulator K, was taken as two to one. Both derive their motion from the inverted levers KK, (Fig. 1.); and hence the range of one will always be proportional to that of the other. When the inverted levers are shifted either way, the needles before, and the regulating ratchet behind, change positions by the same power, and at the same instant. The perpendicular rack gives always more than a full revolution to the feeding crank, but the excess is instantly corrected by the action of the counterpoise N, and thus the relative position of the two frames is uniformly and correctly preserved. When the motion of shift is in the contrary direction, the spindle O is carried with the rest of the apparatus, to which the moving wheel C, being loose, presents no obstruction.

Of the operation of that part which produces the second, or reciprocating motion of the feeding-bar, the most exact idea will be formed by referring to Figures 3. and 4. In Fig. 3. a profile elevation of it is given, in which almost every part may be distinctly seen. Let A represent a cross section of the beam which carries the whole feeding apparatus. From this beam descends two projecting arms; one of which appears at B, and the other is in every respect similar. Their horizontal appearance appears behind R, in Fig. 4. Between these arms is a cross shaft, placed so as to vibrate freely in the centres; and at each end the perpendicular arms are joined by the cross shaft, the arms being fast upon the shaft. From the middle of the shaft, the lever E projects at right angles to the arms, and at the extremity is fixed a weight, in order to give it a tendency to descend; by which descent the perpendicular arms are impelled forward towards the cloth. From the upper part of the perpendicular arms, a connection is formed with the back part of the feeding bar, by means of two wires, with a hook or eye-joint at each end, to prevent them from impeding the circular motion of the bar. When the lever E is at liberty, the weight descends, and the feeders spring forward close to the cloth. When the perpendicular shaft which carries the rack of the feeding machinery (D. Plate CXXXVI. Fig. 6.) reascends, a jointed catch, represented at F, catches the projecting arm E, lifts it up, and produces the retrograde motion of the feeding needles, in order to pull the threads close into the bars of the working needles. When the working needles are shut, and leaving the cloth, a small hammer, fixed to the back wooden roller, by striking a crank, forces back the catch; and the projecting arm E descending, brings the feeding needles again close to the cloth. Thus the reciprocating motion is communicated to the feeding bar. The form of the crank at O is useful for this motion, because it tends, when the bar recedes, to bring back the threads much more fully into the bars of the working needles, than a rectangular crank, where much of the obliquity would still be preserved, could effect. In the first experiments, cranks of the common kind, and similar in appearance to what is represented by the lower dotted lines, were employed, and afterwards abandoned for this special reason, and after their inefficiency had become apparent from actual experience.

The chief parts of this complicated machine being now described, at a length as great as the limits of our work can admit, and perhaps tiresome to some readers, the mechanical description shall be concluded with some remarks upon that part of the machine, which is, of all others, that which requires the greatest portion of attention, and upon the accuracy of which the chief, if not the only difficulty, in actual practice was found. This lies in the construction of the needle, and apparatus belonging to it; and what illustration can be given by representation, without a great multiplication of figures, will be found in Figure 2.

The tambouring bears so strong an analogy to the stocking manufacture in the chaining, that at first the experiments were made with needles in every respect similar to those of the stocking frame, that is to say, with bent pieces of iron-wire, shut by the pressure of an iron bar, and re-opened by their own spring or elasticity. A very few trials proved this to be inapplicable to tambouring, for three reasons: The first of these was, that, by bending the wire, the flexure, which really formed the point of the needle, was too blunt to perforate the cloth, without risk of injury to the fabric; and the metal was too weak to bear sharpening after the flexure was made. The second was, that the pressure of the bar which shut the barbs, also made the stems yield very considerably, and this was apt to injure the cloth. The third reason was, that, in order to present the barbs to the action of the pressing bar, the needles required constantly to be brought back from the position necessary for the pattern, to one where the barbs would be vertically over the stems. In order to remove all these objections, a principle was adopted, by which all those objections were removed. The hook, or needle, was manufactured from solid wire. The barb was made very short, like that represented in the figure. The closing of the barb was effected by a small slider belonging to each needle, and the pressing bar entirely removed. The barb of the needle was cut like those of common fishing hooks; and, like them, the needles were made from steel wire, so as to be susceptible of tempering. This afforded a facility of sharpening the points, as much as those of sewing needles, and removed the other objections, as they could now be opened and shut in any position. In this improved state, their appearance will be found very much such as in
**Plate CXXXVII.**

**Figure 2.** This figure represents a section of the needle frame, the rack by which the handles are made to revolve, and all the apparatus for opening and shutting the needles. The point and barb of the needle appear at $a$; and the slider, which is partially sunk in a groove, sunk longitudinally in the stem of the needle, is at $b$. The slider is merely a piece of pointed wire, which has also a longitudinal groove, and is pointed pretty sharp. The slider was at first fixed to a piece of flat brass, with waxed silk, as fishing hooks are tied; but the silk is often cut, by friction and other causes, so it was found better to cast a socket of tin round them, of the shape which the slider presents in profile. This is a socket of brass, bored so as to fit the handle exactly, and slide freely upon it. The upper part of this socket being flattened, to receive the tin into which the slider is cast, they were screwed together; a slot being cast in the tin to allow it to slide a little back or forward, for the purpose of fitting the tin, so that the points of the slider and needle might correspond when shut. At $f$ is a section of a cast-iron bar extending across the machine, being the same as is represented in Fig. 1. Plate CXXXVI. at $E$. By the oscillatory movement of this bar, the sockets slide backward and forward on the handles, to open and shut the needles, each socket being grooved to admit a notch of the bar. The handle is at $g$, the pinion at $h$, and a profile of the rack at $i$.

These are the principal mechanical parts of the machine, which has been found to answer very well, and is still in use. Its chief defect is its complexity, and the fanciful nature of the work for which it is employed. For this reason, the reader will perhaps pardon the lengthening of the article a little, for the purpose of considering its practical economy, in point of expense, produce, and return, especially as those remarks are accompanied by a description of another machine, since invented, by the writer of this article, the expense of which will not exceed one-tenth part of that of the present, and whose product must be vastly greater. It is also so different in its principle, as to invade no one particular upon which the former patent rests for its validity. Mechanical descriptions, in general, also so very seldom embraced considerations of economy, or mercantile calculation of any kind, as often to be dangerous, instead of proving really useful.

**Economy of this Invention.**

It has been very generally and very justly remarked, that of the numerous speculators and projector in mechanical inventions, very few, if any, derive benefit or emolument either from their genius or their labour; but that those who succeed them very frequently do. The causes of this phenomenon are of the first importance, to both the man of science, who devotes his time, his labour, and generally the most valuable part of his life to pursuits of this kind, and also to the capitalist, who, allured by the prospect of exorbitant profit, after expending large sums in untried speculations, ninety-nine times in a hundred finds his golden dream suddenly interrupted, and heavy loss the consequence of embarking in the dark, with no other guides to direct his course but cupidity and credulity. The experience of this invention affords a very fair, and, if properly considered, a very salutary, lesson to both these descriptions of people; and the author of this article does not know how he can discharge a more important, or more useful duty, than to present to others the results of long and dearly purchased experience. In the expectations of profit to be derived from every new invention, it is necessary, in the first instance, to examine, with as much accuracy as the nature of the business will admit.

1st. What is likely to prove the reduction of labour, and, consequently, of expense attending the improvement, supposing it to be completely successful.

2d. Of what nature is the business, and what prospect does it present of employment, extension, and permanence.

3d. Under the peculiar circumstances of the case, what capital will it require, both to overcome the constant impediments attending new experiments; to mature the invention; and, finally, to establish the business upon such a scale of magnitude, as will ultimately remunerate the adventurers.

Respecting the first of these points, the prospects attending the completion of this discovery were sufficiently alluring. The tambouring business had been established in Scotland for upwards of twenty years, and it might have been very safely assumed, that from twenty to thirty thousand people were either constantly or occasionally employed in it. During all this period, although, in common with every other branch of the muslin manufacture, it had undergone occasional vicissitudes, still, after every stagnation, it had constantly revived, and become equally or more flourishing than ever. Consequently, it seemed sufficiently rational to assume, that it had become a permanently established trade in the country; which, although subject to the vicissitudes common to all trades, and especially to those whose basis is rather founded on luxury than actual necessity, presented every prospect of holding a certain place in the general mass of manufactures at all times. It seemed further warrantable to conclude, that every improvement, which, by diminishing labour, must ultimately lower the price of the commodity produced, would contribute to its further extension, by bringing it within the reach of the most numerous class of the community, who were withheld, not by want of desire, but by want of wealth, from obtaining it. The monopoly attending the possession of the exclusive right of manufacture, also held out the most flattering temptation to the possessors, by affording a prospect of bringing the whole trade almost under their immediate control. Such prospects might very naturally be supposed to operate powerfully, both on the inventor, and those who embarked with him in the speculation; and, indeed, it would have required a more than ordinary share of moderation, not to have been sanguine in the anticipation of success.

Respecting the capital necessary, it was more difficult to form any precise or definite idea. Much must depend on the scale of magnitude upon which the business was to be conducted, and how soon its returns would be sufficient to furnish the means of its own extension, as far as prudence would warrant. When the business was begun, the first difficulty which presented itself, was the most proper means of providing the requisite machinery. At this time
the patent had not been taken, and it became necessary, therefore, that a mechanical establishment should be provided, both in order to preserve the secret until legally secured, and to furnish the means of executing, with facility and dispatch, such improvements as must be constantly suggesting themselves in an infant undertaking.

The number of mechanics, and the tools and materials necessary for their work, required a very great expenditure before any return could be expected; and with the difficulties attendant on first experiments, it was upwards of twelve months before eight machines were completed. When the machines were set to work, almost the whole depended upon keeping the needles in a proper working state; and from the similarity of their construction, men bred to the stocking manufacture, were deemed the fittest for this purpose. But in order to induce these men to abandon the profession to which they had been bred, it was necessary, in the first instance, to hold out at least some stimulus of advantage; consequently the wages were high, generally about seventeen or eighteen shillings weekly. With the disadvantages of a new business, and the impossibility of at once paying wages proportional to the quantity of work, this large sum in a great measure counteracted the diminution of price produced by the quantity wrought by the machine, and the work was not very greatly cheaper than that done in the ordinary way. In order to get rid of this, which in a great degree counteracted the saving, it was proposed to employ boys, who might be procured for five or six shillings a week, and merely keep one or two men as superintendents.

The reduction of price now became much greater, and the business afforded a much fairer prospect of success; but as the formation of the pattern was still entirely at the discretion of the worker, it was found almost impracticable to get giddy children to pay proper attention to the quality of the work. Conscious that if these defects were not remedied, the improvement must be still inefficient, the inventor set himself to contrive some means by which the pattern might be subjected to regular mechanical laws, instead of discretionary operations, upon the accuracy of which certain reliance could not be placed, and had proceeded to a certain extent with his improvements, when he was dispatched to London to procure the patent, and execute the specification. Upon his return, the improvements were completed, and he now indulged the flattering hope that he had at length matured his invention. The other partners, entering into his views, purchased the lease of a large house, with a steam engine, and removed the work to the new situation. Two machines were immediately set to work, and besides great improvement in the work, the average quantity was more than tripled.

When these machines were set to work, boys were still employed to attend them; but this again produced an inconvenience of another kind:—their parents only kept them employed whilst it suited their own convenience; and whenever it appeared advisable to place them as apprentices to any regular business, they were suddenly withdrawn, frequently without notice, and the machines left vacant, until a substitute could be found and instructed. These reasons suggested the idea that young women, not under sixteen years of age, might be more beneficially employed, as the wages might be safely paid fully as high as could be earned by any other employment, and at the same time so low as to yield a great profit upon their work. By these means, and some improvements on the machinery, the work was gradually brought to the state in which the inventor left it. At this period, the following statement, taken from an average of three months, will shew its actual state.

The flowers upon the cloth, it has been already observed, were at an inch distance, and the rows placed in the bosom of each other, so as to form diamonds. When the diamonds were truly formed, there were 72 rows in the yard, and this was most commonly the case, although sometimes the rows were a little more sparse. Hence the number of flowers upon a yard in length were 3888, and in a piece of 10 yards 38,880. But as a small excess of measure is always allowed, in general, it might be assumed, that the flowers upon a yard were 4000, and upon a piece 40,000. The number of loops or stitches in a flower also varied according to the pattern, but the average might be fairly taken at 50 to each. According to the common rate of paying work of this kind by the common manual process, the price might have been pretty fairly estimated at two shillings and sixpence per yard, or twenty-five shillings per piece. These prices, indeed, are liable to almost constant fluctuation, according to the quantity in the market, and the demand for them. Sometimes three shillings, or even three shillings and sixpence were given, at other times they might perhaps be obtained, for a short time, at two shillings, or two and three pence; but the price quoted may be considered as a low average for good work. When wrought by the machine, the price was fixed at nine pence per yard, but in order to stimulate the workers to do their work, when more than 15 yards were done, two pence per yard was allowed. The effects of this system soon became apparent. Ten yards per week were at first thought to be a great quantity, but in less than three months, the minimum (accidents excepted) was 14 yards, and the maximum 22 yards. The average of the whole might be taken at 15 yards, or 60,000 flowers per week. The lowest quantity, compared with very constant exertion in the common way, was in the ratio of about 16 to 1, and in ordinary cases nearly 24 to 1. Every machine therefore enabled one person to do the work of 24. It will appear from this, that the rate of wages had risen very high, and far above that of any other employment. But as this had in a very short time arisen from the great improvement of the business, and as the inventor considered the good faith of the company pledged at least for some time, he prevailed upon them to continue the prices without reduction, so long as he continued to manage the work, which was only a few months. What has been the rate either of work, quality, or wages since that time, he cannot say, for from this period he seldom visited the work, and a few months afterwards, circumstances occurred which made him resolve to visit it no more. Since then he has never seen it. From these premises the following practical conclusion may perhaps be fairly drawn; that the constant demand exists for a manufacture, a reduction of the price of labour...
of at least three fourths of the whole must be a certain source, either of emolument to the adventurers, or of saving to the consumers. If the demand be such, that the former sale prices can be altogether or nearly maintained, while the expense of manufacture is greatly reduced, the emolument must accrue to the speculators. But if from competition, either of the same or similar manufactures, the sale prices are greatly reduced, the speculator may barely receive a competent profit, or may sustain an absolute loss, whilst the consumers derive the whole benefit of the discovery, by a corresponding reduction of price.

A third and middle case probably comes nearer to the actual state of this and many other inventions, than either of the preceding. Taken in one point of view, an immense saving may be apparent; whilst, on the other hand, the manufacture may be so involved in contingent expences, and may require so great an extension of capital, as entirely to consume its profits, and leave an ultimate loss. In this case, an establishment was set on foot to occupy 60 of these machines, but only 12 were set to work. The rent, the millwork, and the engine, were all upon the full scale, while the productive part of the machinery was limited to one-fifth part. Against this, however, it is at least matter of serious reflection to consider, how far it might have been prudent to embark a sum sufficient to employ the whole establishment in the manufacture of a mere article of fancy, subject to every vicissitude of caprice and fashion. Upon the whole, it seems plain, that the business was either carried by much too far, or not far enough. The expence was incurred, a large capital sunk, and both fortitude and exertion were necessary to require what had been risked. A sudden stop of every necessary effort at the most critical moment was certain ruin, and that was the policy unfortunately followed.

The power required to drive this machine being very small, and even that capable of great reduction, by judicious alteration, an expensive establishment of mill work, moved by power, is not by any means inherently necessary for the business. The regularity of motion, produced by machinery, is indeed desirable; but the attendant expence is more than equivalent to any advantage gained by its use. It is desirable that one simple rotatory motion should direct the whole, but this might be easily given by the attendant's hand, in a way entirely similar to what is practised in the inkle loom. The needle frame is a very expensive part of the apparatus, and this, as well as the whole concomitant machinery, may be easily dispensed with. The pattern wheels, instead of being 18 inches in diameter, might be reduced to six inches with equal efficiency; and a pattern might be carried to any extent by constructing them as spirals. It is also very practicable to make common sewing needles answer the purpose of the perforators, and those may be purchased for 9d. per hundred, whereas the former with the sliders, &c. cost upwards of 10 shillings. The quantity of work, upon a plan of this kind, might even be greatly increased, by working two, four, or six rows at once; and, at the same time, a machine might be constructed, by simplifying all its parts, certainly for not more than L. 8 or L. 10, and probably for much less. In such a state as this, the trade might easily revert to its natural and legitimate channel; for the expense being but small, the machines would soon become the property of those who wrought with them. They might be made to occupy so little room, as to be placed easily in an ordinary sized dwelling-house, and the connection between the employers and the employed might be rendered exactly similar to that which at present subsists in the weaving, stocking-weaving, and other branches of manufacture.

A sketch of the general principles of the machine of this kind, which embraces none part of the patent granted for the former, will be found in Plate CXXXVII.

In this Plate, Fig. 6, represents a profile elevation of the machine, in every part of which the most rigid attention has been paid to simplicity and cheapness of construction. The frame work, which extends from the floor to the ceiling, consists merely of two upright posts of flat plank, represented at A, the dimensions of which may be four inches by one. These posts, one of which only is visible, being firmly secured at top and bottom, a single cross rail will be sufficient to connect them, and may be of dimensions similar to the posts, and placed upon edge. In Fig. 6, it is not visible, but appears distinctly at N, in Fig. 7. The top of the posts may be bolted to a cross piece of wood at B, nailed to the joints above. The cloth frame of this machine appears at HH, and from the curvature of its shape, the sides may be very conveniently made of cast iron, and the cross connections of well-seasoned wood. Of these cross connections, the two of principal importance are the triangular pieces at KK; for the top rail at H is merely used for the two suspensory cords, and if these were attached to the sides, both it and the bottom rail might probably be omitted, without any practical inconvenience. At I, I, are the two rollers for stretching the cloth, which may be made like those of any common tambour frame. In this machine the perforators are placed behind the cloth, upon the frame D. They may be made like common sewing needles, excepting that the eye being in the point, that end ought to be sharpened in finishing them, instead of being blunted to resist the thimble, as in the ordinary way. The other end may be filed into a triangular shape like a grover's needle, and is to be fixed in a socket of tin like a stocking frame needle. This is effected by placing the needle in a mould, and pouring in the tin while in a state of fusion. The shape, both of the needle and the socket, may be accurately seen in Figure 8, together with a section of the bar upon which it is placed, and the means of securing it by a bolt and nut, so
that any needle, if broken, injured, or worn out, may be changed at pleasure. The whip, or yam, is placed upon a hollow tin cylinder, as in the former machine, and every thread passes through the eye of the corresponding perforator. The motion given to the perforators is exactly the converse of that in the former machine; for here the perforation is from behind, and the reciprocating motion may either be given by wipers, or by two small cranks upon the ends of the shaft G, which is turned by the operator's hand. The form of the shaft appears in Figure 9. In the front of the cloth is a cross rail, to which is attached a frame carrying a number of perpendicular needles, one being correspondent to each perforator. When the perforators are brought forward, these needles, by the rising of the frame, pass between the perforator and the thread, and thus form a loop, which remains until the perforators are withdrawn and return again, and so on. The proper regulation of this motion is the chief matter of nicety and difficulty in the machine. Copious remarks upon its nature, and the means of effecting it with accuracy, shall therefore be given in the proper place; as upon this rests the only difficulty of which this machine appears to be susceptible, and, at the same time, it is of such importance that this motion should be executed truly and steadily, that without that being accomplished all the rest would be nugatory and illusory. The pattern motion is, in this machine, to be given by two spiral worms, which may be six inches in diameter, or even less if desirable. These are represented in Figure 10, and some description of them may be necessary. They so far resemble in principle the transverse wheels of the former machine, that the figure of the pattern depends solely upon the form into which their rims are cut, and this depends upon the principles of calculation already described. Were a motion introduced to shift the contact of the frames at the end of each revolution, any number of wheels contiguous to each other, upon the same axis, would answer entirely the same purpose; but forming them as spirals will do equally well, and save some additional machinery. In order to avoid the errors to which the ratchet was sometimes liable, on account of the inertia, it is proposed to substitute in this machine an oblique wheel, with what is generally termed by mechanics a double threaded endless screw. This being turned half a revolution for every shift, the whole shifts will be made with a precision, which may in every instance be relied upon.

For the purpose of allowing the cutter to come fairly in contact with every part of the circumference of the spiral traverses; while the pattern is cutting, it will be proper to construct them in pieces equal to one revolution of the spiral, and these pieces may be removed while cutting, and when the cutting is finished, all may be placed on the axis, and secured by screws, or any other sufficient fixture. In order to allow the friction wheels, which are in contact with the rims of the spiral, to traverse freely along, some such contrivance as that represented in Figure 10, may be adopted. To the lower extremity of each lever may be fixed a small bow or brace of iron, at right angles to the lever, and secured by a screw at D. Two cross shafts, one immediately above the other, may be fitted to slide freely in the brace from side to side. To each of these a small friction wheel may be fitted, with a groove in the rim, to lay upon the circumference of each spiral. When the spirals revolve, the friction wheels, by the action of the hollow grooves, will be drawn laterally along them from F towards E; and when they have completed their course, they may be drawn back by a weight or spring, whenever the groove in the friction wheel is removed from the circumference of the spiral. The perpendicular motion of the cloth frame will be very apparent in the elevation, Fig. 2; for the action of the spiral upon the lever L will produce it, by means of the cords OQO, passing over the pulleys in the cross rail N. If these cords are doubled and joined in the middle by the slip-knot used by weavers for the cor- dage of looms, the frame may be tempered to remove any inaccuracy arising from stretching, with great promptitude and facility. The horizontal motion may be given to the cloth frame by a direct connection with the other spiral, as in the former machine.

This will perhaps be the most simple and efficacious mode of giving the traverse motion, where a single row of perforators only is to be used; but as it may be desirable to increase the quantity of work by using different rows of perforators at the same time, and as no insurmountable objection presents itself against this amplification of principle, it may now be proper to extend our views to the means of augmenting the scope of the machine, premising that the ratio of increment can never be so well ascertained or productive of actual benefit, as by practical experience. If, in the first instance, we propose to double the number of our perforators, so as to work two rows of figures similar, but inverted, we may adopt the machinery represented in Figure 11, with rational hopes of complete success. But here it will be evident, that from the very nature of our object, we must abandon the plan of giving the lateral or horizontal shift to the cloth, and communicate it to the perforators, as they must now work in inverted directions. It will also be necessary that the vertical needles, which secure the loops in front, must move along with the perforators, and that this must be done with great accuracy. In this case, therefore, the vertical motion may still be given to the cloth, but the lateral one must be communicated to the perforators. In Fig. 11, if a motion is given to the frame AB, by the action of a spiral traverse upon the lever A, the frame CD will operate constantly in an inverted direction, by means of the pulley and band at G. The upper frame being acted upon by the traverse, is kept pressing upon it by the operation of the weight E, and the lower frame works in constant opposition to it by that of the minor weight E, which preserves the tension of the connecting band at G. If four frames be wanted, the plan in Fig. 12, will effect it. The motion of the middle frames 2 and 3, is exactly as before, and the motion is continued to the upper and lower frames by the cross clasps at H and I. A profile of these clasps is given in the small Figure 19. In using an apparatus so extensive as this, it will be necessary to devise means, either by hinges or otherwise, for speedily removing and replacing the upper frames, so that all may be accessible for the purposes of repair or regulation, without loss of time.
It will now be proper to advert to the means of preserving the relative position of the vertical needles in front to the perforators, and for this reference may be made to Fig. 14. Let the cross rail in front of the cloth, which is to support the needles, which retain the loops, be constructed with a groove nearest to the cloth, into which a small wedge may be driven for each needle, as represented at A. Let the needle be cast into a socket of tin, of the form represented at B, and a small weight be attached to the oblique tail at C. In the side of this needle let a groove be punched, like that of a common stocking needle. As B must also be a socket upon which the tin may vibrate freely from side to side, and the gravity of the oblique weight at C will give the point a constant tendency to incline towards the left hand. The point rising through a groove in the frame at O, its position may be regulated with the utmost precision, by tempering the wedge at A, and thus it will be made to fit the perforator with very great nicety. The rising of this needle between the perforator and thread, will thus seize every loop; and the next consideration is to open these loops, so that the perforator may pass fairly through them at next perforation, without danger of missing. This, it is presumed, may easily be effected with great safety, and little danger of error, by the following addition to the apparatus. Upon the same centre at B, let there be a second needle, shorter than the former, and also fitted with an oblique tail to incline its point towards the left. The point of this short needle D, resting in the groove of the longer needle O, both will rise as one point, and any slight motion to distend them after being raised, will open a loop through which the perforator may pass with the utmost security at the next perforation.

From this general description the ground work of a machine may be obtained, which, embracing all the advantages, and extending the operations of the tambouring machine, avoids its most material defects, complexity and expense. The outlines, rather than a full detail, are given, not from any motive of concealment, but of caution, to represent it merely as what it really is, viz. an untried invention. Wipers of the forms of Figs. 15, 16, and 17, will give all the remaining motions, if fixed on the revolving shaft driven by the operator's hand.

The following table is precisely similar to that employed in the tambour work, and will serve as a rule for cutting either wheels or spirals, so as to produce every angle of obliquity which can be required in any pattern, however comprehensive or varied.

CHAP. II.

Manufacture of Hosiery.

As the tambouring manufacture is produced by Manufactures of linens and stockings, may be regarded merely as the extension of the same to the formation of superficies. In the working of plain hosiery, the loops of the chain are precisely the same as in the tambouring; and the most simple, although tedious, way of producing this, is by means of four small wires directed by the manual operations of women, or what is usually termed knitting. The great time employed in this operation, however, has brought it much into disuse, in all those districts where, from the extension of manufactures, female labour has become valuable and productive; and it is now rarely practised, excepting as the occasional employment of females, whose subsistence does not solely depend on their labour; and in the northern counties and isles of Scotland, where female labour, from the want of manufactures, is neither much in demand, nor high in price. The northern islands of Shetland and Orkney are indeed almost the only places where knitting is now practised to any extent; and the very low prices at which these stockings are sold, sufficiently prove, that very little indeed is charged for the labour of knitting them. The art of knitting by means of wires is so entirely of that kind which can only be acquired by repeated trials and patient application, that it would be a fruitless waste of time to endeavour to teach it by description. The great time necessary for knitting by wires seems early to have been felt, for the invention of the frame is attributed to Mr Lee of Cambridge, so far back as the reign of Queen Elizabeth, and upwards of two hundred years ago, at a period when practical mechanics was neither generally understood, nor extensively practised in Britain. Mr Lee, indeed, it is said, found so very little encouragement, and so many obstacles to the introduction of this machine in his own country, that he emigrated to France, where he found that patronage which he
he had in vain solicited at home. Thus, whatever
title of this most important and useful en-
gine, it is to France that mankind are indebted for
its having ever been matured and rendered practically
useful.

No description or representation of any of the va-
rious stocking-frames in use, is to be found in any
mechanical work hitherto published, as far as the
writer of this article has been able to learn; and what
little is said of it in former Dictionaries of Arts and
Sciences, is confined to the meagre and unsatisfactory
notice that such an engine exists, without the most
distant attempt to describe either the nature of its
construction, or the principles of its operation. It
has been customary to apologise for this omission, by
representing the stocking frame as a machine in-
mensely complicated in its parts, and very difficult
both to represent and to comprehend. The stocking-
frame unquestionably presents this aspect to a stranger
upon a cursory inspection, especially to one who is not
previously intimately acquainted with the theory of
mechanics, and the practical application of the laws
and principles of motion. Yet in reality many com-
 pound engines exist much more complicated in their
operation, which have been the subjects of reiterated
discussion and description. The reason of the ap-
parent complexity of the stocking frame is by no means
to be ascribed either to the number or to the com-
plicity of its motions, for these are neither numerous
nor complicated; but to the great number of its parts,
and to the necessity which exists of compressing these
into a very small compass, in order to fit them for
the operation required. The principle by which a
single loop is formed embraces the whole; and it is
not the difficulty of forming one, but the necessity
of forming many at the same time, that creates the
apparent complexity.

There are now a great variety of different frames
in use for producing various ornamental kinds of ho-
siery, and it would vastly exceed all reasonable limits
to enter into a detailed description of each. A few,
therefore, of those which differ most materially from
each other, have been selected as specimens; and for
an illustration of these the reader is referred to Plate
CXXXVIII. which, although fully forms the ba-
sis of the whole, is that used for weaving or knitting
plain hosiery, and is the common stocking frame.

**Common Stocking Frame.**

Of this engine a profile elevation is given in Fig.
1, the various parts of which are as follow. The
framing is supported by four upright posts, generally
of oak, ash, or other hard wood. Two of these
posts appear at AA, and the connecting cross rails
are at CC. At B is a small additional piece of fra-
mimg, which supports the hosiery seat. The iron-
work of the machine is bolted or screwed to the up-
per rails of the frame work, and consists of two parts.
The first rests upon a sole of polished iron, which
appears at D, and to which a great part of the ma-
Chinery is attached. The other part, which is gen-
erally called the carriage, runs upon the iron sole at
D, and is supported by four small wheels, or trucks
as they are called by the workmen. At the upper
part of the back standard of iron are joints, one of
which appears at Q; and to these is fitted a frame
one side of which is seen extending to H. By means
of these joints, the end at H may be depressed by
the hosiery's hands, and it returns, when relieved,
by the operation of a strong spring of tempered steel,
acting between a cross bar in the frame, and another
below. The action of this spring is very apparent
in Fig. 8. In the front of the frame, immediately
opposite to where the hosiery sits, are placed the
needles which form the loops. These needles, or ra-
ther hooks, are more or less numerous, according to
the coarseness or fineness of the stocking; and this,
although unavoidable, proves a very considerable
abatement of the value of a stocking frame. In
most every other machine, (for example those em-
ployed in spinning or weaving), it is easy to adapt any
one either to work coarser or finer work as it may be
wanted. But in the manufacturing of hosiery, a frame
once finished, is limited for ever in its operation to the
same quality of work, with this exception, that by
changing the stuff, the work may be made a little
more dense or flimsy, but no alteration in the size or
quantity of loops can take place. Hence where the
manufacture is extensively prosecuted, many frames
may be thrown idle by every vicissitude of demand;
and where a poor mechanic can purchase his own
frame, he is for ever limited to the same kind of
work. The gage, as it is called, of a stocking frame
is regulated by the number of loops contained in three
inches of breadth, and varies very much, the coarsest
frames in common use being about what are termed
Forties, and the finest employed in greatest extent about
Fours. The needles are of iron wire, the manufac-
ture of which is very simple; but long practice in the
art is found necessary before a needle-maker attains
that dexterity which will enable him both to execute
his work well, and in sufficient quantity, to render his
labour productive. The process of making the need-
les is as follows. Good sound iron wire, of a pro-
per fineness, is to be selected; that which is liable to
split or splinter, either in filing, punching, or bend-
ing, being totally unfit for the purpose. The wire
is first to be cut into proper lengths, according to the
fineness of the frame for which the needles are desig-
ned; coarse needles being considerably longer than fine
ones. When a sufficient number (generally some thou-
sands) have been cut, the wire must be softened
as much as possible. This is done by laying them in
rows in a flat iron box about an inch deep, with a
close cover; the box being filled with charcoal
under the strata of wires. This box being placed
upon a moderate fire, is gradually heated un-
til both the wires and charcoal have received a mod-
erate red heat, for were the heat increased to what
smiths term the white heat, the wire would be ren-
dered totally unfit for the subsequent processes which
it has to undergo, both in finishing and working.
When the box has been sufficiently heated, it may be
taken from the fire, and placed among hot ashes, un-
til both ashes and box have gradually cooled; for the
slower the wires cool, the softer and easier wrought
they will be. When perfectly cool, the next process
is to punch a longitudinal groove in the stem of every
needle, which receives the point or barb when depre-
sed. This is done by means of a small engine worked

---

**Chainwork.**

**Plates CXXXVIII.**

Method of making the needles.
by the power of a screw and lever. The construction of
these engines is various; but a profile elevation of
one of the most simple and commonly used will be
found in Fig. 11. It consists of two very strong
pieces of malleable iron, represented at A and C, and
these two pieces are connected by a strong well-fitted
joint at B. The lower piece, or sole of the en-
gine at C, is screwed down by bolts to a strong board
or table, and the upper piece A will then rise or sink
at pleasure upon the joint B. In order that A may
be very steady in rising and sinking, which is indis-
tensible to its correct operation, a strong bridle of
iron, which is shewn in section at E, is added to con-
fine it, and direct its motion. In the upper part
of this bridle is a female screw, through which the for-
cing screw passes, which is turned by the handle or
lever D. To the sole of the engine C is fixed a bol-
ster of tempered steel, with a small groove to receive
the wire which is to be punched; and in the upper
or moving part A, is a sharp chisel, which descends
exactly into the groove, when A is depressed by the
screw. These are represented at F and H. At G
is a strong spring, which forces up the chisel when
the pressure of the screw is removed. The appear-
ance of the groove when the punching is finished, will
be rendered familiar by inspecting Fig. 13. When
the punching is finished, the wires are to be brought
to a fine smooth point by filing and burnishing, the
latter of which should be very completely done, as,
besides polishing the wire, it tends greatly to restore
that spring and elasticity which has been removed by
the previous operation of softening. The wire is next
to be bent, in order to form the hook or barb; and
this is done with a small piece of tin plate bent double,
which receives the point of the wire, and by its breadth
regulates the length of the barb. The stem of the
needle is now flattened with a small hammer, to prevent
it from turning in the tin socket in which it is afterwards
to be cast; and the point of the barb being a little cur-
ved by a pair of small pliers, the needle is completed.

In order to fit the needles for the frame, they are
now cast into the tin sockets, or leade as they are
called by the workmen; and this is done by placing
the needles in an iron mould, which opens and shuts
by means of a joint, and pouring in the tin while in a
state of fusion. In common operations, two needles
are cast into the same socket. The form of the
needle when complete and fitted to its place in the
frame, will be seen in Fig. 7, which is a profile sec-
tion of the needle-bar exhibiting one needle. In this
Figure, a section of the presser is represented at F;
the needle appears at G, and the socket or level at K.
At H is a section of the needle-bar, on the fore-
part of which is a small plate of iron, called a verge,
to regulate the position of the needles. When placed
upon the bar resting against the verge, another plate
of iron, generally lined with soft leather, is screwed
down upon the sockets or leads, in order to keep
them all fast. This plate and the screw appear at I.
When the presser at F is forced down upon the barb,
it sinks into the groove of the stem, and the needle is
shut; when the presser rises, the barb opens again
by its own elasticity.

The needles or hooks being all properly fitted, the
next part of the stocking frame to which attention
ought to be paid, is the machinery for forming the
loops; and this consists of two parts. The first of
these, which sinks between every second or alternate
needle, is represented at O, and is one of the most
important parts of the whole-machine. It consists
of two moving parts; the first being a succession of
horizontal levers, moving upon a common centre, and
called jacks, a term applied to vibrating levers in va-
rious kinds of machinery as well as the stocking
frame. One only of these jacks can be represented
in the figure Fig. 1; but the whole are distinctly
shown in a horizontal position, in Fig. 2; and a
profile upon a very enlarged scale is given in
Fig. 3. The jack shown in Fig. 1, extends hori-
zontally from O to I, and the centre of motion
at R. On the front, or right hand part of the jack
at O, is a joint suspending a very thin plate of pol-
ished iron, which is termed a sinker. One of these
jacks and sinkers is allotted for every second or alter-
nate needle. The form of the sinker will appear at
S, Fig. 3; and in order that all may be exactly uni-
form in shape, they are cut out and finished between
two stout pieces of iron, which serve as moulds or
gauges to direct the frames in which the jacks are
made. The other end of the jack at I is tapered to a point; and when the
jacks are in their horizontal position, they are secured
by small iron springs, one of which is represented at
J, each spring having a small obtuse angled notch
to receive the point of the jack, against which it presses
by its own elasticity. In Fig. 3, the centre is at R;
the pointed tail is omitted for want of room, the
joint is at O, and the throat of the sinker, which
forms the loop, is at S. The standards at R, upon
which the jack moves, are called combs, and consist
of pieces of flat smooth brass, parallel to and equi-
distant from each other. The cross bar RR, which
contains the whole, is of iron, with a perpendicular
edge or rim on each side, leaving a vacuity between
them, a space to receive the bottom part or tails of
the combs. The combs are then placed in the bar,
with a flat piece of brass, called a countercomb, be-
 tween each, to ascertain and preserve their distances
from each other. These countercombs are exactly
of the same shape as the combs, but have no tails.
When both combs and countercombs are placed in
the bar, it is luted with clay so as to form a mould,
into which is poured a sufficient quantity of melted
tin. When the tin has had time to cool, the coun-
tercombs having no tails, are easily taken out, and the
combs remain well fastened and secured by the tin,
which has been fused entirely round them. Thus
they form a succession of standards for the jacks;
and a hole being drilled through each jack and each
comb, one polished wire put through, serves as a
common centre for the whole.

The jack sinkers being only used for every alternate
or second needle, in order to complete this part
of the apparatus, a second set of sinkers is employed.
These are, in form and shape, every way the same as
the jack sinkers, but they are jointed at the top into
pieces of tin, all of which are screwed to the sinker
bar H (Fig. 1); and thus: a sinker of each kind
descends between the needles alternately. By these
sinkers, the loops are formed upon all the needles,
and the reason of two sets different in operation being
employed, shall be assigned in describing the mode of
working the frame. The presser of the operation,
of which something has already been said, appears at
F; and of the two arms which support and give mo-
tion to it, one appears very plainly at E, its centre of motion being at C. The circular bend given to these arms, besides having an ornamental effect, is very useful, in order to prevent any part from interfering with the other parts which are behind, by elevating them entirely above them. The extremity of these arms at the termination of the bends behind, are connected by a cross bar, which has also a circular bend in the middle, projecting downwards, for a reason similar to that already assigned. This bend is concealed in Fig. 1, but visible in the front elevation, Fig. 5. From the middle of the bend, the presser is connected with the middle treddle by a depending wire appearing at M, and thus, by the pressure of that treddle, the presser is forced down to close the barbs of the needle. The ascent of the pressure is sometimes effected by means of a counterepoise weight passing over a pulley behind, and sometimes by the reaction of a wooden spring, formed of a strong hoop, like that represented at K. The latter of these is preferred, especially by the Nottingham hosiers, because, as they assert, it makes the presser spring up with greater rapidity, and consequently saves time in working. How far this may be practically the case, it would be superfluous here to investigate; but it is obvious, that the wooden spring, if very stiff, must add much to the hosier's exertion of his foot, already exerted against the united spring of all his barbs; and this inconvenience is much complained of by those who have been accustomed to work with the counterpoise.

At L are two pulleys or wheels, of different diameters, moving upon a common centre, by which the jack sinkers are relieved from the back springs, and thrown downwards to form the loops upon the needles. About the larger wheel is a band of whip cord passing twice round, the extremities of which are attached to what is called the slur, which disengages the jacks from the back springs. The smaller pulley, by another band, communicates with the right and left treddle; so that these treddles, when pressed alternately, turn the pulleys about in an inverted order.

The directions of these bands also appear more plainly in the front elevation, Fig. 5. The construction of the slur, and its effect upon the jacks, will also be rendered apparent by Fig. 4. In this Figure eight jacks are represented in section, the tail part of three of which, 1, 2, 3, are thrown up by the slur in its progress from left to right; the fourth is in the act of rising, and the remaining four, 5, 6, 7, and 8, are still unacted upon, the slur not yet having reached them. As the slur acts in the direction of the dotted line XX (Fig. 2) behind the centres of the jacks, it is hardly necessary to remark, that thus forcing up the tails must of course depress the joints by which the sinkers in front are suspended. The jack sinkers falling successively from loops on every alternate needle, in the way represented in Fig. 6, where both kinds of sinkers appear in section, the light part expressing what is above the point at which the throat of the sinker operates upon the thread, and the dark part what is below. The second set, or as they are called the lead sinkers, from the manner of jointing them, and suspending them from the bar above, appear still elevated; the position of the bar being represented by the line AB. But when these are pulled down to the level of the former by the operator's hands, the whole looping will be completed, and the thread CD, which is still slack, will be brought to its full and proper degree of tension, which is regulated by stop screws, so as to be tempered, or altered at pleasure.

The sinking of the second set of sinkers, may be easily explained by Fig. 8. The direction of the sinkers is expressed by the line E; the bar from which they are suspended will be at A; the top frame is in the direction from A to B; the back standards at D, and the joint at B, is the centre of motion. If E is pulled perpendicularly downwards, the spring C will be contracted, and its upper extreme point G, will be brought nearer to its lower extreme point F, which is fixed. Again, when the force which has depressed E is removed, the spring C will revert to its former state, and the sinkers will rise. The raising of the jack sinkers and jack takes place at the same time, by the hosier raising his hands; and for the cause of this we must revert to Fig. 2. The lead sinkers in rising, lay hold of Fig. 9. notches which raise the extreme parts of the set of jacks ZZ, which are called half jacks. Between the extremities of these, at ZZ, is a cross bar, which, in descending, presses all the intermediate jacks behind the common centre, and restores them to their original posture, where they are secured by the back springs, until they are again relieved by the operation of the slur recrossing at the next course.

**Working of the Frame.**

In order to work a frame, the whole apparatus being previously put into complete order, the hosier places himself on the seat in front, and provides himself with a bobbin of yarn or stuff. This bobbin he places loosely on a vertical pin of wire, driven into one side of the frame contiguous to the needles, so that it may turn freely as the stuff is unwound from it. Taking the thread in his hand, he draws it loosely along the needles behind the barbs and under the throats of the sinkers. He then presses down one of the treddles to pass the slur along, and unlock the jacks from the back springs, that they may fall in succession. When this is done, the number of loops thus formed is doubled by bringing down the lead sinkers, and the new formed loops are lodged under the barbs of the needles by bringing forward the sinkers. The preceding course, and former fabric, being then again pushed back, the barbs are shut by depressing the mid treddle, and forcing down the presser upon the needles. The former work is now easily brought over the shot needles, after which, by raising the bands, both sets of sinkers are raised; the jacks are locked by the back springs, and the hosier goes on to another course.

From this, it will be apparent, that the remark made in the outset is well founded, that there are, in reality, no complicated or difficult movements in the stocking frame. Almost the whole are merely those of levers moving in their respective fulcra, excepting that of the carriage which gives the horizontal motion to the sinkers, and that is merely an alternate motion on four wheels. Yet the frame is a machine which requires considerable experience and care, both to work it to advantage and also to keep it in good order. This circumstance arises greatly from the small compass in which a number of moving parts
must be included. Owing to this, the needles, unless cautiously and delicately handled, are easily bent or injured. The same circumstance applies with equal or greater force to the sinkers, which must be so very thin as to be easily injured. But as these must work freely, both in a perpendicular and horizontal direction between the needles, in a very confined and limited space, the slightest variation in either, from being truly and squarely placed, unavoidably injures the others. When a hosiery, either ignorant of the mechanical laws of their relation to each other, or too impatient to wait for the assistance of another, attempts to rectify defects, he in most cases increases them tenfold, and renders the machine incapable of working at all, until repaired by some more experienced person. This circumstance has given rise to a set of men employed in this trade, and distinguished by the name of upsetters; and these people, besides setting new frames to work, have frequently more employment in repairing old ones injured by want of care or skill, than many country apothecaries, who live in healthy parishes, can find in curing the disorders of mankind.

It seems unnecessary to go further into detail respecting a machine so well known, and which requires practical attention, even more than most others. It may therefore be sufficient to describe shortly some of its varieties, the most simple and common of which is the rib stocking frame.

Rib Stocking Frame.

This frame, which, next to the common frame, is most extensively in use, is employed for working those striped or ribbed stockings, which are very common in all the different materials of which hosiery is formed. In principle it does not differ from the common frame, and not greatly in construction. The former general description will nearly apply to this machine with equal propriety as to the former; that part, however, by which the ribs or stripes are formed, is entirely an addition, and to the application of this additional machinery it may be proper to pay the chief attention, referring chiefly to Fig. 5, which is a front elevation.

This Figure has been already frequently referred to for the illustration of those parts of the machinery which are common to both, and those parts therefore require no recapitulation. The principle of weaving ribbed hosiery possesses considerable affinity to that which subsists in the weaving of that kind of cloth, which is distinguished by the name of tweeling, for the formation of stripes, with some variation arising merely from the different nature of the fabric. In cloth weaving, two different kinds of yarn, intersecting each other at right angles, are employed; in hosiery only one is used. In the tweeling of cloth, striped as dimity, in the cotton or kerseymere, in the woollen manufacture, the stripes are produced by reversing these yarns. In hosiery, where only one kind of yarn is used, a similar effect is produced by reversing the loops. To effect this reversing of the loops, a second set of needles is placed upon a vertical frame, so that the bends of the hooks may be nearly under those of the common needles. These needles are cast into tin moulds, pretty similar to the former, but more oblique or bevelled towards the point, to prevent obstructions in working them. They are also screwed to a bar of iron, generally lighter than the other, and secured by means of plates: this bar is not fixed, but has a pivot in each end, by means of which the bar may have a kind of oscillatory motion on these pivots. Two frames of iron support this bar; that in which it oscillates being nearly vertical, but inclined a little towards the other needles.

Fig. 9, which is a profile elevation, will serve to illustrate the relative position of each bar to the other. The lower, or horizontal frame, the ends only of which can be seen in Fig. 5, under a, a, appears in profile in Fig. 9, where it is distinguished by b. The vertical frame at c is attached to this by two centre screws, which serve as joints for it to move in. On the top of this frame is the rib-needle bar at f in Figs. 1 and 9, and one needle is represented in Fig. 9, at g. At h is a small presser, to shut the barbs of the rib-needles, in the same manner as the large one does those of the frame. At h is one of the frame needles, to show the relative position of the one set to the other. The whole of the rib-bar is not filled with needles like the other; for here needles are only placed where ribs or stripes are to be formed, the intervals being filled up with blank leads, that is to say, with sockets of the same shape as the others, but without needles, being merely designed to fill the bar and preserve the intervals. Two small handles depend from the needle-bar, by which the oscillatory motion upon the upper centres is given. The rising and sinking motion is communicated to this machine by chains, which are attached to iron sliders below, and which are wrought by the hosiery's heel when necessary. The pressure takes place partly by the action of the small presser, and partly by the motion of the needles in descending. A small iron slider is placed behind the rib-needles, which rises as they descend, and serves to free the loops perfectly from each other.

In the weaving of ribbed hosiery, the plain and rib courses are wrought alternately. When the plain is finished, the rib-needles are raised between the others, but no additional stuff is supplied. The rib-needles intersecting the plain ones, merely lay hold of the last thread, and by again bringing it through that which was on the rib-needle before, give it an additional looping, which reverses the line of chaining, and raises the rib above the plain intervals, which have only received a single knitting.

Plated Stocking Frame.

The next description of stocking frame to which we would draw the attention of the reader, is that used for the manufacture of a cheap and showy description of stockings, whose fabric chiefly consists of cotton, but in which silk is so artfully intermixed as to give them an appearance when new, nearly, if not altogether, equal to those which are composed entirely of silk, although, after being exposed to repeated washings, this deception almost entirely disappears, from the swelling of the cotton, which forms the chief part of the fabric. The chief points of difference in this frame consists in the way of shutting or rather covering the barbs of the needles, in order to form the chaining. Of this variety some idea may be formed, by referring to Fig. 10. This Figure is a horizontal plan of the needles, and that part of the apparatus which supersedes the use of the presser, and in some respects fits the frame for purposes to which the presser is not well adapted.
It has not been deemed necessary to represent any part of the machinery of this frame, excepting the needles, and a set of points corresponding with them, which supersedes the operation of a presser. The needles are cast into metal sockets like those of any other frame, and only differ from those commonly used in the length of the barb, which, in this frame, requires only to be of sufficient length to receive the loops, and guard against any danger of their slipping off after being so received. The sockets or leads appear between A and B, and are attached and secured to the needle bar much in the same way as in any other stocking frame. The points are at C, and the short barbs are represented by a black line drawn from each point. At E is another bar, which slides freely backward and forward in two grooves of iron, one being at each side of the frame. This bar has also a circular motion on its ends or pivots, in so far as the points may be elevated or depressed at pleasure, as much as may be necessary. Both these motions are given by the hosier's hand, laying hold for that purpose of the handle at F. The operation of these is as follows: In the stem of the needle there is a groove, as in any other stocking-needle, and in each point there is also a groove. When cast into the socket, the needle is so placed that the groove may be above, as in the common way; but in the points the reverse takes place, the grooves being below. When it becomes necessary to shut the needles, the points being pushed forward over the needles, and a little depressed, the point sinks into the groove in the stem of the needle, and at the same time the groove in the stem of the point being below, receives the short barb of the needle, so that both are completely covered; and the loops may be transferred from the needles to the points, and returned at pleasure. The bar, also, upon which the points are fixed, being fitted so as to have a lateral shift, the loops which were upon one needle may be transferred to another, and returned at pleasure. The effect of the point when the needle is short, may be seen in Fig. 12, which exhibits a needle and point in this situation in profile elevation. The needle is at A, and the point at B. By these means, the texture, instead of being confined to a straight line, direction, as in the rib frame, may be varied at pleasure; and where colours are used, a great variety of stripes, zig-zags, and other ornaments, may be introduced at pleasure. This operation is very analogous to that of weaving lappets by the common weaving loom, and also to what has been already described in the account of the tambouring machinery; all of them depending upon the resolution of two direct into one oblique motion, and the production of circular, elliptical, and other curves, by varying the ratio of inclination.

Fig. 14. exhibits a small hook, very much used by hosiers of every description, for picking up loops, which may be lost by the breaking of a needle, the depression of a barb, which has lost its elasticity; or any other accident which may occur. It is also used in constructing the breadth of the stocking at the ankle, forming the gussets, and all the minutiae of shaping, which can only be acquired by practical experience, and of which, therefore, we have not attempted any description.

CHAP. III.

Principles and Construction of a newly invented Reticulator, or Machine for Weaving Fishing Nets.

A machine of this kind has long been wanted for the extension and improvement of the fisheries, in order to suprass and the inconvenience of procuring nets in sufficient quantity, and at low prices, which must ever be felt whilst they are only to be obtained by the tedious mode of knotting them by hand. It may indeed be said, that the chief part of the labour devolves upon the fishermen and their families, who devote to this employment those annual and which are not employed in the actual prosecution of the fishery. However much this may be the case, it is sufficiently obvious, that in every part of the country many other useful and productive employments may be found, for those who can be spared from the net manufacture; whilst at the same time it must be of the utmost importance to establish a mean by which nets may be cheaply and extensively supplied at all times, and at short notices. This would enable the fishermen to derive every advantage from seasons of uncommon plenty, by increasing their stock of tackle whenever they found it beneficial, and would effectually guard them against those casualties and accidents which must often happen to nets immersed in the sea, and unavoidably exposed to all the dangers of high latitudes, foul bottoms, currents, and other contingencies. Two different scales of construction have occurred to the author of this article, each of which possesses some advantages, and is liable to some objections, which it may be proper to state previously to entering into detail.

The first of these plans has for its object the construction of nets upon a limited scale, so that the machine required for weaving them may be neither bulky nor expensive in the construction. Machines of this kind, it may be presumed, would in some respects be preferable to those of a more extensive kind, even although the saving of labour will not be in the same ratio. Most of the districts of Scotland contiguous to the stations where the herrings are found in the greatest abundance, are hitherto little engaged in other branches of manufacture, and consequently the relative prices both of provisions and labour are proportionally much lower than in the more populous seats of manufacture. It seems however rational to infer, that although this circumstance may be expected to furnish a plentiful supply of workers at low rates, the same assiduity, dexterity, and application, can hardly be expected, which will be found in places where habit has inured people to both the industry and regularity which conduces so much to the extension and prosperity of all manufactures. It seems also rational to conclude, that the introduction of any manufacture into places so situated, ought, in all cases, to be attempted upon a limited scale, and its subsequent extension proportioned to its success, and the dexterity acquired by practical application. In order as far as possible to adapt the projected machine to such a state of society as
this, it ought to be constructed not only of limited dimensions, so as easily to find room in an ordinary cottage, but also with every possible attention to simplicity, so as neither to involve great expense in its original price, nor to be liable to frequent repairs, where it might be difficult, if not impracticable, to find proper mechanics. In order to effect a machine of this kind, it is proposed to limit the extent of net to be wrought to the measure of 36 inches in breadth, or one English yard. For a machine upon such a scale, a space not exceeding 6 feet square will be found amply sufficient, so that it may be accessible in every part; and this, it is presumed, might be spared even in a house of small dimensions, for an object of such material importance to all interested in the prosecution of any of the branches of the fishery, especially those which are carried on to the greatest extent, and which consequently require the most abundant supply of tackling. In order also to avoid all the expenses attendant on the application of mechanical power, it would be proper that one person should be enabled, with facility and dispatch, to communicate to the machine all the motions of which it is susceptible, as in the common weaving loom, the stocking frame, and many other engines. Without actual experience, every calculation of quantity to be produced by any machine must ever be vague, and liable to great uncertainty and possible error, because neither the velocity at which the machine may be made advantageously to move, nor the dexterity of the operator, can be hypothetically calculated, without possessing more accurate data than can be safely assumed. A calculation upon assumed and specified data may however be made; and this, if moderately taken, may afford an approximation to the truth, and at the same time warrant a well-grounded hope, that when the machine has been brought to a proper state of accuracy in all its motions, and the operator has acquired a sufficient degree of practical dexterity, the actual result will rather exceed than fall short of the premised estimate. Upon this ground alone the following assumptions and calculations resulting from them are founded:

Let the breadth of net to be wrought at the same time be 36 inches, and the diagonal of every mesh from the opposite points of the diamond be 2 inches. Of course there will be 18 meshes wrought at the same time; and were it possible to work the machine at the same ratio of velocity with which a mesh may be formed by the common manual process, the ratio of increment of quantity, or diminution of labour, would be as 18 to 1. But as this is not to be expected, let us suppose that the machine, at a moderate velocity of action, would complete one row of 18 meshes even in the space of one minute, which is very slow indeed, and probably much underrated; the space of 36 minutes would then be required for every square yard of netting, and 12 working hours for each day’s labour, the total result would be 18 yards per diem. Thus the labour of three boys or girls would be sufficient, annually, to equip a vessel of 70 or 80 tons burthen with her whole supply of netting. How far any part of the data, upon which this calculation is founded, may prove practically erroneous, it is impossible in the present state of the invention to ascertain; but as a very low rate of velocity is assumed, it may perhaps not be overcharged, and the actual result may be ascertained at a trivial expense, by the construction of a single machine.

Of the second kind of machine to which an allusion has been made, a very brief notice only seems necessary at present. Were machines to be constructed to act by the impetus of mechanical power, a much larger scale would probably be found advantageous. This must involve the preliminary expense of a building adapted to the purpose, with a waterfall and wheel or steam engine for the moving power. The machinery we might then suppose sufficiently large to work at once 6 yards, or the whole depth of a net; and were this done at an equal velocity with what has been assumed, the quantity produced would be immense indeed. The original capital sunk would however necessarily be very large, and, divested of every other impediment, much of the profit would necessarily depend upon the economy of management, and internal regulation. As, besides this, many parts of the same general principles would be common to both machines, the latter seems more legitimately calculated to be brought into efficiency, as an extension and improvement of the former, founded upon practical experience and observation, than as the first effort of an infant and unascertained mechanical experiment.

When, according to the first plan, a sufficient quantity of webs of netting, of the breadth of 36, 54, or 72 inches had been formed, they might easily be joined, by intercalary meshes formed in the common way, into nets of any requisite dimensions; and if a supply of netting in webs, rolled up in a convenient form, were kept in the holds of fishing vessels, or in stores contiguous to the fishing stations, all accidents might be instantly repaired, all deficiencies supplied, and the stock of nets speedily increased, according to the exigencies which might occur.

Respecting the economy, or eventual reduction of expense, in the fitting out of vessels for the fishery, it is also impossible to enter into any estimate with precision. From what has been said above, if three boys or girls could, by one twelvemonth’s labour, supply 20,000 square yards of netting, being what is represented as the quantity proper for a vessel of 80 tons, and if we suppose the labour of each of these to be estimated at four shillings per week, which in these districts is probably high, we have the whole quantity woven for L. 39, or at the rate of little more than one half-penny per square yard. On the advantages resulting from the creation of such a source of emolument, in districts where labour is scarce, and habits of industry at an early age peculiarly desirable, with the correspondent increase of the necessities of life, upon which it is fair to calculate, it will not be necessary to enlarge. If a quantity of nets can also be at all times procured at so low a rate as here specified, adding a fair profit to the intermediate dealers, it must also prove of the utmost consequence to those who embark capital in the prosecution of the fisheries. The benefit to the salmon, trout, and other inferior branches of the fishery, though less in national importance, are also objects of attention to those immediately interested.

How far the plan detailed in the subsequent part of this article may conduct, either wholly or partially, to promote this great object, must be left to the consideration of those particularly interested in the
prosecution of the fisheries. The inventor has been formerly practically employed in superintending and constructing machinery, novel in its principle, and vastly more complicated in its various operations than what is here proposed, and has consequently the less difficulty in estimating both the attendant obstacles, and ultimate practicability of his plan, subject to those variations, adaptations, and improvements of the particular parts, which experience alone will point out in their practical effects, and perseverance only will remove.

Of the general principle by which labour is to be obviated, it may be proper to say something, previously to entering into the particular details of the various parts of the proposed machine, and a description of the explanatory drawings which conclude the article.

Many species of reticulation, besides that exclusively adapted to the manufacture of fishing nets, have been already effected by the agency of machinery. Of these, the lace and stocking manufacture are, perhaps, the most prominent and extensive. That species of ornamental work called tambouring, is also a branch of the same. For the construction of machinery adapted to this branch, the inventor of the present plan some years ago obtained his majesty's letters patent, and the business is still conducted by those with whom he was connected in the invention. These circumstances naturally led him to consider, with some attention, all these various branches of the art, the practical purposes for which they were intended, and the shades of difference which subsisted between them. This circumstance led to that train of reflection which has produced this invention. The great distinction between the manufacture of nets for the fisheries, and other branches of reticulation, it is apprehended, consists chiefly in the manner of knotting;—but the great requisite in fishing nets, is the complete fastening of the knots which connect the meshes, so that no fish may be allowed to escape, whether enclosed by hauling, or seized by the gills, in attempting to force a passage through the intersections of a stationary net. In no other species of reticulation, hitherto attempted by the agency of machinery, has this particular ever been deemed of paramount importance; and, consequently, the inventors of all the others have been contented with adopting slip knots, or loops sufficiently adapted to the objects which they had in view, but by no means so for the fisheries. The mesh knot, used in weaving fishing nets by the common operatives, might certainly be tried by machinery, but it is by no means well adapted for dispatch; and, while the machine to proceed by one mesh at a time, no benefit whatever could accrue from the invention. Presuming, therefore, that any other knot which is not liable to slip, might be substituted for the mesh knot, the inventor, in the first place, bent his attention to analyse the various kinds of fast knots in use, especially those preferred by mariners, which he conceived to be the best adapted to his purpose. Among these he selected what is called the ring knot, both because it is equally fast with the mesh knot, and is also better adapted to the weaving of nets by machinery, although by no means equally so, for working them by single meshes. The ring knot, is called also the fisher's knot, and is that used for connect-

ing lines of horse hair employed in angling. If, according to our former supposition, the webs from which nets are afterwards to be formed, consist of meshes, the diagonals of which are two inches each, and the whole breadth of each web is to be 26 inches, or one English yard, it follows, that 18 meshes will be contained in the breadth; and it was proposed, that, assuming this for the scale of a first experiment, these 18 meshes are to be formed and knotted at one and the same time, by the operation of the machine. From the diagonal form in which the meshes succeed each other, that part which, for distinction's sake, may be called the mesh frame, may therefore consist of 18 compartments, one being allowed for each mesh, and these might be variously constructed. One mode, which seems sufficiently well adapted for the purpose, is represented by Figures 1 and 2, Plate CXXXIX. as it appears in an elevated state; and its horizontal appearance, viewed from above, is given in Figures 3 and 4 of the same Plate. Perhaps, however, these may be better understood after a cursory description of Fig. 5, which contains a horizontal plan of the principal parts of the machinery, and of Fig. 6, which contains an elevation of the front part. It may here be premised, that the twine, or cordage, previously to the commencement of the process of weaving, is to be wound upon a certain number of bobbins of a particular construction; and when the reticulation is completed, the finished net work is received upon a roller or beam, from which it may be cut in such lengths as are best adapted to the proposed dimensions of the intended nets, so as to avoid waste or remnants; at AA, Fig. 5, appear the two side rails which compose the upper part of the framing of the machine. At BB, is the receiving roller, or beam, upon which the net is to be received when finished; and at CC are two ratchet wheels to regulate its motion. At DD is the mesh frame for forming the knots; and at F and G are cross rails of wood, which serve to regulate the motions of the twine while forming the meshes. In Fig. 6, A.A are two of the upright posts which support the framing, and of which there are four. BB is a cross horizontal rail of wood, which serves as a framing for the bushes in which the spindles or axes which support the mesh frames revolve. The particulars of the construction of the mesh frames, or moulds, will be the subject of future description. In this plan, nine of them appear between F and F, which is the number required for a net of 18 inches in breadth, the diagonal measure of each mesh being supposed two inches when equally distended both ways, in the form of a diamond. At C is another cross rail, perpendicularly under that at B, which supports the lower extremity of the spindles. At DD is a third cross rail, the use of which is to contain a number of sheaves or pulleys, by which the cords or bands which move the spindles are directed; and at EE appears the end of a vibrating frame, which communicates a rotatory motion to the spindles, by means to be afterwards explained. These form the principal parts necessary for the machine, the respective uses of which it may now be proper to explain at more length.

The principal part of the whole, and that to the accuracy and regularity of whose motions it will be necessary to pay the most sedulous attention, is that
The Chainwork.

Construction and Use of the Meshing Frame.

In Plate CXXXIX, Figs. 1 and 2, are two vertical representations of this part of the machine, shewing the different forms which it assumes in various stages of the operation. Fig. 1 represents it in its close state; that is to say, in the way in which it appears after the formation of the mesh and the knotting to secure it are completed. Fig. 2 represents it in its open state, as it appears previous to, and during the formation of the mesh and knotting. In Fig. 3 is given a horizontal plan of the same apparatus, necessary to elucidate some of the principles of its construction, and mode of its operation; and in Fig. 4 is given a section of the bobbins upon which the twine is wound, to explain also their particular construction and operation. This last, like Fig. 1 and 2, is a vertical representation or elevation.

In order to form the ring knot, it is well known that two twines or cords are to be laid parallel to, and in contact with, each other; that they are then turned round in a circular form similar to that of a ring, (whence probably the name is derived,) and one end of both twines being passed through the ring, the knot is completed. This mode of knotting seems to afford a particular advantage over all others not liable to slip in this respect, that the two twines to be knotted being parallel and contiguous to each other, the requisite motions and crossings of both are precisely the same, and consequently when knotted by the aid of machinery, the process becomes more simple than where the motions of the two twines and their features and crossings are different. The twine of the net being wound upon bobbins, and these disposed in pairs, so that two threads may be contiguous, and the further extremities attached to the receiving beam, we are ready to commence the operation, the mesh frames being in the open state as represented by Fig. 2. It is proper to keep in mind, however, that there are four upright arms in each frame similar to those at CC, although only two are represented, the other two being at right angles to those which appear at B, which will be very plain by inspecting the horizontal plan, Fig. 3. The whole four diverging equally, form a diamond, and by passing two twines round at the points CC, a ring is formed for the knot. When the twines are thus passed round so as to form somewhat more than a circle, that part which crosses must be done below the other. If the bobbins are then raised, brought over the ring, again sunk in its centre, and pulled tight, the ring knot will be complete, and the tension of the ends will close the frame until the points meet in the centre, as in Fig. 1. The knot may be then slipped off, and the upright arms at CC will revert to the open state by their own gravity. This may be very well seen by inspecting Fig. 3. It is thus that the ring knot may be formed with the greatest accuracy and dispatch; and were the same twines always contiguous and knotted together, the operation would be simple indeed. But it is evidently necessary to complete the diagonal or diamond shape of the mesh, that the contiguity of the twines should be changed at every alternate knotting. Thus at one knotting, the twines 1, 2, 4, 5, &c. (see Fig. 5.) should be contiguous, and, at the next, that 2, 3, 4, 5, &c. should come into contact. For this purpose some addition is necessary to the apparatus, and an idea of its construction and use will be gathered from Figs. 3 and 4, Plate CXXXIX.

In addition to the exterior apparatus or folding arms of the frame, another part is necessary, which is partially represented at L, Fig. 1, but which will be better understood by referring to Figs. 3 and 4. Fig. 3 exhibits a horizontal plan of the meshing frame and contiguous apparatus. The standards upon which the upright arms of the frame are jointed, appear plainly as quadrants of a circle at DD. That part of the apparatus which directs the operation of the bobbins at L, will also be distinctly seen in this figure. When the operation commences, the apparatus L, which moves horizontally on a centre, is in the situation of L2, that is to say, just without the circumference of the meshing frame. Now let the whole apparatus of this frame revolve upon the common centre of motion, or spindle which supports it, (A, Fig. 1.) and the two contiguous twines at NN, &c. will form the ring of the knot, the arms of the meshing frame serving to keep the ring distended. The two bobbins being at the lower part of the spindle on which they revolve, will cross under the twines which are round the frame at the point near M. The bobbins are then to be raised upon the upper spindle. The cross rail, with projecting pins at O, being next shifted in a direction towards the upper part of the figure, the apparatus at L will change its position until it is right over the centre of motion, when the bobbins being let down into the centre of the ring, the knot will be formed, and the distended arms brought into contact as in Fig. 1. An inverted shift of the shaft O will then bring the bobbins again without the ring, and one series of meshes will be completed. The next operation then, will be to change the contiguity of the bobbins for the next mesh. In order to effect this, reference may be made to the vertical section, Fig. 4. In this figure the vertical spindles are placed at a little distance, the one being perpendicularly over the other. This interval or chasm is to allow them to change freely from the outside to the inside of the ring after it has been formed, the twines passing through the interval. The lower part of the bobbin spindle A1, moves upon the centre at D, as already described. All the upper parts at A2 are fixed in a shaft of wood F, extending across the machine. This shaft, by means of grooves or slit holes, slides freely from side to side upon another shaft E, and this latter shaft, by means of a crank at each end, is susceptible of the same motion as that at A below, so that one may be always perpendicularly over the other. In order to guard as much as possible against those trivial inaccuracies to which machinery of every kind is in some degree liable, it may be proper to give each spindle a sharpened point, so that they may approach each other like inverted cones. If the bobbins be also countersunk at each end, there will be little danger of their missing the proper direction while shift.
Iving upwards or downwards, or presenting any ob-
struction to the operation. The section of B and C
will serve to render this obvious. In bringing the
spindles to a point, it will not be necessary that it
should be very acute, for, if the bobbins are of wood,
this would rather be prejudicial than of any ser-
vice. A row of meshes being finished, the receiving
beam is to be moved one notch off the regulating
wheel, in order to wind up a portion of finished net
equal to one mesh. A second row of meshes being
then formed, are to be wound up as before, and so
on until the whole operation is completed. From
the above description a general idea of the operation
may be gathered, and this is perhaps as much as can be
expected without an actual model. In the next place,
it may be proper to say some attention to the gen-
eral operation, and of this perhaps the most accurate
idea may be formed by a regular analyses of the re-
spective motions of the projected reticulator. Let
us suppose that a mesh has just been completed, and
wound up on the receiving beam, and that we are
then proceeding to form a second row, the motions
then will occur in the following succession:

1st. The shifting motion of the upper bobbin.
At this stage of the operation, both bobbins are up-
on the lower spindle; but as the upper bobbin is to
be shifted, those must first be lifted upon the upper
one. This may very easily be accomplished, by hang-
ing a shaft above, with a vertical motion, and fur-
nished with wire hooks corresponding to each bob-
bin. If a small groove is turned in both bobbins,
either one or both may be lifted at pleasure. For if
the hooks lay hold of the lower bobbin, both must
rise; and if, as in this case, the upper only is laid
hold of, the under will not be at all affected. When
the upper bobbin has been lifted, the shaft may be
moved from right to left, or vice versa as the case
may be, and the shift completed. This operation
may be effected easily by one or both of the opera-
tor's hands. This part of the apparatus is so simple,
that it has not been deemed necessary to give any
drawing; although this deficiency, if the experiment
were to be tried, might very easily and speedily be
supplied. The shift being completed, both bobbins
are to be let down upon the lower spindle, and each
should be furnished with a small eye to guide the
twine properly round the meshing-frame. The ap-
paratus is now ready for the second motion.

2d Motion. This is the circular revolution which
the mesh-frame takes upon its own axis, carrying
with it the attendant apparatus in order to form
the ring. For the principle of this, of which something
has been already said, reference may again be made
to Drawing 1st. Fig. 1 and 2. In Fig. 1, it will be
obvious that the cord which passes round the pulley
at F will turn it either from right to left, or vice ver-
sa, every time that the shaft I is elevated or depre-
sed. This shaft may be constructed as an oblong
frame placed horizontally along the whole machine,
and moved on centres directly behind the spindle
A. Then if that part at the left hand which appears
elevated be depressed, the other end at the right will
rise, and the whole spindle will turn round one, one
and a quarter, or one and a half turns, as may be
most convenient, and by sinking the right again,
it will revert to its present position; these motions may
be conveniently given by two treddles like those of a
weaving loom. Thus the circular motion of the
twine to form the ring may be produced.

3d Motion. Of this something has already been
said, it being entirely analogous to the first motion.
Both bobbins are to be lifted by a shaft and hooks,
to bring them upon the upper spindle. The whole
is then to be moved until the bobbins are over the
centre of the ring, when they may be let down
and tightened to form the knot. This being done, the
spindle returns to the outside of the ring. The mo-
tions are seen very plainly in Fig. 3., both being ef-
ected merely by moving the shaft O, which may ei-
ther be done by the hand or foot, as experience may
show to be preferable.

4th Motion. The knot being drawn tight, is to
be lifted off the points at C, which may be done by
raising any of the directing shafts, without any addi-
tional apparatus. The receiving beam being then mo-
v ed one notch, the operation is completed. The sim-
plity of these motions, and the smallness of their num-
ber, must be evidently advantageous to a practical
machine, whether wrought by the operator, or put in
motion by mechanical power. In particular arrange-
ment for the former of those plans, the most efficient
practical rule always is, to employ both the hands
and feet of the operator, allowing as much as can be
done without the inconveniency of too frequent shift-
ing to be performed by the feet. The obvious rea-
son of this is, that the less that the hands are employ-
ed in the production of motion, the more they will
be at liberty to remove or correct casual impediments
without retarding the operation.

It will be obvious that what has been written is
rather to be viewed in the light of general and lead-
ing principles, than as a detailed description. No-
ting could be farther, however, from the writer's in-
tention, than to pass any thing in a cursory or su-
perficial way for the purpose of concealment. Ex-
perience has convinced him, that in the description
of infant and speculative inventions in mechanics, it is
always more safe, and certainly much more candid,
merely to state principles of action in a general way,
than to incur the risk of misleading others, by laying
down, in a certain and didactic form, what has not
yet been proved by the only infallible criterion, viz.
the results of actual trial and practical experience.
In the present state of the invention, what remains
may be confined to general and miscellaneous remarks,
and what further description is necessary to convey
such an idea of the drawings as has not hitherto been
given.

Figure 7. exhibits a general view of a profile ele-
vation of the machine as viewed from the right hand.
The posts are at AA; the top rail of the framing
at B; the receiving roller at C; a section of the
directing pins at D and E; an elevation of the
mesh frame at F; the vibrating frame which com-
unicates the rotatory motion to the mesh frame at
G; the two directing pulleys at HH; one treddle
at L.

Figures 8, 9, 10, 11, 12, are intended to show more
clearly the adaptation of certain parts which are im-
perfectly represented, or omitted in the general figures.

Fig. 8. exhibits a barrel by which the rotatory
motion may very conveniently be given to the mesh.
frame. Two cords may be attached to the wheel at $B$, and passing round it in opposite directions, will move the vibrating frame. From the smaller part of this barrel or cylinder at $A$, two similar cords will complete the connection with the treddles 1 and 2. Thus the depression of the treddle 1 will produce one motion, and that of the treddle 2 will in like manner give the inverted one. Fig. 9. is a profile of the same apparatus. Figures 10. and 11. exhibit two different ways of giving motion to the cross rails and pins for changing the mesh. In Fig. 10. this is done by a band passing over a pulley. In Fig. 11. the same is done by two inverted racks, and an intermediate pinion. The first of these will be the cheapest plan of construction, but the second is by much the most steady and certain in its operation. Fig. 12. is a plan for shifting the receiving beam to wind up the finished net. It is done merely by pulling a handle at $A$, a weight (not represented) being suspended from the other extremity $B$ of the cord.

Some idea of the nature of the machine may be collected from these drawings. With regard to the expense of the construction, the writer intended to conclude this description with an estimate; but upon reflection he has been induced to postpone this, at least for the present, for the following reasons.

1st. For two very conclusive and unavoidable reasons; the first trial of every mechanical experiment is conducted at a much greater expense than what becomes necessary in a more advanced stage. It is hardly to be expected that any projector, however conversant he may be both with the theory and practice of mechanics, can at once arrange and mature a complicated and extensive body of machinery, so as both to give it the greatest possible efficiency, and construct it with the strictest attention to simplicity and economy. It is perhaps as much as ever has been effected in new machinery, if the advantage gained by its adoption be sufficient to counterbalance the difficulties to which it is exposed, and leave an ultimate profit in its favour. Hence projectors very frequently, from forming expectations more sanguine than reason will warrant, are apt to involve both themselves and others in disappointments, the more severe in proportion to the expectations which have been excited. But were the engineer capable of even much greater precision in all the minutiae of his plan than is generally found to be the case, it would still be impossible that he could conduct his first experiments upon terms nearly equal to those which may be obtained afterwards. Every operative mechanic whom he may have occasion to employ, must have a considerable practice before he can execute his work either so perfectly or so speedily as in matured businesses. It is also impossible to allot or apportion the various departments of the work in that order and method necessary to produce that division of labour which is the very essence of every business. Upon the whole, perhaps the most economical plan is merely to try the experiment upon a very limited scale for some time, and thus to purchase that experience which must be purchased at as small an expense as possible. (J. D.)

CHALCEDONY. See ORYCTOGENSY.

CHALDEA. See BABYLON.

CHALK. See ORYCTOGENSY.

CHALLENGE, (Calumnia,) is generally un-

derstood, in common language, to signify a summons or provocation to fight a duel, in consequence of an affront offered in derogation of honour. This is considered, in law, as an offence against the peace; and, therefore, to send a verbal or written challenge, or to be the bearer of it, are punishable by fine and imprisonment, according to circumstances. The merely endeavouring to provoke another to send a challenge is also deemed a high offence; and if the challenge, arise on account of money won by gaming, the offender, by Stat. 9 Ann. c. 14. shall forfeit all his goods to the crown, and suffer two years imprisonment. The Court of King's Bench frequently grant informations against persons sending challenges to justices of the peace, and in other heinous cases. See DUEL.

Challenge is also a legal term, and generally signifies an exception taken against jurors, who are returned by the sheriff to pass on a trial. Challenges to jurors, in civil cases, are of two sorts, challenges to the array, and challenges to the polls. Challenges to the array are an exception at once to the whole panel, in which the jury are arrayed by the sheriff in his return, and may be made upon account of partiality, or some default in the sheriff or his under officer. Although there should be no personal objection against the sheriff, yet it is a good ground of challenge to the array, if he arrays the panel at the nomination, or under the direction of either party. Challenges to the polls are exceptions to particular jurors, and are made. 1. Propter honoris respectum; as if a lord of parliament be impanneled on a jury, he may be challenged by either party, or may challenge himself. 2. Propter defectum, on account of a suspicion of bias or partiality. This may be either a principal challenge, or to the favour. A principal challenge is when the cause assigned carries with it prima facie evident marks of suspicion: Challenges to the favour, on the other hand, are when only probable circumstances of suspicion are assigned, the validity of which is left to the determination of triors, who are two indifferent persons named by the court. 4. Propter delictum, on account of some crime or misdemeanour, which affects the person's credit, and renders him infamous.

Challenges upon any of the foregoing accounts are stiled challenges for cause; and they may be made without limitation in both civil and criminal trials. But in trials for felony, the English law, in favorem vitae, allows the prisoner a peremptory challenge to a certain number of jurors, without shewing any cause at all. By stat. 22 Hen. VIII. c. 14. the number of peremptory challenges is limited to twenty. This privilege of peremptory challenges is denied to the king, by stat. 33 Edw. I. st. 4. It is held, however, that the king need not assign his cause of challenge, till all the panel is gone through, and unless there cannot be a full jury, without the persons so challenged; in which case the king's counsel must shew cause, otherwise the juror shall be sworn. In cases of high treason, the prisoner may, by stat. 7 W. III. peremptorily challenge thirty-five jurors.

Members of a court martial may be challenged by the prisoner on the score of partiality. The prisoner, however, must assign his cause of challenge, of the relevancy, propriety, and validity of which the members are themselves the judges. This privilege of
CHALONS, sur MARNE, a town of France, and capital of the department of the Marne, is situated between two fine meadows on the banks of the Marne. The principal public buildings and curiosities of this place are the court-house, the principal church with its spires, the triumphal arch dedicated to Bonaparte, and the promenade called Le Jard, which is reckoned the finest in France. There is here also a botanic garden, a public library, a cabinet of natural history, and a society of agriculture, commerce, science, and the arts. A very considerable trade in corn and wines was formerly carried on in this place, but it has greatly diminished since the formation of the canal of Briare. Corn and oats, and white and red wines, are still carried to Paris, and very considerable quantities of smoked and salted bacon. There are here also several distilleries, a paper manufactory, and a nitre works. Hemp and cotton thread, hosiery goods, a kind of drab called espagnolettes, and several other linen and woollen stuffs, are manufactured here in great quantities. Population 11,150. (w)

CHALONS, sur SAONE, the Cabillonum of the ancients, is a town in the department of the Saone and the Loire, is situated in a beautiful and fertile valley, on the right bank of the Saone. It is surrounded by walls, and defended by a citadel, and consists of the old town, the new town, and the suburbs of St Lawrence. The chief public buildings and curiosities are the principal church, the court-house, and the library or ancient college, the hospitals of Charity and St Lawrence, the dispensary, an orphan school, the public baths, and the hydraulic machine. The saloon, which contains the library, is very handsome, and the books, though in great confusion, are still numerous and valuable. It was originally composed of books left by the Jesuits, and since the revolution it has been augmented by the magnificent collection belonging to the suppressed Abbey of La Ferlo. There are here two globes made of tin plate five feet in diameter, and executed by Father Le Grand in 1792. The theatre, which is constructed in the late church of the Jesuits, has a wretched appearance, but the internal decorations are good. In the middle of the market place is a fountain adorned with a statue of Neptune, and there is a handsome coffee-house called the Rondou, which is decorated chiefly with beautiful English engravings. The promenades are upon the quay and on the ramparts of Santa Maria, St Lawrence, and Gloriette. This town carries on a considerable trade in the wines, grain, and iron of the surrounding county, and is also the entrepot of all the merchandise which is sent from the north to the south, and from the south to the north of France. The essence of the east, which gives the peculiar colour and brilliancy to artificial pearls, is manufactured here from the scales of the bleak (Cyprinus alburnus) which are caught in great abundance. The canal du centre, which joins the Saone and the Loire, begins at Chalons and terminates at Digoin.

The remains of a Roman amphitheatre and several inscriptions attest the antiquity of this town, which is situated on the great Roman way from Lyons to Boulogne. Population 12,000. (w)

CHAMEДΟRIA, a genus of plants of the class Dicotydea, and order Hexandria. See Botany, p. 337.

CHAMELEON. See Mammalia.

CHAMEROPS, a genus of plants of the class Polygama, and order Dicotydea. See Botany, p. 346.

CABERLAN, (Camerarius,) an officer, various in rank and in duty according to the chamber or employment with which he is connected; as,

1st, The Lord Chamberlain of Great Britain, who is commonly reckoned the sixth great officer of the crown. The office is hereditary; and where it descends to one or more females, it is executed by deputy, who must be approved of by the king, and must not be of a degree inferior to a knight. This officer is charged with the pomp and ceremony necessary to be observed at royal coronations, and on certain other solemn occasions; to him belongs the government of the palace at Westminster; he is answerable for the due arrangements necessary for the convenience of the House of Lords in the time of Parliament; he claims livery and lodgings in the king's court, &c. and the gentleman usher of the black rod, yeoman, usher, &c. are under his authority.

2d, The Lord Chamberlain of the Household, who has the superintendence of all officers belonging to the king's chamber, (except the bed-chamber, which is under the grooms of the stole,) and also of the wardrobe, of artificers retained in the king's service, messengers, comedians, &c. The serjeants at arms are likewise under his inspection, and the king's chaplains, physicians, apothecaries, &c. He has under him a vice-chamberlain, who, along with the chamberlain himself, are always privy-councillors.

3d, There were formerly Chamberlains of the King's Courts, of whom still remain Chamberlains of the Exchequer, who keep a controlment of the pells, of receipts and disbursements, and have in their custody the leagues and treaties with foreign princes, many ancient records, and the standards of money, weights, and measures.

4th, The Chamberlains of London, Chester, and other cities or local jurisdictions; the principal duty of whom, is, to receive the rents and other revenues payable into their respective chambers. (n.b.)

CHAMBERY, formerly the principal town of Savoy, but now the chief place of the department of Mont Blanc, is situated in a delightful valley surrounded with mountains, on the left bank of the river Lcisse, and upon the small river Albano. Its suburbs are large and elegant, the houses have all piazzas, and the principal public buildings are, the ancient ducal palace in the centre of the town, and the Salle de Spectacle. It is defended only by a castle placed on an eminence. The principal manufactures of Chambery are those of stockings, silk thread, works in marble, and leather. Liqueurs held in great estimation are likewise distilled here. Population in 1810, 12,000. See Tynn Almanach du Commerce, p. 728. (w)

CHAMERAPHYS, a genus of plants of the class Triandria, and order Trigynia. See Botany; and R. Brown's Prodromus Plant, Nov. Holl. &c. p. 19.

CHAMOIS. See Mammalia.
This celebrated vale lies north from Mount Blanc, and south east from the lake of Geneva. The river Arve, which rises in the Col de Balme, flows through the centre of the valley. Near the middle of its course it receives the Arveiron on the left, an impetuous torrent, chiefly noted for its magnificent origin in the glacier of Bois. (See the art. Alpes, vol. i.) The vale of Chamouni forms but the first and smallest portion of the channel of the Arve. Upon quitting the valley through which it had winded in a south westerly direction, it takes a bend to the north, and afterwards proceeds to the north west, and enters the Rhone below Geneva. Chamouni can be approached with ease and safety only from the north; and the stations from which travellers usually commence the journey are Geneva, and Martigny, a town situated in the west of the Vailais. The route from the latter place passes over the Tete Noire, or the Col de Balme, (see art. Alpes,) and introduces the traveller at the head of the valley. The road from Geneva winds along the banks of the Arve, and enters the valley at its southern extremity. This route, though not destitute of Alpine scenery, is less wild and picturesque than the other; but it is upon the whole a more agreeable approach, and better accommodated to the generality of travellers. From Geneva to the Priory, the distance is reckoned about 40 English miles, and can easily be travelled in one day. The roads from Geneva to Sallenche, which is considerably more than half of the journey, are well made, and accommodated to every kind of vehicle; but upon leaving the latter place, the country assumes a more alpine appearance, and the roads acquire a similar character, and can be passed only on horse-back, or in a char a banc. But on whatever side he approaches the valley, the view of it, when seen for the first time from some of the heights over which the road passes, throws the traveller into a kind of astonishment which cannot be expressed. He seems introduced into a new world. The majestic summits of the pointed rocks, covered with ice and eternal snow; the mountains which appear to support the sky, and whose height alarms the senses, and can with difficulty be grasped by the imagination; the striking contrast of the red colour of the primitive rocks with the dazzling white of the snow which covers them; the glaciers which descend from their lofty summits to the very edge of the valley; the beautiful variety of colours exhibited by the towers, pyramids, and obelisks which rise from the surface of the glaciers, when illuminated by the sun; the sombre colour of the forests of fir; the pure verdure of the pasturages and meadows; the cottages, churches, and hamlets scattered through the valley; the women and children occupied in country labour, in their garden, or before their houses, with their eye upon the flocks feeding around them: the whole forms a picture whose beauty it is easier to feel than to describe. What is improperly called the vale of Chamouni, extends from the source of the Arve to about two miles beyond the village of Ouches, and is near 18 miles in length. Its breadth no where exceeds a mile and a half, and in some places it is considerably less. The greatest portion of the valley stretches from north east to south west. About a mile, however, south from the Priory, the direction is changed to west, and afterwards to north west, by which means the traveller is prevented from seeing the whole at one view. Mount Breven, and a long range of mountains called La chaîne des Aiguilles, form its western boundary; while on the east side rises Montanvert to the height of 2752 feet above the bottom of the valley, beautifully wooded to the top; and beyond which are seen several immense masses of perpendicular rocks, with pointed summits. From each extremity of Montanvert range other mountains of less note, which complete the eastern boundary, and between which descend those immense glaciers which form one of the most striking features of this interesting scene. All the glaciers enter the valley on the eastern side, and in the following order, viz. Taconnà at the southern extremity, opposite the village of Ouches; Bossons Montanvert between the mountain and a range of pointed rocks; Bois, near the source of the Arveiron; Argentiere and Tour, near the source of the Arve.

When we consider the great elevation of the valley above the level of the sea, (3354 feet,) and the immediate neighbourhood of these immense masses of ice and snow, it is somewhat surprising, that its mean temperature should seldom be more than 10° or 11° below that of Geneva. Bouclet gives the following state of the thermometer as the average temperature of the summer:—at nine in the morning, 52 degrees Fahrenheit; at mid-day, 66; and in the evening, 57. This uncommon mildness of the climate may be in some measure owing to the general tendency of valleys to concentrate the rays of the sun; but more, perhaps to the particular direction of the valley, by which it is exposed for near ten hours in summer to the direct action of the sun's rays. The climate, however, even in summer, is very variable. Saussure states, that on the 25th of July, at noon, in the shade, the thermometer rose to 77 degrees; while on the 22d of the same month, it was only 66; and in the morning of the 23d there was a strong hoar frost. The fine season usually commences in June, and ends in September; though October, and even November, are sometimes agreeable months. Winter, in general, begins in November, and ends in May. During that time, the valley is completely covered with snow to a considerable depth; the nights are clear; and the thermometer often falls to 22 degrees below the freezing point. While this dreary season continues, the inhabitants seldom go abroad, the women occupy themselves in spinning, and the men in attending to the cattle.

The following remarks of Saussure will enable the reader to form some idea of the length and severity of the winter. "I arrived at Chamouni," says he, "on the 24th of March, and found the whole valley covered with snow. At the Priory it was a foot and a half deep, at Argentiere four feet, and at Tour twelve feet. The heat of the sun softened the snow in the day-time; but it froze again during the night to such a degree, that loaded mules passed over it without leaving any impression of their feet." The appearance of the valley at this season is grand, but by no means interesting. The immense space between the summits of the mountains and the bottom of the valley, presents one uniform white surface, unbroken except by some rocks, whose steep sides cannot retain the snow. The forests have a greyish hue, and the Arve, which winds through the centre of the valley, appears
like a black thread. The glaciers, which add so much to the beauty of the landscape, when the valley is clothed in green, produce no effect in the midst of all this white; but the pyramids of ice, whose steep sides have remained bare, appear like emeralds under the fresh white snow which covers their summits. The whole prospect, when illuminated by the sun, has, with all its grandeur and dazzling light, something dead and melancholy. The severity of the winter, and the shortness of the summer, which scarcely allows sufficient time for the labours of the field, render it highly important to hasten, if possible, the melting of the snow. The contrivance used for this purpose by the inhabitants of the higher part of the valley, is both simple and elegant, and attended with small expense. It consists in scattering black earth on the top of the snow, which, by absorbing more of the sun’s rays than the white surface, facilitates the clearing of the fields, and advances the labours of agriculture about three weeks.

Their chief crops are flax, barley, oats, beans, and potatoes. Flax succeeds better in the valley than in the open country, and the potato crop is uncommonly productive. No wheat is sown except on some small spots in the bottom of the valley, and no more is raised than what is necessary for the consumption of the inhabitants. Their principal crop is hay for the cattle during winter. Every proprietor divides his lands into two equal portions; the one half is laid out in corn fields, the other in meadows. This arrangement continues for six years, after which the meadows are ploughed up, and the corn fields converted into meadow. The whole of the bottom of the valley is laid out in this manner. But the chief source of their wealth arises from the pasturages among the mountains. The wealthier peasants have meadows, and even dwelling houses at different heights. They live in the lower part of the valley during winter; but at the approach of spring they quit their winter habitations, and ascend gradually to the more elevated pasturages, following the progress of vegetation. At the approach of autumn they descend by the same gradations, and thus pass the summer in a pleasant and varied style, enjoying a perpetual spring. Besides the pasturages, which are private property, there are others common to all the inhabitants of the valley. These commons are very valuable to the middling ranks of the community; but it is much to be regretted that the poorer sort, for whose benefit they are chiefly intended, cannot avail themselves of the advantage. For not only is money required to purchase cows, but it is also necessary to have the means of supporting them during the winter; and though by collecting the dried leaves of the ash tree, and by cutting hay in the unfrequented parts of the mountains, it is possible for one man to maintain a single cow during the winter; yet this is nothing compared to the advantage gained by those who possess a few acres of meadow land, and can send six or seven cows to the common pastures. Their cattle, as we formerly observed, is the chief source of their wealth. It is by the sale of their butter and cheese that they are furnished with the means of purchasing foreign luxuries, and those necessities and conveniences which even their simple style of life requires. Next to cheese, the most valuable production of the valley is honey. It is of a pure white colour, and has a brilliant grain resembling sugar. It has an exquisite taste, and an aromatic odour. It is sold in little barrels which cost a crown a piece. It has long been a puzzling enquiry how the honey of Chamouni acquires those peculiar properties. The bees are the same as those of the neighbouring villages, and the hives of Chamouni are often recruited from them, and yet, beyond the precincts of the valley, the honey is not distinguished by any of those peculiar qualities. Sausserre conjectures that it may be owing to the larch trees which abound in Chamouni, the leaves of which exude, at certain seasons, a kind of manna, in which the bees take great delight. Though the profit arising from the culture of bees in the valley is very considerable, yet the trouble and risk are proportionally great, arising not only from the length and severity of the winter, but chiefly from the too early appearance of fine weather, which tempts the bees to go abroad before the valley is cleared, by which means they die among the snow, or, if forcibly detained, destroy one another in the hive.

Honey is perhaps the only native luxury of which Chamouni can boast. Fruit of any kind is rarely met with, and the vine is entirely unknown. The apples, cherries, and plums, which grow there, are all of the wild kind, and seldom arrive at maturity. The oak, the chestnut, and walnut tree, are never seen.

The population of the valley is very considerable for its extent. If we were to judge, however, of the number of the inhabitants, from the crowds which appear in every village upon the arrival of a stranger, we should form rather too high an estimate of its population, for, on those occasions, every male person in the district presents himself, in the expectation of being hired as a guide. The valley is divided into three parishes; Ouches, in the south west; Argentiere, in the north east; and the Priory in the middle. Bourrit, who visited the country about 30 years ago, gives the following statement of the population, viz.: 300 in the district of Vaudagne, 1000 in the parish of Ouches, 1200 in the Priory, 500 in Argentiere. It is probable that since that period the number of the inhabitants has considerably increased, for even then the progress of population was very discernible, owing no doubt to the great influx of strangers from all parts of Europe during the summer months—a practice which had begun only a few years before Bourrit wrote, and which, it is likely, has since that time become more general, unless checked, perhaps, by the present disturbed state of the continent. The effect of these visits upon the industry of a people secluded from the world, like those of Chamouni, must obviously be very great, not only by circulating a quantity of money, and exciting a new demand for the productions of the valley, but by improving the roads, and opening, as it were, a direct communication with foreign countries. Accordingly Bourrit remarks, that those who a few years prior to his arrival had only three or four hives of bees, had then 40; that cheese and butter, which had formerly been made for home consumption only, was then a great article of exportation; that woods, which used to rot on the place where they grew, had been cut down, and the land cleared and converted into corn fields and meadows; that small and very inconvenient
houses had been replaced by others more spacious and airy, and consequently more healthy.

It is to be feared, however, that these occasional visits of strangers sometimes produce the very opposite effect, by leading the people to prefer the high, but precarious profits of being hired as guides, to the more slow but sure gains of regular industry. Hence we find a spirit of enterprise, and a desire of acquiring sudden wealth, the great spring of all their pursuits. For while the whole labours of the field devolve upon the women, not even excepting those severe labours, which in other countries are always the peculiar province of the other sex, as ploughing the fields, cutting the woods, mowing the hay, and threshing the corn; the men are employed as guides, in searching for crystals, in hunting the chamois, or in discovering the lurking places of the marmot. (For a minute and interesting account of all these occupations, we refer our readers to Sauvage.) The same love of gain induces the remaining part of the male population to go abroad to Paris and the cities of Germany, or to hire themselves during the summer months to the people of the Tarentaise and the valley of Aosta, for the purpose of making cheese, in which they are said greatly to excel. Even their winter amusements have something of the same character, especially in the large villages, where the men, perhaps for want of some employment to occupy their active minds, pass the greater part of their time in taverns, and play at games of hazard, in which they have sometimes been known to risk their whole property. In the small hamlets, however, the winter evenings are spent in a different manner. The whole village assemble in the house which has the largest room with a fire. The women spin, dress flax, and tell stories; while the men occupy themselves in making milk-pails, spoons, and other utensils in wood. The mistress of the house is at no other expense for their entertainment than a pitcher of water and a basket of wild apples, which are roasted under the ashes.

The men of Chamouni are of a middle stature, stout and active. They have a lively and penetrating air, and a gay character, inclined to raillery. They are in general honest, faithful, religious, and particularly distinguished for acts of charity and beneficence. They have no hospitals or foundations in behalf of the poor; but the old men and orphans, who have no means of subsistence, live at the houses of the inhabitants of the parish in regular succession. The government of the valley is that of a small republic, and is entrusted to a register, a syndic, and seven councillors. The chapter of Sallanches enjoys the sovereignty in all ecclesiastical matters; names the curates, and draws the church revenues. The curate of the priory has the title of administrator, because, besides possessing the cure of souls, he has also the management of the temporalities of the chapter. (5)

CHAMPARTY, (campi partitio,) in English law, an offence against public justice, whereby the champertor engages to carry on, at his own expense, the suit of the plaintiff or defendant, on condition of having the land, or other property in dispute, divided between them in the event of success in the suit. It is a species of maintenance, or the undue encouragement of law suits, to the oppression and disturbance of the honest and peaceable. Like that offence, it is punished at common law by fine and imprisonment, and by statute 32 Hen. VIII. c. 9. by a forfeiture of ten pounds. Such avaricious or malignant disturbers of other men's quiet, have been regarded as proper objects of chastisement by the laws of every well regulated state, and particularly by those of ancient Rome, which enact, qui improbre comitii in alienam li- tem, ut quicquid ex condensatione in rem ipsius re- dactum fuerit, inter eos communicaret, lege Julia de vi privata, tenentur; and accordingly perpetual in- famy, with the forfeiture of a third part of their goods, was the consequence of a conviction. (J. B.)

CHAMPION, he who undertakes to maintain, by single combat, his own right or that of another. By the law of England, a species of trial was formerly in use, known by the name of wager of battel, a rude mode of terminating disputes practised by most barbarous nations. In this judicial combat, the parties appeared either themselves, or (as came afterwards to be more usually the case) by their champions, having their armour on, and attended with every circumstane of pomp and ceremony that could give dignity to the spectacle. The weapons used were more or less dangerous according to the nature of the cause, as military, civil, or criminal. The consequences likewise, even when the unsuccessful combatant escaped unhurt, were more or less serious, both to the champion himself and his principal. If the champion of a woman, charged with a capital offence, was overcome, or proved recreunt, the woman was burnt, and her champion hanged; and so with regard to smaller offences. Principals seem originally to have been allowed to wage their battle from casualties of sex, nonage, or other excusable disability; but as the better ranks became more effeminate, or wise, proxies came to be allowed in all cases, being either retained as a standing officer among the great lord's other dependents, or hired for the special occasion.

The king's champion is an officer still employed at the coronation of our kings, as a relic of the ancient manner of that solemnity. In the true spirit of the wager of battel, he rides armed cap-a-pie into Westminster Hall where the king is at dinner, and makes challenge by proclamation of a herald. That if any man shall deny the king's title to the crown, he is there ready to defend it in single combat. The office is hereditary. (J. B.)

CHAMPLAIN LAKE. See CANADA, p. 930.

CHANCELLOR, a judicial officer, who appears originally to have been only a principal register or scribe under the emperors; but in modern times has greatly advanced in dignity, having become, in different kingdoms of Europe, the chief administrator of justice. The name has also been extended to a variety of inferior officers, but all of them of a judi- ciary character; as chancellor of a diocese, or of a bishop; chancellor of a university, of the exchequer, &c. Its etymology, as in so many other instances, is disputed; some deriving it from cancellari, because anciently the cancellarius is said to have sat within an inclosed place, or lattice, to protect him from the press of persons who had occasion to transact business with him: others preferring cancellare, to delete or cancel, because, as the highest point of his jurisdiction, he has the right of cancelling, by his own proper authority, the king's letters patent, when
grant contrary to law; an etymology, however, which is plainly inconsistent with the originally subordinate nature of the office.

The Lord High Chancellor of Great Britain is the chief magistrate in the judicial establishment of the country. He takes precedence of the nobility, and also of all the spiritual lords, except the Archbishop of Canterbury. The office is, in later times, conferred by his majesty merely delivering the custody of his great seal; and is, in like manner, determined by the seal being resumed or resigned. It implies a very high, and, in many respects, an undefined authority in its judiciary capacity; and comprehends, besides, certain political dignities. With regard to the former, though all other judges in England are bound to give judgment by the strict rules of law, yet the chancellor, like the ancient prpopos, has power to mitigate the severities which would otherwise frequently arise from its undistinguishable dictates, and to regulate his decisions secundum aquum et bonum. Or, in the words of Staundford, the chancellor has two powers, one absolute, the other ordinary; meaning, that although, by his ordinary power, he must, in some cases, observe the form of proceeding as other judges, in his absolute power he is not limited by the law, but by conscience and equity, according to the circumstances of things. Besides this exclusive jurisdiction which he exercises in his court of chancery, the justices of the peace throughout the kingdom are of his appointment. And having been formerly, for the most part, an ecclesiastic, when few else could be found sufficiently learned for the office, he presided over the royal chapel, and became what is called Keeper of the king's conscience, a phrase, as we understand it, which implies that he was a sort of chief confessor to the king, or the expounder of his casuistical difficulties on points of religion and justice. He is also visitor, in right of the king, of all hospitals and colleges of the king's foundation, and patron of all the king's livings under the value of twenty marks a-year in the king's books. He is, besides, the general guardian of all infants, idiots, and lunatics, and has the general superintendence of charitable uses. With regard to his political dignities, the principal seem to be that of being a member of the privy council, in virtue of his office, and also, (according to Lord Ellesmere,) of being prolocutor of the House of Lords.

Previously to the statute 5 Eliz. c. 18, the chancellor and lord keeper were distinct officers, having different powers; but by that statute both officers are declared to have one and the same power, so that there cannot, since that statute, be a lord keeper and a lord chancellor at the same time.

With regard to the variety of inferior officers to whom the appellation of chancellor has, in modern times, been extended, we cannot take room to detail any part of their different local or subordinate jurisdictions and dignities. The principal officers so denominated are, the chancellor of the exchequer, who manages the royal revenues, and, along with the treasurer, chief baron, and other judges, presides in the court of equity held in the exchequer-chamber; chancellor of the order of the garter, and of other military orders; chancellor of the duchy of Lancaster; chancellors of universities; chancellors in cathedral churches; and chancellor of a diocese, or of a
ly redress the injury, and refers that conscientious

task to the chancellor, the keeper of his conscience.

In this ordinary court," continues the same writer,

is kept the officina justicia, from which issue all
original writs that pass the great seal, all commissions
of charitable uses, sewers, bankruptcy, lunacy, and
the like; and for which it is always open to
the subject, who may have there at any time demand and
have, ex debito justicia, any writ that his occasions
may call for." The extraordinary court, on the
other hand, proceeding by the rules of equity, softens
the rigour, but by no means opposes the spirit, of
the common law, in those cases where, by reason of
the unavoidable generality of that law, manifest in-
justice would result by its undistinguished applica-
tion. Accordingly, this court interposes in all cases
of frauds, deceitful or rash engagements, &c. which
admit not of remedy at common law. It gives relief
in the case of minors, against as well as for them; of
married women pending their coverture, and in cer-
tain suits at their instance against their husbands; of
breach of trust; loss of titles to lands, &c.

Without, however, attempting to elucidate further
the nature of the jurisdiction of this high court, or to
enumerate the variety of pleas to which it is com-
petent, (a task which has puzzled the ablest writers,
even when free to investigate the subject in the fullest
manner,) we shall content ourselves with one or two
general observations on this and other courts of equi-
ty, taken from a modern treatise of respectable char-
acter. "Early in the history of our jurisprudence,"
says Mr Mitford in his work on the Pleadings in
Chancery, "the administration of justice by the or-
der courts appears to have been incomplete. To
supply the defect, the courts of equity have gained an
establishment; assuming the power of enforcing the

principles upon which the ordinary courts also decide,
when the powers of those courts, or their modes of
proceeding, are insufficient for the purpose; of pre-
venting those principles, when enforced by the ordi-
nary courts, from becoming, contrary to the purpose
of their original establishment, instruments of injus-
tice; and of deciding on principles of universal jus-
tice, where the interference of a court of judicature
is necessary to prevent a wrong, and the positive law
is silent. The courts of equity also administer to the
ends of justice, by removing impediments to the fair
decision of a question in other courts; by provid-
ing for the safety of property in dispute, pending a
litigation; by restraining the assertion of doubtful
rights, in a manner productive of irreparable damage;
by preventing injury to a third person from the
doubtful title of others; and by putting a bound to
vexatious and oppressive litigations, and preventing
unnecessary multiplicity of suits; and, without pro-
nouncing any judgment on the subject, by compel-
ling a discovery which may enable other courts to
give their judgment; and by preserving testimony,
when in danger of being lost, before the matter to
which it relates can be made the subject of judi-
cial investigation. This establishment has obtained
throughout the whole system of our judicial policy;
most of the inferior branches of that system having
their peculiar courts of equity, (e. g. the court of ex-
chequer, courts of Wides, the counties palatine, cinque
ports, &c.) and the court of chancery assuming a gen-
eral jurisdiction in cases which are not within the
bounds, or which are beyond the powers of other jur-
isdiction."

Pleadings in Chancery, &c. (a. b.)

1. The doctrine of chances, considered as a mathe-
tatical theory, treats of the probability of the hap-
pening of such events as cannot be accurately pre-
predicted, either on account of our being ignorant of
their precise causes, or else because the number of cir-
cumstances to be taken into account, in estimating
the effects of those causes, is too great to be fully com-
prehended by the human mind.

This theory treats particularly of the chances of
play, in such games as depend on circumstances be-

beyond the control of the players. Of this nature
are lotteries, and all games depending on the throw-
ing of dice, or shuffling of cards. It is also applica-
tible to certain moral and political events; such as the
credibility of human testimony, and the decision of
questions by a majority of votes; but one of its most
valuable applications is to the resolution of questions
depending on the probability of the duration of hu-
man life; a subject which is become of the highest
importance to individuals, as well as to communities,
on account of the great number of life insurances, an-
nuities depending on lives, benefit societies, &c. which
are now so common.

2. This branch of the mathematics is entirely mo-

dern, it having been first cultivated by Pascal and
Fermat about the middle of the 17th century. The
following problem was one of the earliest that enga-
ged Pascal's attention, and was proposed by him to
Fermat: "Two persons sit down to play for a cer-
tain sum of money, and agree that he who first gets
three games shall be the winner. One of them has
got two games and the other one, but being unwill-
ing to continue their play, they resolve to divide the
stake; how much should each receive?" Fermat
resolved the problem by the method of combinations,
but Pascal had previously found out its solution by
a different method.

3. The researches of these mathematicians on this
subject remained for many years among their papers;
and in that interval Huygens, having heard proba-

bly of what had passed between them, turned his at-

tention to the subject, and composed his work, De
ratiociniis in Ludo alea, which Schooten published
for the first time in 1655, at the end of his Exercita-
tiones Mathematicae. The rudiments of the theory
were here demonstrated for the first time; and this
was nearly all that was done previous to the middle
of the 17th century; hardly anything having been
added during the remainder of it, if we except a short
paper by Saveur on the game of Bassette, inserted in
the Journal des Savans (1679), a letter on the game
of Tennis by an anonymous writer, and another small
4. The celebrated James Bernoulli is the next writer whose labours require to be particularly noticed. He began by proposing the following problem in the *Journal des Sçavans* for 1690: "Two persons, A and B, play with a dice; the condition is, that whoever gets a certain number of points first wins the game. A begins by throwing the die once; then B throws it once. A next throws the die twice; afterwards B throws it twice; then A three times, and B three times; and so on. What is the ratio of their respective chances of winning?" The problem remained without an answer, until its ingenious author gave one in the *Leipsic Acts* for 1690. This called the attention of Leibnitz to the same subject, who gave also a solution in the same *Acts*. Bernoulli was now preparing his *Ars Conjectandi*, a work which, besides such questions as were agitated by Pascal and Fermat, contains a multitude of others, increasing in difficulty. He has also attempted to apply his theory to moral and political events. He died, however, before he could give his labours the degree of perfection he wished for; and they did not appear until the year 1715, when they were published by his nephew Nicolau Bernoulli, who had himself treated of the same theory in the *Leipsic Acts* for 1711, in a memoir called *Specimina artis conjectandi ad quæstiones juris applicatae*.

5. In the interval between the completion of James Bernoulli's discoveries and their publication, the theory of chances was handled by two excellent mathematicians, Montmort and De Moivre. The first of these turned his attention to the subject, with a view to compensate for the loss of Bernoulli's labours, in the event of their never being published. De Moivre began by communicating to the Royal Society, in 1711, a memoir entitled, *De Mensura sortis*. He afterwards published, in 1716, his *Doctrine of Chances*, a work justly regarded as one of the most valuable that has ever appeared on the subject. The best edition is the third, printed in 1756, together with his *Treatise of Annuities on Lives*. His *Miscellanea Analytica* also contains some disquisitions on the same subject.

6. Mr Thomas Simpson has likewise treated of this subject, in a work called the *Nature and Laws of Chance*, first published in 1740. This treatise is concise, and at the same time perspicuous, and, like the ingenious author's other writings, is remarkable for its originality.

7. The application of the doctrine of chances to questions connected with political economy, is by far the most interesting branch of this theory. The subject of Life Annuities, in particular, is highly important. Van Hudden, and the celebrated pensionary of Holland, De Witt, appear to have been the earliest who considered it; and Sir William Petty also turned his attention to it, but without any degree of success, probably on account of his want of mathematical knowledge. Dr Halley was the first who made any considerable progress in its improvement, by constructing tables of the probability of human life, from a comparison of the bills of mortality of Breslaw in Silesia. De Moivre carried on what Dr Halley had begun; and Simpson greatly contributed to the perfection of the theory. The labours of Dodson, the friend of Dr Moivre, are also justly entitled to notice; in his *Mathematical Repository*, the subject of annuities, as well as the doctrine of chances in general, are treated with great clearness, and in a manner well suited to persons having but an ordinary share of mathematical knowledge. Indeed, we have freely availed ourselves of his labours in the compilation of the brief view we here give of the subject.

We shall now explain some of the more useful parts of this theory, and exemplify the mode of reasoning it requires by a series of problems.

### Problem I.

8. Suppose a circular piece of metal having two opposite faces, the one white and the other black, is thrown up, in order to see which of its faces will be uppermost after it has fallen to the ground. When, if the white face be uppermost, a person is to be entitled to L.5, or any other sum of money; it is required to determine, before the event, what chance or probability that person has of receiving the L.5; and what sum he may reasonably expect should be paid to him, in consideration of resigning his chance to another person?

**Solution.**—Since by supposition there is nothing in the shape of the metal to determine one face to come up rather than the other, there is an equal chance for the appearance of either face; or in other words, there is one chance out of two for the appearance of the white face. Therefore, the probability that it is uppermost may be expressed by the fraction \( \frac{1}{2} \). And if any other person should be willing to purchase this chance, the proprietor may reasonably expect \( \frac{1}{2} \) of L.5 in consideration of his resigning his chance thereof.

### Problem II.

9. Suppose there are three cards, each of different suits, viz. one heart, one diamond, and one club, laid on a table with their faces downward, out of which, if a person at one trial takes the heart, he is to be entitled to L.5, or any other sum of money. It is required to determine, before the event, what chance or probability he has of winning and missing the said L.5; and what sum he may reasonably expect to be paid to him, in consideration of his resigning his chance to another.

**Solution.**—Since it is supposed that there is nothing in the external appearance of the cards to induce the person to choose one rather than another; and since he is to have but one choice, it follows that he has but one chance in three for obtaining the money: therefore the probability of his getting it may be expressed by the fraction \( \frac{1}{3} \). Again, since two cards remain after he has had his choice, either of which may be the heart, there are two chances out of three that he will miss it; and the probability
10. Suppose that there are five counters, of which four are black and one white, out of which, when mixed together, a person blindfolded is to draw one, and is to be entitled to L. 5, or any other sum of money, if he happens to draw the white counter. It is required to determine, before the event, what chance he has of winning and of missing the said L. 5; and what sum he may reasonably expect, upon transferring his chance to another.

**Solution.**—By reasoning in this as in the two foregoing problems, it will appear, that the person has only one chance in five of obtaining the L. 5, and four chances out of five for missing it; therefore, the probability of his obtaining it may be expressed by the fraction $\frac{1}{5}$; and the probability of his missing it by the fraction $\frac{4}{5}$. And he will be entitled to $\frac{1}{5}$ of the L. 5, if he transfers his chance to another.

**Problem IV.**

11. Suppose there are five counters, three black, and the other two white; out of which, when mixed together, a person blindfolded is to draw one, and is to be entitled to five pounds, or any other sum, if he happens to draw either of the white ones. It is required to determine, before the event, what chance or probability he has of winning, and missing, the said five pounds; and what sum he may reasonably expect to be paid to him for resigning his chance to another.

**Solution.**—In this case, the person has manifestly only two chances out of five for taking a white counter, and three for taking a black one: Therefore the probability of winning may be expressed by the fraction $\frac{2}{5}$, and that of missing by the fraction $\frac{3}{5}$: Also he ought to receive $\frac{2}{5}$ of the five pounds if he parts with his chance to another.

12. What has been said in these four problems concerning cards, counters, &c. may easily be conceived to extend to any other things which are the objects of chance. For instance, if, at the conclusion of the drawing of a lottery, there should remain in one wheel five tickets or numbers only, and in the other, two equal prizes and three blanks; then, the possessor of one of these tickets would be exactly in the situation of the person mentioned in the last question.

In general, if the number of blanks in a lottery be represented by $m$, and the number of prizes by $n$, then the probability of having one prize with one ticket will be $\frac{n}{m+n}$; and the probability of having a blank $\frac{m}{m+n}$. From which it appears,

1. That the probability of the happening of any event, considered as resulting from chance, may be expressed by a fraction, whose numerator is the number of chances for the happening of the event, and the denominator is the number of all the chances whereby it may both happen and fail. And the probability of such an event's failing, may be expressed by a fraction whose numerator is the number of chances for its not happening, and denominator the same as that of the former fraction.

2. The sum of the two fractions representing the probability of the happening and the failing of an event is equal to unity: Therefore, when one of them is given, the other may be found by subtraction.

3. The expectation, that is, the sum which the person who has a chance for the happening of an event is entitled to, if he resign his chance to another, is always the product of the fraction representing the probability multiplied into the sum expected: Therefore, if that sum be denoted by unity, the expectation will be denoted by the probability itself: Or, in general, if the expectation of an event be divided by the value of the thing expected, the quotient will express the probability of the event.

**Problem V.**

13. What is the probability that a person playing with a single die throws an ace each time for two successive throws?

**Solution.**—Suppose that the person is to receive L. 1, provided he succeeds in throwing an ace each time. Now, if an ace were to come up the first time, then, because the die has six faces, only one of which is favourable to him, his expectation on the second throw would be $\frac{1}{6} \times L.1$, (Art. 12.) But we may consider the first event, viz. the throwing an ace the first throw as the condition of obtaining this sum $\frac{1}{6} \times L.1$; and the probability of this event being also $\frac{1}{6}$, the expectation before the first throw must necessarily be $\frac{1}{6} \times \frac{1}{6} \times L.1$, (Art. 12.); and as in this case the probability is expressed by the same fraction as the expectation, the probability of throwing an ace each time for two successive throws is $\frac{1}{6} \times \frac{1}{6} = \frac{1}{36}$.

**Corollary.**—As it is evidently the same whether a single die be thrown twice successively, or two dice be thrown at once; therefore, the probability of throwing two aces (or any given face) at one throw with two dice, is also expressed by the fraction $\frac{1}{6} \times \frac{1}{6} = \frac{1}{36}$.

**Problem VI.**

14. A person offers to lay a wager of L. 1, that out of a purse containing $m+n$ counters, whereof $m$ are black, and $n$ white, he will, blindfolded, at the first trial draw a white counter; and also, that out of another purse containing $M+N$ counters, whereof $M$ are black, and $N$ white, he will also at the first trial draw a white counter, and that if he fails in either trial his wager shall be lost. It is required to determine the probability he has of succeeding therein.

**Solution.**—If, as in the last problem, we suppose he has already succeeded in the first trial, then it will follow, as has been there explained, that his expectation on the second will be $\frac{N}{M+N} \times L.1$, or simply $\frac{N}{M+N}$. And if, as in the same problem, we consider the success of his first trial as the condition of obtaining this expectation, then its probability will be $\frac{n}{m+n}$; which multiplied into that ex-
CHANCES.

Expectation, will give \( \frac{n}{m+n} \times \frac{N}{M+N} \) for the probability required. Hence it appears, that the probability of the happening of two independent events is equal to the product of the probabilities of their happening separately.

Cor. If the two events are both of the same kind, then the probability will be \( \frac{n^2}{(m+n)^2} \).

**Problem VII.**

15. A person offers to lay a wager of \( \frac{L}{1} \) that a white ball will come out of a certain drawer, containing \( n \) white and \( m \) black balls, on condition that he shall throw a die and receive a prize if the number of the face appearing be either an odd number or less than 5. Now, the probability of his losing the wager is \( \frac{5}{6} \times \frac{m}{m+n} \), and the probability of his winning it is \( \frac{1}{6} \times \frac{n}{m+n} \); hence the probability of either event is \( \frac{1}{6} \) times \( \frac{m}{m+n} \), and \( \frac{5}{6} \) times \( \frac{n}{m+n} \), and the probability of the two events is \( \frac{1}{6} \times \frac{m}{m+n} \) and \( \frac{5}{6} \times \frac{n}{m+n} \).

**Solution.**—By reasoning as in the last problem, it will appear, that the probability is expressed by \( \frac{m}{m+n} \) and the probability of succeeding in the second trial being \( \frac{m}{m+n} \), and the probability of failing in the second trial being \( \frac{n}{m+n} \), the product of these two fractions, or \( \frac{m}{m+n} \times \frac{n}{m+n} \), will be the probability required, (Art. 14.)

In like manner it appears, that the probability of failing in both experiments is the product of the probabilities of their failing separately, viz. \( \left( \frac{m}{m+n} \right)^2 \).

Cor. If the events be both of the same kind, the probability of failing in the first trial, and succeeding in the second, will be \( \left( \frac{m}{m+n} \right) \times \left( \frac{n}{m+n} \right) \), and that of failing in both \( \left( \frac{m}{m+n} \right)^2 \).

16. We may deduce the probability of the happening of three independent events from that of two, and the probability of four from that of three, and so on, by reasoning as follows: Suppose that the receiving of a sum of money, as \( \frac{L}{1} \), depends on the happening of three events, the probabilities of which are \( \frac{a}{b} \), \( \frac{c}{d} \), \( \frac{e}{f} \), respectively. Then, if the two first events had actually happened, so that the receiving of the sum depended on the third event only, the value of the expectation on that event would be \( \frac{e}{f} \times \frac{L}{1} \), (Art. 12.) Therefore we may consider \( \frac{e}{f} \times \frac{L}{1} \) as a sum to be received, provided the two first events happen. Now, we may regard the happening of the first two as a single event, the probability of which is \( \frac{a}{b} \times \frac{c}{d} \times \frac{e}{f} \) (Art. 14.); therefore the value of the expectation on all the three is \( \frac{a}{b} \times \frac{c}{d} \times \frac{e}{f} \times L \times \frac{1}{1} \), and the probability of their happening is \( \frac{a}{b} \times \frac{c}{d} \times \frac{e}{f} \) (Art. 12.)

In general, whatever be the number of independent events, the probability of their all happening is equal to the continual product of their separate probabilities.

**Problem VIII.**

17. What is the probability of throwing with a single die one ace, or more, in two throws, that is, either at the first or second throw, or at both?

**Solution.**—In this problem, we may consider the probability required as made up of two other probabilities, viz. that of throwing an ace at the first throw, and that of missing it at the first throw, and throwing it at the second: Therefore, if we estimate these separately, their sum will be the probability required.

In order to render the conclusion general, let \( g \) (the number of faces of the die) = \( n \). Then the probability of throwing an ace at the first throw is \( \frac{1}{n} \); and that of missing it, \( \frac{n-1}{n} \). Also the probability of throwing an ace at the second throw is \( \frac{1}{n} \); and, connecting this with the probability of missing it the first trial, we have the probability of missing it at the first trial and throwing it the second, expressed by \( \frac{n-1}{n} \times \frac{1}{n} \), (Art. 14.)

Therefore the probability required is \( \frac{1}{n} \times \frac{n-1}{n} = \frac{2n-1}{n^2} \). Hence, if we estimate the former of these probabilities, and subtract it from unity, the remainder must be the latter. Now, the probability of missing an ace at the first throw is \( \frac{n-1}{n} \), (Art. 12.) and the probability of missing it the second is also \( \frac{n-1}{n} \); therefore the probability of missing it twice is \( \frac{(n-1)^2}{n^2} \) (Art. 14.); and hence the probability of throwing it once at least in two trials, is \( \frac{1}{n^2} - \frac{(n-1)^2}{n^2} = \frac{(n-1)^2}{n^2} \), the same as before.

Cor. Hence it appears, that the probability of throwing one ace or more at a single throw with two dice, is \( \frac{n^2 - (n-1)^2}{2n^2} \). For it is evidently the same.
CHANCES.

18. What is the probability of throwing an ace, or any proposed face of the die, in three throws, that is, either at the first, second, or third throw?

Solution.—The probability required may be considered as composed of the separate probabilities of two events, viz. first, of the probability of throwing an ace either at the first or second throw; and, secondly, of the probability of missing it both at the first and second throws, and throwing it at the third.

The probability of throwing an ace in two throws has been found, by the last problem, to be \( \frac{n^2 - (n-1)^2}{n^3} \); and therefore (Art. 14.) the probability of missing it both throws, is \( 1 - \frac{n^2 - (n-1)^2}{n^3} \).

Again, the probability of throwing an ace at the third throw, is \( \frac{1}{n} \); and consequently the probability of missing it the first two throws, and succeeding at the third, is \( \frac{1}{n^3} \) \( (n-1)^2 \). \( \frac{n}{n^3} \) \( (n-1)^2 \).

Adding now the two probabilities, we have the probability required, expressed by \( \frac{n^2 - (n-1)^2}{n^3} + \frac{1}{n^3} = \frac{n^2 - (n-1)^2 + 1}{n^3} \).

In numbers the probability is \( \frac{2}{5} \).

The problem may also be resolved, by finding the probability of missing an ace three times successively, which will be \( \frac{n-1}{n} \) \( \frac{n-1}{n} \) \( \frac{n-1}{n} \) \( (\text{Art. 16.}) \), and this subtracted from unity, gives us \( 1 - \frac{n^2 - (n-1)^2 + 1}{n^3} \) for the probability of throwing an ace once or more in three throws, as before.

Cor.—Hence it appears, that the probability of throwing one ace, at least, by three dice, at one single throw, is \( \frac{n^2 - (n-1)^2}{n^3} \).

PROBLEM X.

19. What is the probability of throwing an ace, or more in \( m \) throws, \( m \) being put for any number whatever?

Solution.—Following the second mode of solution employed in the two preceding problems, we find that the probability of missing an ace \( m \) times successively, is \( \frac{n-1}{n} \) \( \frac{n-1}{n} \) \( \frac{n-1}{n} \) \( \ldots \) \( (\text{to} m \text{ factors}) = \frac{(n-1)^m}{n^m} \), and this expression subtracted from unity, leaves \( 1 - \frac{(n-1)^m}{n^m} = \frac{n^m - (n-1)^m}{n^m} \), for the probability of throwing one ace, or more, in \( m \) successive throws.

Cor.—The same expression is the measure of the probability of throwing an ace, or more, with \( m \) dice at one throw.

PROBLEM XI.

20. What is the probability of throwing one ace, and no more, with a single die, in two throws?

Solution.—The probability of throwing one ace, or more, at two throws, may evidently be regarded as the sum of two probabilities, viz.

1st, The probability of throwing one ace and no more.
2dly, The probability of throwing two aces.

Therefore, the probability of throwing one ace, and no more, must be measured by the difference between the probability of throwing one ace or more, and the probability of throwing two aces at two throws.

Now, the first of the two latter probabilities is \( \frac{n^3 - (n-1)^3}{n^4} \) (Art. 17.), and the second is \( \frac{1}{n} \) (Art. 18.) and their difference, or the probability required, is \( \frac{n^3 - (n-1)^3 - 1}{n^3} = \frac{(n-1)^3}{n^3} \).

Cor. The probability of throwing one ace, and no more, at a single throw, with two dice, is also \( \frac{2(n-1)^3}{n^3} \).

PROBLEM XII.

21. What is the probability of throwing one ace, and no more, in three throws?

Solution.—This probability may be considered as made up of two probabilities, viz. that of throwing an ace at the first throw, and missing an ace at each of the remaining throws; and that of missing an ace at the first throw, and throwing one ace, and no more, in the two remaining throws.

To estimate these, we must consider that the probability of throwing an ace at one throw is \( \frac{1}{n} \); and that of missing an ace in two successive throws, is \( \frac{(n-1)^3}{n^3} \) (Art. 17.); therefore the probability of throwing an ace at the first throw, and missing it at the second and third throws, is \( \frac{1}{n} \) \( \frac{(n-1)^3}{n^3} \) (Art. 14.) \( \frac{(n-1)^3}{n^3} \).

Again, the probability of missing an ace at one throw is \( \frac{n-1}{n} \); and that of throwing one ace, and no more, in two successive throws, is \( \frac{2(n-1)^3}{n^3} \) (Art. 20.); therefore, the probability of missing an ace at the first throw, and throwing an ace, and no more, in the two remaining throws, is \( \frac{n-1}{n} \) \( \frac{2(n-1)^3}{n^3} \) (Art. 14.) \( \frac{2(n-1)^3}{n^3} \).

Taking now the sum of these probabilities, we have \( \frac{(n-1)^3}{n^3} + \frac{2(n-1)^3}{n^3} = \frac{3(n-1)^3}{n^3} \).
for the probability required, which, in numbers, is
\[
\frac{3 \times 25}{216} = \frac{25}{72}
\]

Cor. The probability of throwing one ace, and no
more, at one throw, by three dice, is also \(\frac{3(n-1)^3}{n^3}\).

**Problem XIII.**

22. What is the probability of throwing one ace, and no
more, in four throws?

Solution.—This problem is the sum of the
probability of throwing an ace at the first throw, and
missing it in all the remaining three; and of the
probability of missing an ace at the first throw, and
throwing one, and no more, in the three remaining
throws.

The probability of throwing an ace at one throw
is \(\frac{1}{n}\); and that of missing to throw an ace, in three
successive throws, is \(\frac{(n-1)^3}{n^3}\) (Art. 16.); and therefore
the probability of throwing an ace at the first throw, and
missing it in the three following throws, is
\[
\frac{1}{n} \cdot \frac{(n-1)^3}{n^3} = \frac{(n-1)^3}{n^4}.
\]

Again, the probability of missing to throw an ace
at one throw is \(\frac{n-1}{n}\), and that of throwing one ace,
and no more, in three successive throws, is \(\frac{3(n-1)^3}{n^3}\)
(Art. 21.); and therefore the probability of missing
an ace at the first throw, and throwing one, and no more, in the three following throws, is
\[
\frac{n-1}{n} \cdot \frac{3(n-1)^3}{n^3} = \frac{3(n-1)^3}{n^4}.
\]

Therefore, the probability required is
\[
\frac{(n-1)^3}{n^4} + \frac{3(n-1)^3}{n^4} = \frac{4(n-1)^3}{n^4}
\]

In numbers, \(\frac{4125}{1296} = \frac{25}{72}\).

Cor. The probability of throwing one ace, and
no more, with four dice, at a single throw, is also
\(\frac{4(n-1)^3}{n^4}\).

**Problem XIV.**

23. What is the probability of throwing one ace,
and no more, in \(m\) throws, \(m\) being any number
whatever?

Solution.—We have found in the 11th, 12th, and
13th problems, that when the values of \(\frac{1}{n}\) and \(\frac{1}{n^3}\),
then the probabilities required, are
\[
\frac{2(n-1)}{n^3} \text{ and } \frac{3(n-1)^3}{n^4},
\]
respectively. By reasoning as above, these problems, we
should find, that when \(m=2\), then the probability is
\(\frac{3(n-1)^3}{n^m}\). Therefore, in general, the probability of throwing one ace, and
no more, in \(m\) throws, is \(\frac{m(n-1)^3}{n^m}\).

Cor. The same formula also expresses the probability of throwing a single ace at one throw with \(m\) dice.

**Problem XV.**

24. What is the probability of throwing two aces,
or more, in three throws, with a single die?

Solution.—Besides the event in question, there
is just one other that can possibly happen: either
never an ace will come up in the three throws; or else one, and no more, will be thrown. These three
events, then, making up certainty, the sum of their
probabilities must be unity. Therefore, the probability
required will be found, by subtracting the other
two from 1.

Now, the probability of throwing never an ace is
three throws is \(\frac{(n-1)^3}{n^3}\) (Art. 16); and the probability
of throwing one ace, and no more, is \(\frac{3(n-1)^3}{n^3}\) (Art.
23.); therefore, the probability of throwing two
aces, or more, in three throws, will be
\[
1 - \frac{(n-1)^3}{n^3} - \frac{3(n-1)^3}{n^3} = \frac{n^3 - (n-1)^3 - 3(n-1)^3}{n^3}
\]

which, in numbers, is \(\frac{216 - 125 - 3 \times 25}{216} = \frac{2}{27}\).

Cor. The probability of throwing two aces, or more, at one throw, with three dice, is expressed by
the same formula.

**Problem XVI.**

25. What is the probability of throwing
two aces, or more, in four throws?

Solution.—In this case we must subtract \(\frac{(n-1)^4}{n^4}\), the probability
of throwing never an ace in four throws, and \(\frac{n^4}{n^4}\), the probability
of throwing one (ace), or more, in four throws, and \(\frac{n^4}{n^4}\), the probability
of throwing one ace, or more, in three throws; and
\(\frac{n^4}{n^4}\), the remainder, the probability
required, which, in numbers, is \(\frac{19}{144}\).

The same formula expresses the probability
of throwing two or more aces at one throw with four
dice.

**Problem XVII.**

26. What is the probability of throwing two aces,
or more, in \(m\) throws, with a single die?

Solution.—By following the mode of reasoning
employed in Prob. 15. and 16. and observing the law
according to which the results are formed, it will
appear, that \(m\) being any number whatever, the
probability required is \(\frac{n^m - (n-1)^m - m(n-1)^m - 1}{n^m}\).

Cor. The probability of throwing two or more
aces, with \(m\) dice, at one throw, is expressed by
the same number.
The probability of throwing two aces, and no
more, in three throws, is \( \frac{n^3 - (n-1)^2}{n^3} \) \( = \frac{3(n-1)}{n^3} \) (Art. 21.)

and the probability of throwing three aces is \( \frac{1}{n^3} \); therefore, the probability of throwing two aces, and
no more, in three throws, is
\[
\frac{n^3 - (n-1)^2 - 3(n-1)^2}{n^3} \frac{1}{n^3} = \frac{3(n-1)}{n^3}.
\]

which, in numbers, is \( \frac{5}{72} \).

Cor. The same formula expresses the probability of throwing two aces, and no more, with three dice, at one throw.

**Problem XX.**

29. The probability of throwing two aces, and no
more, in five throws, is required.

Proceeding as in the last problem, the probability of throwing an ace the first throw, and only one more
in the four remaining throws, will be, by Art. 12 and
22,
\[
\frac{1}{n^5} \cdot \frac{4(n-1)}{n^4} \cdot \frac{4(n-1)^3}{n^3} = \frac{4(n-1)^4}{n^5}.
\]

And the probability of missing an ace the first throw,
and throwing two and no more in the remaining
throws, will be, by Art. 12 and 28,
\[
\frac{n-1}{n^5} \cdot \frac{6(n-1)^3}{n^4} = \frac{6(n-1)^4}{n^5}.
\]

Therefore, the probability of throwing two aces and
no more in five throws, is
\[
\frac{4(n-1)^4}{n^5} + \frac{6(n-1)^4}{n^5} = \frac{10(n-1)^4}{n^5};
\]

which, expressed in numbers, is \( \frac{625}{3888} \).

Cor.—This formula also expresses the probability of throwing two aces at one throw with five dice.

**Problem XXI.**

30. The probability of throwing two aces, and no
more, in \( m \) throws, is required.

It appears from the solution of the three last
problems, that when the values of \( m \) are 3, 4, and 5, the
probabilities in question are,
\[
\begin{align*}
3.2 &= \frac{1}{n^3}, \\
4.3 &= \frac{1}{n^4}, \\
5.4 &= \frac{1}{n^5},
\end{align*}
\]

respectively. Hence, by induction, we may infer, that
\( m \) being any number whatever, the probability
required is,
\[
\frac{m(m-1)(n-1)^{m-2}}{n^m}.
\]

Cor. This formula also expresses the probability of throwing two aces and no more at one throw with
\( m \) dice.

**Problem XXII.**

31. The respective probabilities of throwing any
number of points with two dice, are required.

Solution.—It will appear upon consideration,
that 2 points and 12 points can each be thrown in one
way only, the first by the two aces coming up, and
the second by the two sixes.

That 3 and 11 may each be thrown in two ways,
the former by 1, 2 and 2, 1, and the latter by 5, 6,
1, 6, 5. In like manner, 4 and 10 may each come
up three ways, 5 and 9 in four ways, 6 and 8 inive ways, and 7 in six ways. Hence the whole
numbers of chances is 2 + 4 + 6 + 4 + 8 + 10 + 6 = 36.
And the probability of 2 or 12 coming up is \( \frac{1}{36} \).
The probability of 3 or 11 is \( \frac{2}{36} = \frac{1}{18} \).
The probability of 4 or 10 is \( \frac{3}{36} = \frac{1}{12} \).
The probability of 5 or 9 is \( \frac{4}{36} = \frac{1}{9} \).
The probability of 6 or 8 is \( \frac{5}{36} = \frac{5}{18} \).
And the probability of throwing 7 is \( \frac{6}{36} = \frac{1}{6} \).

**Problem XXIII.**

32. Suppose two heaps, each containing \( n \) counters,
whereof \( a \) are white and \( b \) black. If a person
draws a counter out of each heap, what is the proba-
Solution.—The probability of his drawing a black counter out of the first heap, and a white counter out of the second, is (Art. 15.)

\[
\left(1 - \frac{a}{a+b}\right) \times \frac{a}{a+b} = \frac{a b}{(a+b)^2}.
\]

And the probability of his drawing a white counter out of the first heap, and a black counter out of the second, is, in like manner, \(\frac{b}{a+b}\). Now the probability required, is manifestly the sum of these two:

Therefore its measure is \(\frac{2ab}{(a+b)^2}\).

Cor. If \(a\) and \(b\) represent the number of chances for the happening and failing of an event at one trial, then every chance relating to such events that can possibly happen in two trials, may be expressed by a fraction, whose numerator consists of one or more terms of the second power of the binomial \(a+b\), and whose denominator is that power itself.

For instance, the probability in two trials of the happening of

Two events, is \(\frac{a^2}{(a+b)^2}\), Prob. 6.

Only one of them, is \(\frac{2ab}{(a+b)^2}\), Prob. 23.

Neither of them, is \(\frac{(a+b)^2}{(a+b)^2}\), Prob. 7.

The sum of these three probabilities is manifestly unity, as it ought to be.

Again, the probability of both the events happening, is

\[
\frac{a^2 + 2ab}{(a+b)^2} = \frac{(a+b)^2 - b^2}{(a+b)^2};
\]

and the probability that both will not happen, is

\[
\frac{2ab + b^2}{(a+b)^2} = \frac{(a+b)^2 - a^2}{(a+b)^2}.
\]

**Problem XXIV.**

33. Suppose three heaps, each containing \(a\) white and \(b\) black counters, and that a person draws one out of each, what probability is there that they shall be all white?

Solution.—If he draws a white counter out of the first heap, the probability of which is \(\frac{a}{a+b}\), then he must draw two white counters also out of the remaining heaps, the probability of which is \(\frac{a^3}{(a+b)^2}\); but neither of these events will be effectual without the happening of the other, and therefore \(\frac{a}{a+b} \cdot \frac{a^3}{(a+b)^2} = \frac{a^4}{(a+b)^3}\) will be the probability required.

Cor. In like manner, the probability of drawing three black counters, or of failing to draw a white one at each attempt, is \(\frac{b^3}{(a+b)^3}\).

**Problem XXV.**

34. The same things being supposed as in the last problem, what is the probability that two of the counters drawn and no more shall be white?

Solution.—If the person draws a black counter the first time, the probability of which is \(\frac{b}{a+b}\), then he must draw two white counters out of the remaining heaps, the probability of which is \(\frac{a^2}{(a+b)^2}\); and therefore the probability of succeeding by drawing in that manner, is \(\frac{a^2}{a+b} \cdot \frac{a^2}{(a+b)^2} = \frac{a^4}{(a+b)^3}\).

Again, if he draws a white counter the first time, the probability of which is \(\frac{a}{a+b}\), then he must draw only one white counter out of the two remaining heaps, the probability of which is \(\frac{2ab}{(a+b)^2}\) (Art. 32.) therefore the probability of succeeding in this way, is \(\frac{a}{a+b} \cdot \frac{2ab}{(a+b)^2} = \frac{2a^3}{(a+b)^3}\). Now the whole probability required, is manifestly the sum of these two; therefore it is \(\frac{a^4}{(a+b)^3} + \frac{2a^3}{(a+b)^3} = \frac{a^4}{(a+b)^3}\).

Cor. As the probability of drawing two white counters or more, is the sum of the probabilities investigated in the two last problems, it will be \(\frac{a^3 + 2a^2b}{(a+b)^3}\).

**Problem XXVI.**

35. The same things being supposed as in the two last questions, what is the probability that one white counter and no more shall be drawn?

Solution.—If he draws a white counter the first time, then at the other two trials he must draw two black ones, the probability of doing both of which is \(\frac{a}{a+b} \cdot \frac{b^2}{(a+b)^2} = \frac{a^3}{(a+b)^3}\).

If he draws a black counter the first time, then at the other two trials he must draw one black and one white counter, the probability of doing which is \(\frac{b}{a+b} \cdot \frac{(a+b)^2}{(a+b)^2} = \frac{b^3}{(a+b)^3}\).

Therefore the probability required will be, \(\frac{a^3}{(a+b)^3} + \frac{3a^2b}{(a+b)^3} = \frac{3a^2b}{(a+b)^3}\).

Cor. 1. The probability of drawing either one or two white counters, will be \(\frac{3a^2b}{(a+b)^3} + \frac{3ab^2}{(a+b)^3} = \frac{3ab^2}{(a+b)^3}\).

Cor. 2. The probability of drawing either one, or three white counters, is \(\frac{a^3}{(a+b)^3} + \frac{3a^2b}{(a+b)^3} + \frac{3ab^2}{(a+b)^3} = \frac{(a+b)^3}{(a+b)^3}\).

Cor. 3. The probability of drawing none, or at most but one white counter, is \(\frac{3ab^2}{(a+b)^3}\).

Cor. 4. The probability of drawing none, or at most but two white counters, is \(\frac{(a+b)^3}{(a+b)^3}\).

Cor. 5. Hence it appears, that one or more of the terms of the binomial \(a+b\), raised to the third power, will be the numerators of fractions which express the probabilities of all the varieties that can possibly happen in three trials concerning events, the number of chances for the happening or failing of which are \(a\).
and \( b \) respectively; and that the common denominator of all the fractions will be \((a+b)^n\).

For instance, the probability in three trials of the happening of

\[
\begin{align*}
\text{The three events,} & \quad \left( \frac{a^1}{3a^1b}, \frac{a^1}{3a^2b}, \frac{a^1}{3a^3b} \right) \quad \text{Prob. 24.}\n\text{Only two of them,} & \quad \left( \frac{a^1}{3a^1b}, \frac{a^1}{3a^2b} \right) \quad \text{Prob. 25.}\n\text{Only one of them,} & \quad \left( \frac{a^1}{3a^1b}, \frac{a^2}{3a^2b} \right) \quad \text{Prob. 26.}\n\text{Neither of them,} & \quad \left( \frac{a^1}{3a^1b}, \frac{a^2}{3a^2b} \right) \quad \text{Cor. to Prob. 21.}
\end{align*}
\]

The sum of these four probabilities is evidently unity, as it ought to be.

36. Supposing \( a \) to express the number of chances for the happening of an event, and \( b \) for the chances of its failing, then it is evident from the foregoing problems, that every question that can possibly be proposed respecting the happening or failing of any number of such events in \( n \) trials, will be answered by means of, one or more terms of the development of \((a+b)^n\), as a numerator, and the whole expression, as a denominator. In particular,

1. The probability of the happening of the \( m \) events, will be

\[
\frac{(a+b)^m}{\binom{n}{m}}
\]

2. The probability of the happening of \( m-1 \) of the events, will be

\[
\frac{m(a+b)^{m-1}b}{\binom{n}{m}}
\]

3d. The probability of the happening of \( m \) events, \( m-2 \), \&c., at least, of but \( m-a \), such events will be

\[
\frac{\binom{m}{m-a}a^m}{\binom{n}{m}}
\]

the numerator of which fraction being supposed to consist of \( n+1 \) terms.

And the probability of the happening of at least one such event, will be

\[
\frac{(a+b)^n}{\binom{n}{m}}
\]

37. A lottery, in which the number of prizes is to the number of blanks as 1 to 39; how many tickets must be purchased, that the buyer may have an equal chance for one or more prizes?

SOLUTION.—The probability of having one prize, or more in \( n \) tickets, in a lottery wherein the prizes are to the blanks, as 1 to 39, is the same with that of throwing one ace or more in \( n \) throws, with a die that has 1 + 39 = 40 faces. Therefore, putting \( 40 = n \), this probability will (by Prob. X) be

\[
\frac{n}{(a+b)^n}
\]

whence

\[
\frac{b^n}{(a+b)^n} = \frac{1}{a+b}
\]

The probability of missing, is

\[
\frac{a^n}{(a+b)^n}
\]

by hypothesis, is to be an equal chance of the having or missing one or more prizes. Now, if the uncertainty of the having or missing one or more prizes be denoted by unity, then the probabilities of an equal chance, for having or missing one or more of them, will each of them be denoted by

\[
\frac{1}{(a+b)^n}
\]

Therefore

\[
\frac{(a+b)^n}{(a+b)^n} = \frac{b^n}{(a+b)^n} = 1
\]

or

\[
\log_2 \frac{(a+b)^n}{b^n} = \log_2 \frac{1}{(a+b)^n}
\]

and hence

\[
\log_2 \frac{(a+b)^n}{b^n} = \log_2 \frac{1}{(a+b)^n}
\]

Now, \( \log_2 39 = 5.0103 \); and \( \log_2 \frac{(a+b)^n}{(a+b)^n} = \log_2 40 = 5.0000 \). Therefore, \( m = \frac{5.0103}{5.0000} = 1.0106 \). By which it appears, that the number of tickets must be greater than 27.

The sum of \( \frac{b^n}{(a+b)^n} \) and \( \frac{a^n}{(a+b)^n} \) will express the probability of its not happening twice in \( m \) trials and

\[
\frac{b^n + m(b^n - a^n)}{(a+b)^n}
\]

expresses the probability of its not happening thrice and so on. And because the question requires how many times the event will happen in \( n \) trials upon an equality of chance, it will follow, that when the event is to happen once, then

\[
\frac{b^n}{(a+b)^n} = \frac{1}{2}
\]

and when it is to happen twice, then

\[
\frac{b^n + m(b^n - a^n)}{(a+b)^n} = \frac{1}{2}
\]

and when it is to happen thrice, then

\[
\frac{b^n + m(b^n - a^n) + m(m-1)}{(a+b)^n} = \frac{1}{2}
\]
Now in the present question, where \( a = b \), we have
\[ p = 1, \text{ therefore } \left( 1 + \frac{1}{p} \right)^m = (1 + 1)^m \];
but in the development of this quantity, the terms equally distant
from either extremity are equal, therefore \( \frac{1}{2} (1 + 1)^m \)
will consist of half the terms in \( (1 + 1)^m \); and as the whole number of
terms is \( m + 1 \), therefore the answer
will be \( \frac{m + 1}{2} \).

Cor. If \( r \) represent the number of times that the
proposed event is to happen, then, when there is
an equality of chance for its happening or failing,
\[ r = \frac{m + 1}{2} \] by the problem. Therefore \( m \), the number
of trials in which it will be an equal chance, whether
the event shall happen or not, will be \( 2r - 1 \).
And therefore in a lottery, in which the number
of prizes is equal to the number of blanks, if it be
required to know how many tickets should be bought,
in order to have \( r \) or more prizes, the answer will be
\( 2r - 1 \) tickets; that is, in order to have an equal chance
for \( 1, 2, 3, 4, 5, \) &c. or more prizes, there
should be bought \( 1, 3, 5, 7, 9, \) &c. tickets.

PROBLEM XXIX.

39. In a pack of 59 cards, consisting of 13 hearts,
13 spades, and 13 clubs, if \( m \) cards be dealt to any
one, how many may he, on an equality of chance, expect
to be hearts?

Solution.—If \( a, b, \) and \( p \), represent the same as
in last problem, and \( r \) be the number required; then
because there are two chances for a black card to be
dealt, and but one for a red card, we have \( b = 2 \) and
\( a = 1 \), and consequently \( p = 2 \). Therefore
\[ \frac{1}{2} \left( 1 + \frac{1}{p} \right)^m = \frac{1}{2} \left( \frac{1}{2} \right)^m, \] and in this case

\[ 1 + m \cdot \frac{1}{p} + \frac{m(m - 1)}{1 \cdot 2} + \frac{m(m - 1)(m - 2)}{1 \cdot 2 \cdot 3} + \ldots, \]
&c. (to \( r \) terms) \( = \frac{1}{2} \left( \frac{1}{2} \right)^m \).

The whole difficulty of the problem is now reduced
to the finding of \( r \), the number of terms of the
series that must be added together to make \( \frac{1}{2} \left( \frac{1}{2} \right)^m \).
Now in the last problem we found \( r \) by a direct pro-
cess, but in this we cannot find it otherwise than by
trials. The manner of proceeding may be as follows.

(1) When \( m = 1 \), then \( \frac{1}{2} \left( \frac{1}{2} \right)^m = 0.75; \) and when \( m = 2 \), \( \frac{1}{2} \left( \frac{1}{2} \right)^m = 1.125. \)

Now the first term of the series
\[ 1 + m \cdot \frac{1}{p} + \frac{m(m - 1)}{1 \cdot 2} + \ldots, \] is manifestly greater than the former of these numbers,
but less than the latter; hence it appears, that,
when \( m = 1 \), then 1 term is greater than \( \frac{1}{2} \left( \frac{1}{2} \right)^m \),
when \( m = 2 \), then 1 term is less than \( \frac{1}{2} \left( \frac{1}{2} \right)^m \).

(2) Again, if \( m = 4 \), then \( \frac{1}{2} \left( \frac{1}{2} \right)^m = 0.75, \) &c.,
and if \( m = 5 \), \( \frac{1}{2} \left( \frac{1}{2} \right)^m = 0.879, \) &c.

(Here the values of \( \frac{1}{2} \left( \frac{1}{2} \right)^m \) are only found to two places
of decimals, these being sufficient for our purpose;
and to facilitate the operations, the calculations
may be made by logarithms.) Taking now
two terms of the series, we have
\[ 1 + 4 \times \frac{1}{4} = 3, \] and \( 1 + 8 \times \frac{1}{4} = 3.5. \)

Hence it appears, that
when \( m = 4 \), then 2 terms are greater than \( \frac{1}{2} \left( \frac{1}{2} \right)^m, \)
when \( m = 5 \), 2 terms are less than \( \frac{1}{2} \left( \frac{1}{2} \right)^m \).

(3) If \( m = 7 \), then \( \frac{1}{2} \left( \frac{1}{2} \right)^m = 0.879, \) &c.,
and if \( m = 9 \), \( \frac{1}{2} \left( \frac{1}{2} \right)^m = 0.879, \) &c.

Now, taking three terms of the series, we have
\[ 1 + 7 \times \frac{1}{4} + 8 \times \frac{1}{4} = 9.75, \] and \( 1 + 8 \times \frac{1}{4} + 8 \times \frac{1}{4} = 12.0. \)

Hence it appears, that
when \( m = 7 \), then 3 terms are greater than \( \frac{1}{2} \left( \frac{1}{2} \right)^m, \)
when \( m = 8 \), 3 terms are less than \( \frac{1}{2} \left( \frac{1}{2} \right)^m \).

(4.) By a like mode of proceeding we find, by taking
four terms of the series, that
when \( m = 10 \), then 4 terms are greater than \( \frac{1}{2} \left( \frac{1}{2} \right)^m, \)
when \( m = 11 \), 4 terms are less than \( \frac{1}{2} \left( \frac{1}{2} \right)^m, \)
and in general, putting \( x \) for any number whatever,
when \( m \) is
\[ \frac{3x + 1}{2} \text{ then } x + 1 \text{ terms } \{ \text{greater} \} \text{ than } \frac{1}{2} \left( \frac{1}{2} \right)^m, \]
\[ \frac{3x + 2}{2} \text{ are } \{ \text{less} \} \text{ than } \frac{1}{2} \left( \frac{1}{2} \right)^m. \]

But when the chances for the event's not happening
\( r \) times in \( m \) trials, (which are expressed by the
series,) are less than \( \frac{1}{2} \) the power; then the chances
for its happening must be greater than that number.
Therefore, when \( m = 3x + 2 \), there will be more than an
equal chance for the event’s happening $(x+1)$ times. Let us now put $r=x+1$, then $x=r-1$; and since $m=x+3$, therefore $m=3(r-1)+2=3r-1$, and $r=\frac{m+1}{3}$. That is, if $m$ cards be dealt, it is more than an equal chance that there should be $\frac{m+1}{3}$ hearts.

**Cor.** Because $m=3r-1$, therefore, if in a lottery containing two blanks to a prize, it be required to know how many tickets should be bought in order to have an equal chance for $r$ prizes, the answer will be $3r-1$ tickets; that is, in order to have an equal chance for obtaining $1, 2, 3, 4, 5, \&c.$ prizes, there must be bought $2, 5, 8, 11, 14, \&c.$ tickets.

**Problem XXX.**

40. In a pack of 52 cards, consisting of 13 of each suit, if $m$ cards be dealt to me, how many may I, on an equality of chance, expect to be trumps?

**Solution.**—The same symbols being retained as in the two last problems, then because there are three blanks of trumps to one suit of prizes, (or trumps, $b=3$ and $a=1$). Therefore $p=3$; and $\frac{1}{3}(1+\frac{1}{p})^m$

$=\left(\frac{4}{3}\right)^m$. And in this case,

$1+\frac{m}{1}+\frac{m(m-1)}{1\cdot 2}+\&c.$ (to $r$ terms) $=\left(\frac{4}{3}\right)^m$.

Here, as in the last problem, we must determine $r$ by repeated trials. Accordingly, by proceeding as in that problem, we shall find that when

\[m \begin{cases} \frac{1}{3} \text{ of the series is greater than } & \text{than} \\ \text{are } & \text{less than } \frac{1}{2}(\frac{4}{3})^m \end{cases}\]

Then, when $m=4x+3$, there will be something more than an equal chance of the event’s happening $r$ times. Now, since $m=4x+3$, therefore $x=\frac{m-1}{4}$. And since $x=r-1$, therefore $r=\frac{m-3}{4}$ and $r=\frac{m+1}{4}$. That is, if $m$ cards are dealt, it will be more than an equal chance that there will be $\frac{m+1}{4}$ trumps. Therefore, in the game of whist, where 13 cards are dealt, there is more than an equal chance for any particular person having 13+1 $=\frac{14}{4}$ trumps. And since this is more than an equal chance, if any player have but three trumps, or less, he may justly conclude that his partner has four trumps, or more.

**Cor.** Since $x=r-1=\frac{m-3}{4}$, therefore $m=4r-1$;

Hence it follows, that in a lottery where there are three blanks to a prize, if it be required to know how many tickets should be bought in order to have $r$ prizes, the answer will be $4r-1$ tickets; thus, in order to have 1, 2, 3, 4, 5, \&c. prizes, there must be bought 3, 7, 11, 15, 19, \&c. tickets.

**Problem XXXI.**

41. In a lottery which has four blanks to a prize, if a person purchase $m$ tickets, how many prizes may he expect, on an equality of chance?

**Solution.**—The same symbols being retained as before, we have, in this case, $b=5$ and $a=1$; and therefore $p=\frac{1}{5}$, and $\left(1+\frac{1}{p}\right)^m = \left(\frac{6}{5}\right)^m$. Therefore in this case we must find $r$ the number of terms of the series

$1+\frac{m}{1}+\frac{m(m-1)}{1\cdot 2}+\frac{m(m-1)(m-2)}{1\cdot 2\cdot 3}+\&c.$

the sum of which is $\left(\frac{6}{5}\right)^m$.

By proceeding as in Prob. XXIX. it will be found by trials, that when

\[
\begin{array}{ll}
m = 3 & \text{then one term of the series is greater than } \frac{1}{2}(\frac{6}{5})^m \\
m = 8 & \text{then two terms are greater than } \frac{1}{2}(\frac{6}{5})^m \\
m = 13 & \text{then three terms are greater than } \frac{1}{2}(\frac{6}{5})^m \\
m = 18 & \text{then four terms are greater than } \frac{1}{2}(\frac{6}{5})^m \\
m = 19 & \text{are } \text{less than } \frac{1}{2}(\frac{6}{5})^m \\
\end{array}
\]

Therefore, in general, when

$m = \left\{ \begin{array}{ll} \frac{5x+3}{2} & \text{then } x+1 \\ \frac{5x+4}{2} & \text{terms are greater than } \frac{1}{2}(\frac{6}{5})^m \end{array} \right.$

Therefore, when $m=5x+4$, there will be something more than an equal chance of the required effect’s happening $x+1$ times.

And since $m=5x+4$, therefore $x=\frac{m-4}{5}$; also since $r=x+1$, therefore $r=\frac{m}{5}$, hence $r=\frac{m-4}{5}$, and $r=\frac{m+1}{5}$. That is, $\frac{m+1}{5}$ prizes may, on an equality of chance, be expected in $m$ tickets.

**Cor.** Since $r=\frac{m-4}{5}$, therefore $m=5r-1$.

Hence it appears, that in such a lottery, in order to have an equal chance for $r$ prizes, there must be purchased $5r-1$ tickets; that is, 1, 2, 3, 4, 5, \&c. prizes require 4, 9, 14, 19, 24, \&c. tickets.

**Problem XXXII.**

42. If a person playing with a single die determines to cast it $m$ times, how many times out of that number may he, on an equality of chance, undertake to cast an ace. Or, (which is the same thing,) if he cast $m$ dice at once, how many of them may he, on an equality of chance, expect to be aces?

**Solution.**—Retaining the same symbols, in this case, $b=5$, $a=2$, $p=5$, and $\left(1+\frac{1}{p}\right)^m = \left(\frac{6}{5}\right)^m$.

We must now find $r$ the number of terms of the series

$1+\frac{m}{1}+\frac{m(m-1)}{1\cdot 2}+\frac{m(m-1)(m-2)}{1\cdot 2\cdot 3}+\&c.$

which are equivalent to $\left(\frac{6}{5}\right)^m$.
Therefore we may conclude, that the same thing will happen in all succeeding questions of this sort; and consequently, that if the first term of the series can be obtained, then all the rest will be found by the addition of \( (a+\ell) \).

Now the first term of this series may be found by Prob. XXVII. where the number of tickets which must be purchased, that the buyer may have an equal chance to have one prize, is 

\[
\log \left( \frac{a+b}{a} \right) - \log \frac{b}{a}.
\]

Therefore this quotient, if an integer, or the next greater integer if a fraction, will be the first term of the series. And if we call this quotient \( q \) and put \( a+b=q \), then, in order to have an equal chance for 1, 2, 3, 4, 5 prizes, we must purchase \( q, q+x, q+x+2, q+x+3, q+x+4 \), &c. tickets. Or universally, in order to have an equal chance for \( p \) prizes, we must purchase \( q+(p-1)\ell \) tickets.

For the application of the doctrine of chances to annuities, see **Annuities**.

**Essai d'analyse sur les jeux de hasard**, par Montmort. 
De Moivre's *Doctrine of Chances*. 
**Miscellanea Analytica**, by the same author. 
Specimen artis conjectandi ad questiones juris applicatae, by Nicolas Bernoulli, in the *Leipsic Acts*, 1711.

Opuscules Mathematiques; par D'Alembert. 
Essay sur l'application de l'analyse à la probabilité des decisions à la pluralité des voix, par Condorcet. 
Doddson's *Mathematical Repository*.

Emerson *On the Laws of Chance*, in his *Miscellaneies*.

**CHANTORY**, or **CHAUNTRY**, (**Cantaria**), a small chapel or church, or private altar in a cathedral or other public place of worship, with an endowment for one or more priests, on condition that they should *sing mass*, and perform other divine services for the soul of the founder, or of such also of his descendants or other relations as he may have provided for by the grant. These endowments, however, as originating in the Roman superstition, were effectually abolished by Stat. 1 Ed. VI, c. 14, which declares all entry into the lands, or other revenues, in terms of the foundation, unlawful, and confers the property upon the king, under certain exceptions in favour of universities and other public seminaries. From Dugdale's history of St Paul's, it appears that not fewer than forty-seven chantries belonged to that church. (r. n.)

**CHAPEL** (**Capella**), a place of divine worship, and of which there are commonly reckoned four different sorts. 1st, *Chapels of ease*, which are provided for the ease or convenience of the parishioners,
where the parish is of great extent. In England, these chapels are served by inferior curates provided at the charge of the rector, or other parish priest, and they are accordingly removable at his pleasure; although in some instances chapels of ease have right, by custom, to a distinct minister, and to sacra-
ments and other church privileges, and are endowed with tithes. In Scotland, the minister is, for the most part, of the parishioners own appointment, and is maintained by a salary arising from the seat rents. He has right to sacraments, &c. but has no voice in
any of the church courts. 2d, Free chapels, which have been endowed by the sovereign, or by pious and charitable persons, and are therefore called free, being no charge upon the parish, or rather perhaps because they are exempt from all ordinary jurisdiction.
3d, Chapels belonging to universities, or to particular
 colleges in universities, which are consecrated, and
have right to sacraments, &c. but are not liable to any visitations but that of the founder. 4th, Private or domestic chapels, which are built and maintained by noble and wealthy families for private worship, or
near their own houses. These need not be con-
secrated, and may be erected without leave of any
superior, nor are they subject to ordinary jurisdiction. Besides these, there are what are called parochial chapes; but these differ from parish churches only in name, and seem to be so denominated only because they are generally smaller than most churches, and the inhabitants within the district few. Burial places, also, which have been erected by great families adjoining to, or within a cathedral or other
church, are sometimes denominated chapels. (s. b.)

Chaplain. (Capellanus,) one attendant on the household of the king, or other honourable person, to say divine service, which is commonly performed in the family private chapel. Each individual of the royal family may retain any number of chaplains; but by stat. 21 Hen. VIII. c. 13, an archbishop is limited to eight; a duke or a bishop six; marquis or earl five; viscount four; baron, knight of the garter, or lord chancellor, three; a duchess, marchioness, countess, baroness, (being widows,) the treasurer and comptroller of the king's house, the king's secre-
tary, dean of the chapel, almoner, and master of the
rolls, each of them two; the chief justice of the
king's bench, and warden of the cinque ports, one.
And by stat. 25 Hen. VIII. c. 16, every judge of
the king's bench and common pleas, the chancellor and chief baron of the exchequer, and the king's attor-
ney and solicitor general, may each of them have one chaplain attendant on his person. And by 33 Hen. VIII. c. 28, the groom of the stole, treasurer of
the king's chamber, and chancellor of the duchy of Lancaster, may also retain each one chaplain. Under
the 21 of Henry, the statute first quoted, the chaplains thereby allowed may purchase a licence or
dispensation, and take two benefices with cure of
souls; but those allowed by the two last can have one benefice only, on which they may be non-resi-

dent.

In England, the king has commonly forty-eight chaplains in appointment, four for each month of the
year, whose duty is to preach in the chapels-royal, and read the service to the family. They have no
salary, being commonly well provided otherwise. In
Scotland he has six, who have each a salary of £ 50,
and three of these have besides the deanery of the
chapel-royal divided among them, which extends their emolument to upwards of £ 100 each. The
sum of their duty is to say prayers at the election of
the sixteen representative peers for Scotland. (J. b.)

CHARA. See Astronomy, p. 750.

CHARA, a genus of plants of the class Monocœa,
and order Monandria. See Botany, p. 310.

CHARACTER, (from the Greek ἀγγαρέω, I cut, engrave, or indetent,) in the literal and radical sense

denotes any thing cut or engraved; hence any kind
of peculiar mark cut, drawn, or any way set or im-
pressed upon a substance capable of receiving and
retaining it. From this radical sense the word is now
applied to denote, 1st, A mark or figure drawn or
formed, for the purpose of denoting or suggesting
some particular object or idea otherwise than by di-
rect representation. 2d, The peculiar and dis-
inguishing properties belonging to an individual,
the marks, as it were, by which that individual is
distinguished from all others. 3d, By a natural tran-
sition from the last, the persons or agents exhibi-
ted in narrative or poetical composition, such
agents being necessarily marked by peculiar and dis-
tinctive qualities.

1. A mark or figure drawn or formed, for the
purpose of denoting or suggesting some particular
object or idea otherwise than by direct representation.
The invention and application of marks to denote
and suggest objects of which they are not the direct
pictures, has its rise from the well known principle
of association; and the same necessity of mutual
communication, which led originally to the formation
of oral language, could not fail, at a very early pe-
riod, to give rise also to the invention and use of visi-
tible figures, for fixing and exhibiting to the eye what
oral language was either insufficient to convey, or
incapable of permanently retaining. In the forma-
tion of such signs, recourse would at first be had to
direct and immediate representation, the mark would
probably be nothing more than a picture more or
less perfect of the object to be denoted. Altera-
tions, however, would soon arise; convenience would
introduce abbreviations even in picture marks exhib-
itng objects capable of direct delineation; and ex-
perience would as quickly indicate an immense multi-
tude of objects necessary to be denoted, but totally
unsusceptible of immediate ocular delineation. For
the denoting of these, therefore, arbitrary or conventional
marks could only be employed; these marks might
be formed at first from some real or supposed ana-
logy to the objects of sight, but afterwards might gra-
dually assume peculiar and distinctive forms, suggest-
ing by association the objects intended to be pointed
out. * In this manner, it is not improbable, most of

* The following well known story affords a good example of the natural rise and progress of such character marks. A ta-
vern-keeper in Hungary unable to write, kept account of the sums due to him by strokes chalked on his door; to each series
of strokes was annexed a figure to denote the customer to whom they applied. The soldier was represented by the figure of
a musket, the carpenter by a saw, the smith by a hammer. In a short time for convenience, the musket was reduced to a
straight line, the saw to a zig-zag line, the hammer to a cross; and this began to be formed a set of characters gradually re-
siding from the original figure. The resemblance at last might be entirely lost sight of, and the figures become mere arbi-
trary marks. Such probably was the rise of a great part of the Chinese characters.
CHARACTER.

In every branch of knowledge, therefore, characters may be introduced and employed. To multiply them, however, too much, would impede instead of facilitating the means of mutual communication: their number and varieties will be determined by the necessity or convenience which may render this aid to oral language desirable. When a series of characters have been invented and brought into use, susceptible of very general application, the necessity of other classes of more limited use is in a great measure superseded. When characters adapted to express all the words of a language have been formed, it will not often be necessary to devise or retain separate sets for denoting the terms of each particular science. Experience, however, has shewn, that even where general characters are in use, there are particular subjects, in which vast advantage will be found from employing appropriate and distinctive characters; convenience or habit may likewise, in certain branches of knowledge, occasionally bring into, or keep in use, peculiar symbols, which, though not absolutely necessary, may be useful, as furnishing means of easy and expeditious expression. Different species of characters will thus arise, none of them without their appropriate use. It is, however, always to be wished, that, in every case, the characters employed be distinct and clear in their form, easily recognised and understood, and never so extended or multiplied as to fatigue and encumber, instead of aiding the memory and understanding.

It would be an almost endless task to go through all the various kinds and classes of characters, invented and employed for denoting the objects of thought; it will be sufficient to take notice of such as, from their intrinsic importance and general use, particularly merit attention.

The species of characters most commonly in use, may be arranged under the heads of literal characters, numeral characters, and symbolical characters.

I. Literal Characters, including all such as are used for denoting language in general. These may be distinguished into alphabetical characters, used for denoting the elemental sounds of language, and, by combination, expressing all the varieties of words; and real characters, employed or intended as the signs of things or ideas independent of sounds. For a full account of both, in regard to their nature, origin, and use, see Alphabet. Of these two kinds of character, alphabetic characters are by far most generally in use. The adoption of the real or ideal characters appears to be confined to the Chinese, or the nations immediately connected with China. Judging no less from reason than experience, we are fully warranted in asserting the immense superiority of alphabetic writing.

The form of alphabetic characters differs much among different people. The Hebrew, or some of its kindred dialects, may probably claim the highest antiquity; from its cognate the Phoenician, arose the old Pelasgic and Grecian alphabets; from these was formed the Latin character, in common use through the greater part of Europe to the present day. The Syriac, Chaldee, and Arabic character, were evidently formed from the ancient Hebrew, which was in use before the Babylonish captivity, and is still found on some medals, commonly termed Samaritan. The square Hebrew at present in use, was only introduced among the Jews subsequent to the captivity. The Greek character, in more ancient times, consisted entirely of majuscule letters, or capitals; and it is this mode of writing alone which is found in all the ancient inscriptions and medals, as well as in those manuscripts that are not of modern date. The smaller Greek character is comparatively a recent invention. Medalists observe, that the Greek character preserved its uniformity down to the time of Gallienus, after which it appears weaker and rounder. From the time of Constantine to Michael, the Latin character chiefly prevails; the Greek characters then commence, though altered, in some respects like the language, by the mixture of Latin. The Latin medals preserved their character, as well as language, till the translation of the empire to Constantinople. Before the time of Decius, the Latin character began to lose its roundness and beauty; and after the time of Justin gradually degenerated into the Gothic. The modern European character, formed from the Latin, is too well known to require any particular notice. It is used in most parts of Europe. The Germans, however, have a peculiar character, compounded of the Gothic and Latin; but of late, even among them, the Roman character used in the other European countries has been gaining ground, and may probably in time supersede the other. The modern Greeks still adhere to the proper Greek character; and the Russians make use of a character of their own, formed in part from the Greek capitals, though in several of the letters considerably altered. The Oriental alphabets are numerous, and their characters extremely diversified. The figures of the letters are frequently complicated and inelegant, and may, in general, be pronounced inferior, both for beauty and convenience, to the ancient Greek or the modern European character. Specimens of different kinds of character, as well ancient as modern, are given under the article already referred to.

The real character is constructed on different principles from the alphabetic. The object of the latter is to express, by figures, the fundamental sounds of speech, separately, or in their various combinations. The object of the former, or real character, is to express only things or ideas, without regard to the particular sounds by which these are communicated in speech, so that persons, whose oral language is totally dissimilar, may, by the use of this species of character, at once understand and communicate with each other, though their speech may be mutually unintelligible. Such is actually the case with the written characters of the Chinese and Japanese; and such, though in a more limited degree, is the case in regard to the numeral characters of the inhabitants of modern Europe. For an account of the real character, see the above mentioned article Alphabet.

The only people among whom the real character appears to have come into actual use, are the Chinese, and those immediately connected with them;
for the Egyptian hieroglyphics cannot be said to belong to this class. Judging from the progress of knowledge and state of society among these nations where the real character prevails, we should not be inclined to estimate too highly the benefits of this mode of communication. Yet some ingenious philosophers have attempted to devise, and bring into use, such a mode of writing. One of the most celebrated of these attempts is that of Bishop Wilkins, in his Essay towards the formation of a real Character and Philosophical Language. M. Leibnitz projected something of a similar nature, under the title of what he termed an Alphabet of Human Thoughts, but he never completed his scheme. M. Lodovic, in the Philosophical Transactions, proposed a plan of an universal alphabet or character; and in the Journal Litteraire for the year 1720, the formation of an universal character is suggested, by the application of the Arabic numerals in various combinations. None of these schemes, however ingenious in structure, have been found applicable to purposes of practical utility. It is not difficult to devise a new character, but to bring it into use will probably always be found impracticable; and even if it were practicable, the advantage of it is extremely questionable.

2. NUMERAL CHARACTERS, or marks used for notation of numbers.

Next in use and importance to alphabetic characters, is that class of characters known by the name of numerals. These are unquestionably one species of real character, and probably the only one that could with advantage be adopted into general use. For an account of the origin and progress of numeral notation, see Arithmetic.

The idea of number suggests itself, by abstracting from objects every circumstance except their individuality. It is probable, that, when men first began the practice of numeration, they would proceed by taking some of the objects immediately before their eyes, and intimating, that those of which they were speaking were equal to them in number. As the objects most universally present to all men are the fingers, these would of course be the earliest measure of numbers; and numeration would thus be formed into a scale either of *fives* or *tens*. The former have sometimes been found, but the latter, or the decuple progression, is nearly universal. The process of numeration being commenced, it would be necessary, in order to carry it on, that some marks should be found to denote the numbers in their progress. It is probable that the earliest, as it was the simplest species of mark, would be a mere notch upon a board, the repetition of which would designate the number of objects to be counted. It is evident, that, in this mode of notation, the eye can easily and readily recognise the different numbers only a very little way. One, two, three, and even four, can be easily distinguished, as we find in the dials of church clocks, but farther than this the power of distinction becomes difficult, and is at last entirely lost. After four strokes are put down, therefore, it is necessary to make some alteration in the mark, to show where a new series is to commence. This could most easily be done, by making a diagonal stroke through the four preceding. A progression would then take place by a new series of strokes, and, at the end of the second five, a diagonal in the opposite direction would point out the second termination. Here we have the evident origin of the Roman mode of notation. The first diagonal produced the V, the mark of five, the second the X, the mark of ten. After ten the same notation would go on to a second ten, which would be denoted by a double X, a third by a triple, and a fourth by a quadruple X. The same difficulty of distinguishing by the eye beyond four similar figures, would make it necessary, at the fifth ten, to introduce another change. This was done by a horizontal line at the bottom, making a figure similar to L. At the tenth ten another addition became necessary, which produced the figure C, afterwards modified into a C for one hundred. By a similar process, the fifth hundred was marked by a new line 100, which soon passed into a D, the mark for 500. The tenth hundred became double CCC, easily changing into an M for 1000. This mode of notation of numbers, which is the rudest and most simple, was retained to the last among the Romans, improved in a small degree by certain abbreviations; and it is radically the same as at this day is used by the Chinese; only as the Chinese mode of writing is in perpendicular, not horizontal lines, the position of their numeral marks corresponds to that peculiarity in their mode of writing.

The inconvenience of this mode of notation, where the objects of numeration were much extended, would soon be felt, and some more convenient way of reckoning would be sought. Among those people where the use of letters had been introduced, a ready substitute was found in the alphabetic characters; and these we find actually so employed at a very early period among the Hebrews; and their immediate neighbours, from whom the invention passed to the Greeks. The Hebrew alphabet had only 22 letters, but several of these having two forms, it became easy to construct three series of numeral marks, nine in each, and, by using these according to the decuple progression, to denote units, tens, and hundreds, numeral notation as far as a thousand was made easy. Thousands were expressed, by using the same marks with an accent annexed. This mode of numeral notation was exactly copied by the Greeks, who, to complete their three series of nine, inserted three additional marks, called the epsilon, the kappa, and the sigma. Thousands they expressed also by the same characters, with an accent below.

In this manner an extensive numeral notation was obtained; but it had the great inconvenience, that the large numbers being expressed by one entire mark, could not readily, in performing arithmetical operations, be broken into smaller constituent parts. These

* The Greeks had two other modes of numeral notation; one by using the letters for numeral marks just according to their place in the alphabet; the other by the adoption of the following marks: I to denote one, ι five, Δ ten, ιι one hundred, Χ a thousand, Μ ten thousand. It is commonly supposed, that these marks came to be so used, as being the initial letters of the words denoting the respective numbers. May they not rather have been the remains of a mode of notation similar to the Roman, in which they originally served as the distinguishing marks of the respective series, and, for convenience, were retained, after a better notation was introduced?
operations, therefore, became cumbersome and difficult in a high degree. The complete remedy for this inconvenience was found, by that immense improvement in the mode of numeral notation, of confining the whole numeral characters to one series only, and giving this series successively the power of the second, the third, or any higher series, by means of position alone; the same characters in the first row denoting units, in the second tens, in the third hundreds, and so forward as far as numeral expression is required.

This may justly be set down as the perfection of numeral notation, and gives modern arithmetic the most decided superiority over the ancient. It is commonly supposed to have been derived to us from the Arabs, who are thought to have learned it from the Indians. Some doubts, however, have been lately started upon this point; and Anse de Villioison, in the 2d volume of his Anecdota Graeca, quotes an Italian author, who maintains, that our modern numeral characters were derived from the Greeks, having been used by them in the times of the emperors for expressing weights and measures, and afterwards extended to express any kind of number. It is not perhaps easy to determine the point, nor is it of much importance; but it is curious to observe, that something of this mode of notation appears in the Hebrew numerals; for though with them three series of characters were used for units, tens and hundreds, and thousands were denoted by applying to these respectively an accentual mark, yet frequently, too, when both thousands and hundreds were to be put down together, the thousands were signified, by merely placing the proper numeral without an accent, before the mark for the hundreds,—an approach undoubtedly to the modern mode of notation, though it does not appear to have ever led to further improvements.

As the best illustration of this subject, specimens of different kinds of numeral characters are given in Plate XL. See also Number and Numeral Notation.

3. Symbolical Characters, or characters intended to express a particular object or idea by means of a mark bearing some supposed or imaginary analogy to the thing represented.

Symbolical characters differ from the two former classes of characters in this, that in the former, the signification of the mark is purely arbitrary; in the symbolical, it is connected with the object by some real or supposed resemblance, sometimes in appearance, but more commonly in properties, operations, or effects. Symbolical characters probably had their rise from picture-writing, and were at first mere abbreviations, but afterwards became specific marks, formed by peculiar though arbitrary rules. Of this class of characters there are numerous kinds, such as hieroglyphics, symbols, armorial bearings and other heraldic signs; to which may be added, musical notes, scientific abbreviations, &c. For the account of each, see under the proper heads, Hieroglyphics, Symbols, Heraldry, Music, Algebra, &c.

11. The peculiar and distinguishing properties belonging to an individual. This application of the term arises from these peculiar properties being regarded as the marks by which different individuals of the same species were distinguished and recognised.

It is seldom, if ever, applied to bodily powers; and even in mental qualities, refers generally, though not universally, rather to moral than intellectual endowments. See Moral Philosophy.

111. The persons or agents exhibited in poetical or narrative composition. The distinctive properties of individuals, when in any way remarkable, forming, as it were, the marks by which they are recognised, these are frequently regarded as constituting the individual himself, especially when, by the influence or operation of such peculiar qualities, important events are produced upon the situation and conduct of other men. From this species of personification, the denomination of characters has been introduced, as denoting the individuals by whom the actions or events, which form the subject of composition, either poetical or narrative, are carried on. In regard to what belongs to such characters, and in what manner their introduction, development, and operations, are to be regulated, see under the heads of Epic Poetry, Tragedy, Comedy, Novel Writing, History, Biography, &c.

Besides the foregoing different applications of the form, character, there are other subordinate ones; but as they all relate immediately, or remotely, to those already considered, they require no particular notice. (3)

CHARACTER of Keys, in music. Most of those writers who have brought forward irregular systems of temperament, or such wherein an invariable law is not observed (as far as the scale or number of notes in the octave will admit) in the temperament of the different concords, as in regular diatessarcs for instance, in the case where eleven of the fifths are tuned equal, have insisted much on the advantages of what they call the peculiar character of certain keys, arising from their varied and often very considerable degrees of imperfection, in the principal concords of such keys. Earl Stanhope was one of those who insisted on the advantage of the great contrast of the harmony in some of the keys in his temperament, when compared with others. This gave rise to a controversy on the subject in the Monthly Magazine, vol. 22 and 23, in which the very able and much to be lamented Dr Callcott took a part. From all, however, that we have read or heard, we are disposed entirely to disregard the characters of keys derived from their imperfections; and to contend, that nothing seems wanting to heighten the pleasure of hearing modulation skillfully conducted, on regularly tempered scales, and where the different keys are exactly alike tempered, as on D. Loeschman's patent instruments with 41 strings or pipes in each octave, or by able singers or violin players, who use no tempered harmonies whatever; and the same has lately been more fully confirmed, by often hearing the Rev. Henry Liston's patent organ, where every harmony is given absolutely perfect, and yet nothing seemed wanting in the effects of its modulations, or of the pieces performed upon it in different keys. (2)

CHARACTERISTIC Notes, in music, are the leading note, and the subdominant. Their uses in pointing out the key of a piece of music, where the proper number of sharps or flats happens not to have been affixed to the beginning of the piece, or supplied
The charcoal which is employed as fuel, is obtained generally from wood of different kinds; the most dense and hard being preferred. The white and resinous woods are commonly rejected. Large timber is seldom employed for this purpose, both because it is too expensive, and because it does not yield charcoal equal in quality to that procured from coppice wood. Pieces of three or four inches thick must be cleft into four pieces.

It is an object of some moment to ascertain the most productive wood in the preparation of charcoal; and although accurate results are not to be expected on the great scale, yet experiments made by Mr. Mushet afford very good general proportions, which may be the rule by which the products may be estimated.

The following Table exhibits very satisfactorily the results of these experiments.

In Scotland very large quantities of charcoal are prepared for the iron works, in the following way: A platform, having a diameter of from twenty to thirty feet, is formed on the ground, by laying strata of earth upon it, and giving it a slightly convex surface. On the centre of this circular area, a circle of sticks are placed to cross each other a little below the top, and thus to form a cavity resembling an inverted cone, around which successive concentric layers of truncheons, having a diameter of from one to ten inches, are placed; care being taken, that the truncheons in the same circle are of the same size, and as few interstices as possible left. The exterior circle is composed entirely of brushwood. When the platform is nearly covered, a coating of turf is laid on the pile, the grassy side being next to the wood; dry earth is then heaped up around the lower part, and well rammed down, so as to exclude all air. The pile is then lighted, by placing a few inflamed chips of wood in the interior cavity; and when these are consumed, others are added during the first three or four days. When the upper part of the pile is completely inflamed, a row of holes, each of which has a diameter of two inches, is made around it at a few inches below the top, and the opening at that part is closed up. The flame then gradually descends to the circle of holes, and its arrival there is announced by a very perceptible diminution of smoke and vapour. Another row of air holes is then made at a distance of six or eight inches below the first row, which are closed up, and the same operation is repeated until the flame has been conducted to the lowest part of the pile, which generally happens in about a fortnight; when the whole is carefully covered until the fire is extinguished. Such pieces as are not completely charred, are separated, and reserved as fuel for the next pile.

The charcoal produced from the truncheons is laid aside for particular uses; and that obtained from the brushwood is sold, under the name of small coal, as fuel.

In France there is some difference in the mode of preparing the charcoal: it therefore is worth while to give an outline of the various processes there adopted.

The wood is cut down in large faggots, and after having been well dried for some months, it is divided into brushwood, small and large faggots. The last are cut into truncheons of three or four feet in length. The turf is then taken off a square or circular space, having a diameter of about fifteen feet, and the earth beaten until the surface becomes dry and solid. A stake is next fixed in the middle of the area, and some brushwood laid on the surface as a foundation for the remainder. A stratum of truncheons is then laid on the brushwood, and the same alternatives are repeated, until the pile is completed to the height of about six feet in the form of a truncated cone or pyramid. As soon as this is done, the whole surface of the pile is covered to the thickness of about two inches with dry earth, over which sods are very compactly laid, except at the base, where considerable spaces are left between them. The central stake is now withdrawn, and the cavity is filled with chips, which are lighted at the top; the whole of the chips become inflamed, and after a considerable quantity of smoke has been poured out, a light flame rushes from the chimney in the centre of the pile; the aperture of which is immediately closed by laying a piece of turf over it.

During the next ten or twelve hours, considerable attention is necessary to prevent any mischief resulting from the sudden disengagement, and consequent combustion of carburetted hydrogen, which take place during that period of the manufacture. The explosion is announced by a rumbling noise, and seldom does any other injury than that of throwing off some portion of the covering, and through the opening thus formed flame and smoke issue. It is necessary to close up all such openings with a few spadesful of dry earth. When the smoke decreases, and the explosions have entirely ceased, the interstices between the sods at the lower part of the pile must be closed. At this stage little attention is required, the combustion gradually extends to the surface, and in about thirty or thirty-four hours after the process commenced the whole pile becomes a glowing mass. The wood is thoroughly charred, the whole is covered with dry earth, and in four or five days it may
be taken down. The particular stage at which it is proper to do so, is determined by making a small opening into the pile: if no flame appears, it is fit to be taken down; if it bursts forth, the aperture must be again closed, and allowed to remain so for another day.

Great nicety is requisite in the preparation of charcoal for the manufacture of gunpowder and other delicate chemical processes. And the manufacturers select the stems of the willow, alder, dogwood, and some others, which they prepare with peculiar care. In most of the large manufactories, the charcoal is distilled from iron vessels; by which means it is obtained in a state of considerable purity, and the other products are saved. As all charcoal contains minute portions of earthy and metallic substances, lamp black is commonly used in nice chemical experiments. Lamp black is obtained by the turpentine manufacturers, from the combustion of the refuse of their operations in furnaces appropriated to that purpose. The smoke deposits itself on the sacking which is hung up; it is swept off, and sold for common use, without further preparation. The lamp black in this state contains some oil, which is separated by being heated to redness in a close vessel.

The chief consumption of charcoal is as fuel. It is also employed as a tooth powder, and to purify tainted meat. No mode of preparation for the first of these objects is at all necessary, and for the two last, it must merely be reduced to a fine powder.

It forms a part of all reducing fluxes. It is an indispensable constituent of gunpowder. (See Gunpowder.) It is the basis of most black paints and varnishes. It is used to polish brass and copper, and is an excellent clarifier.

Powdered charcoal must be heated to redness in a covered crucible, with an opening in the middle of the cover, and kept in that state till no flame issues out; it must be then withdrawn, allowed to cool, and then put into close vessels and kept for use. Whenever either wine, vinegar, or any other fluid is to be clarified, it is simply to be mixed with the liquor; a froth appears at the surface, and after infibration, it is pure and colourless. See *Philosophical Magazine*, vol. iii. p. 1. No. 17. 8vo; *Annales de Chimie*, vols. xxxi. xxxii. xxxvi. xlii.; Nicholson's *Journal*, 4to. vol. iv. (c. m.)

CHARENTE, the name of one of the departments of France, which was formed out of Angoumois, and takes its name from the river Charente which passes through it. It is bounded on the north by the departments of the two Sevres and Vienne, on the west by Lower Charente and Dordogne, and on the east by Dordogne and Upper Vienne. It extends about 56 miles from south-west to north-east, and its mean breadth is about 30 miles. It contains 6310 square kilometers, or about 1,153,684 square acres. The principal rivers are the Charente, the Vienne, and the Touvre. The Charente is navigable from Angouleme to the sea, and is of great service in transporting from Limousin to the port of Rochefort the wood which is required for ship-building. The source of the Touvre is a noble spring, nearly equal to that of Vaucluse, and having its water cold in summer and warm in winter. The forests of this department occupy about 24 thousand hectares, the half of which belong to individuals, and the other half to the nation. The contributions in 1803 amounted to 2,978,099 francs. Population 339,000. The principal towns are Angouleme, Cognac, Ruffec, Confolens, and Barbezieux. See Angoumois for an account of the productions of this department. (j).

CHARENTE, LOWER, a maritime department of France, formed out of Auinis and part of Saintonge. It is situated on the north of the river Gironde, and is bounded on the north by the departments of the two Sevres and La Vendee, on the west by the sea, on the south by the departments of the Gironde and the Dordogne, and on the east by the department of Charente. It is about 80 miles long, and is 10, 20, and in some places 40 miles broad. It contains 7200 square kilometers, or 478 square leagues of 2000 toises. The principal productions of the department are corn of all kinds, wines, hemp, flax, brandy, salt, fish, and iron. The isle of Oleron is very fertile; and the isle of Re, which also abounds in wines, is famous for the liquer called anisette. The navigable rivers are the Gironde, the Charente, the Bouonne, which is navigable from St Jean D'Angeli to Charente, the Sevre Niortaise, and the Seudre, which is navigable from Mornac to the sea. The forests occupy 38,000 hectares, belonging almost wholly to individuals, about one fifteenth only being the property of the communes and the nation. The contributions in 1803 were 4,105,914. Population 402,000. The principal towns are Saintes, Rochefort, Rochelle, St Jean D'Angeli, Marennes, and Jonzac. See Rochefort and Rochelle. (j)

CHARLESTOWN, the capital city of South Carolina, one of the United States of America, is situated on a tongue of land, formed by the confluence of the rivers Ashley and Cooper. These two streams, short in their course, but wide and navigable, unite immediately below the city, and form a spacious and convenient harbour, communicative with the ocean below Sullivan's island, which it leaves on the north, seven miles southward of Charlestown. A sand-bank at the mouth of this harbour, extending from shore to shore, is very dangerous to vessels, particularly when the wind blows strong into the harbour. It is composed of hard sand; but has four openings, by which vessels are navigated across it. The deepest of those openings has fourteen feet of water when the tide flows, and twelve feet when it has ebbed; in spring tides it is covered to the depth of twenty feet. Immediately before this bank there is excellent anchorage ground, of which, however, ships seldom venture to avail themselves, unless the wind be faint, and the billows moderate. From the sand-bank up to Charlestown, the anchorage is good, and is best in the immediate vicinity of the town.

Charlestown was founded in the year 1680, by the first group of colonists who emigrated from England to South Carolina. They had landed about the year 1670 near Port-Royal, from which they removed in the following year to the western banks of Ashley river. There they laid the foundation of a
town, the site of which still retains the name of Old Charlestown; but finding it inaccessible to large vessels, they renounced it for Oyster Point, where they founded the present city. In the construction of the houses of Charlestown, the first object of attention is to moderate the excessive heat. For this purpose, the windows are made open; the doors pass through both sides of the houses; the upper part of the house is sheltered by large galleries from the rays of the sun; and only the cooling north-east wind is admitted to blow through the rooms. In the formation of the streets, less attention has been paid to the peculiarities of climate and situation. The principal streets extend in a straight line from river to river, and thus open agreeable prospects to the east and west. These streets are intersected by others nearly at right angles, dividing the town into a number of squares, which have dwelling-houses in front, and office-houses and small gardens behind. In general, however, they are most uncomfortably narrow; and the pernicious effects resulting from the want of a free circulation of air in that burning climate, are greatly increased by the slovenly negligence of the inhabitants. Cleanliness is not much attended to either in the houses or in the streets; and the burying-grounds in the midst of the town frequently present the disgusting spectacle of carcases uninterred. Fortunately the deficiency of the police is in some measure remedied by the voracity of the turkey buzzard, which devours the carcase before it has time to putrefy; and the inhabitants regard with a kind of veneration the useful bird, which thus saves them the trouble of being cleanly.

Fire, whose ravages, though dreadful at the time, often contribute essentially to the improvement of ill-built towns, has been extremely useful in this respect to Charlestown. At various times, whole streets have been burned to the ground; and have always been replaced by others more spacious and elegant. Several of the modern streets, too, are as wide as any in the world; and experience will certainly teach the inhabitants the necessity of greater attention to their own comforts. The houses, though mean in their external appearance, are in general commodious and well furnished. Some of those recently built can even boast of a degree of elegance. The most remarkable public buildings are an exchange, a state-house, an armory, a poor-house, and an hospital for orphans.

The site of Charlestown, though originally a mere quagmire, is now drier and more elevated than any other part of the low country of South Carolina. This salutary change has been effected, partly by draining, and partly by the accumulation of offals and rubbish. Creeks and ponds have been converted into solid land, and afford now firm and dry foundations for extensive streets.

The society in Charlestown is extremely agreeable. The inhabitants are distinguished by frankness, politeness, and hospitality. Its superior salubrity attracts numbers of planters from the surrounding country; and its vicinity to the Leeward Islands, makes it a favourite resort for rich West Indians. From these causes, it is the gayest town in the United States; and there are few places where social amusements, and refined and elegant pleasures, can be enjoyed in greater perfection. In science and literature the inhabitants of Charlestown are as far advanced as any of the Americans. As yet, indeed, they have few literary institutions; but a spirit of improvement has lately arisen among them, which promises the most beneficial consequences. A medical society was instituted in Charlestown in 1789, and incorporated in 1794. It meets monthly, when a conversation takes place on the prevailing diseases; the meteorological observations of the members are examined and recorded; and a medical question or subject is discussed. Under the auspices of this association, a botanical society was formed and incorporated in the year 1805. From the medical society it received three hundred dollars, fifty dollars per annum, and a large field which had been presented to them by a lady, to be cultivated as a botanic garden. This institution has flourished beyond the most sanguine expectation; and the garden is now enriched with a considerable number of plants, both indigenous and exotic, arranged according to the system of Linnaeus.

For 120 years after the first settlement of South Carolina, Charlestown continued to be the seat of government. The great increase of population to the westward, however, made it desirable that the residence of government should be in a more central situation. The beauty, salubrity, and convenience of Columbia, as a point of general communication, recommended it as the most proper site for the new establishment. A city was immediately begun; and the legislature convened there for the first time in 1790.

Charlestown was incorporated in 1789, and divided into three wards, which choose as many wardens, from among whom the inhabitants elect an intendant of the city. The town-council is composed of the intendant and wardens, who have power to make and enforce bye-laws for the regulation of the town. The value of exports from this city amounted, in 1794, to 3,846,992 dollars. Its population was computed, in 1791, to be 16,859 inhabitants, of whom 7684 were slaves. CHARTS. See Geography and Maps.

CHARTRES, a city of France, in the department of the Eure and Loire; is situated upon the river Eure, over which is a bridge built by the celebrated Vauban. The houses have a very singular appearance, from the great number of crosses. The principal curiosity of this town is the church of Notre Dame, with its two spires, one of which is the admiration of strangers, from its enormous mass, and from its pyramidal and finely tapering form; while the other is admired for the strength of its architecture, and the richness and delicacy of its ornaments. A fine piece of sculpture by Bridaut, the subject of which is the assumption of the Virgin, adorns the principal altar of this church. The arabesque figures engraved on the pillars are singularly beautiful, and a magnificent groupe on white marble is reckoned the masterpiece of the celebrated sculptor Coustou. The Marshal Vauban considered the bold construction of the spire of St Andrews as one of the wonders of
of those parchments, using them afterwards as covers to books. Among those parchments young Chatterton, whose mind was now labouring with a plan of deceiving the public, pretended to have discovered the poetry of Rowley, a priest of the 15th century. He communicated some of his pretended treasures to a Mr Catcott, a pewterer of Bristol, and to Barret, a surgeon, both ignorant and credulous judges, who in return supplied the youth with some books and money, and introduced him into better company than he had been accustomed to keep. At his request, Mr Barret lent him also some medical books, and gave him a few instructions in surgery. The course of his studies was now enlarged, and he employed his pen, both in prose and verse, for the Town and Country Magazine.

Encouraged by this partial success in his native city, he addressed (in 1769) a letter to the Hon. Horace Walpole, offering to furnish him with a history of a series of eminent ancient painters at Bristol, and enclosing specimens of the Rowleian poetry. Walpole sent him a polite answer, requesting farther information. In the mean time, he shewed the specimens of poetry to capable judges, who pronounced them forgeries; so that when Chatterton wrote to him again, relating the circumstances of his life, and soliciting his patronage, Walpole replied in a cold monitory epistle, which he intended to close their correspondence. He set out to Paris, however, neglecting to return the manuscripts, which occasioned two successive letters from Chatterton, in the latter of which he demanded back the writings, in terms which Walpole chose to consider offensive and insolent; so that he inclosed the papers to Chatterton, without deigning to write to him. This is the whole story of their connection. Undoubtedly, Walpole might have been more courteous towards a youth whose circumstances would have appeared interesting to a liberal mind; and after neglecting to restore the papers before going abroad, he ought, on his return, to have made an apology. But though his conduct was cold, it cannot be pronounced criminally negligent; for Chatterton came to him in a questionable shape. The odium against Walpole, which occasioned his published Vindication of his Conduct respecting Chatterton, was carried to a most unjustifiable violence. After this event, the stirrings of Chatterton's mind vented themselves in froward communications to the Magazine, consisting of personal and political satire, to which he added some Saxon poems in the manner of Ossian, from his pretended Rowley. A change at this early period of life took place in his religious belief; he became a deist, and connecting infidelity with despair, he avowed his determination of terminating a miserable life by self-destruction. On perusing this threat, which he left in a last will or testament, his master, the attorney, dismissed him from his office and house, after he had continued there two years and nine months.

Reanimated by this emanicipation, and by the promises of some London booksellers, he laid aside his project of suicide, and with the hopes and plans of a literary adventurer, came to the metropolis aged 17 years and five months. His letters during the first few weeks after his arrival describe the most sanguine prospects, and a multiplicity of literary employments; a History of England, a History of London, Essays...
in the daily papers, and Songs for the public gardens, were his actual or projected tasks. An extraordinary elevation was given to his spirits, by the notice which his political principles attracted from the Lord Mayor Beckford, to whom he was introduced. On this, as on every other circumstance which filled his heart with high anticipation, he wrote with much affection to his mother and sisters, promising they should be partakers in his future fortune, and even sending them presents at times, when there was every probability that he was himself nearly, if not of the necessities of life. During two months from the date of his arrival, it appears from the list of his communications to public papers, and from his songs, &c., that he was industrious in the midst of this intoxicating dream of success. But his hopes had been probably founded in the extravagant idea of making himself of political consequence by his writings; and when that delusion vanished, he found that unremitting industry alone would ensure to him a competence among the dealers in literary ware. No delusion is more common to persons ambitious than to overrate the future powers of patient drudgery. Chatterton set out, therefore, with the fire of the racer, but his unequal spirits seem to have sunk under the burthen of the course. The history of his few remaining days is melancholy, but obscure. About the end of July, he removed from a house in Shoreditch, to the house of a Mrs. Angel, a sack-maker in Brook-street, Holborn, where he became poor and unhappy, abandoning his literary pursuits, and proposing to go out to Africa as a naval surgeon's mate. He had picked up some knowledge of surgery, and now requested that gentleman's recommendation, which Mr. Barret thought proper to refuse. It is certain, that either from want of encouragement from the booksellers, or, which is much more probable, from the gloomy despondency of his mind, he no longer employed his pen, and that the short remainder of his days was spent in a conflict between pride and poverty. On the day preceding his death, he refused an offer from Mrs. Angel to partake of her dinner, assuring her that he was not hungry. At that time she believed that he had eaten nothing for two or three days. On the 25th of August, he was found dead, in consequence of having swallowed poison. He was buried in a shell in the burying-ground belonging to Shoe lane workhouse. Previous to his death he had torn all his manuscripts in small pieces.

On the short and tragic career of "this mighty striping," it is impossible to reflect without regret and astonishment. The authenticity of Rowley's poems is now given up. Mr.Watson has proved, that, wonderful as it may seem for Chatterton to have written them, it is impossible that they could have been written by Rowley; and these must have been composed by the boy of Bristol before he had completed his 16th year. Some deduction may perhaps be made from the admiration with which they are contemplated through the medium of an antiquated language; but the intrinsic value of some of those pieces is sterling, independent of all considerations either of their author's age, or of the veil of language which softens their defects by obscurity. Among these is the ballad of Sir Charles Baudin. The heroic conception of character, the simple and well-chosen incidents, the pathos and picturesqueness of this poem, would do honour to the matured imagination of the greatest genius. The chorus in Godwayne, beginning,

"When Freedom drear in bloodstain'd vest—
To many a knight her war-song sung," &c.

is fraught with the boldest spirit of lyrical enthusiasm.

His life (says Lord Orford) should be compared with the powers of his mind; the perfection of his poetry; his knowledge of the world, which, though in some respects erroneous, spoke quick intuition; his humour, his vein of satire, and above all, the amazing number of books he must have looked into, though chained down to a laborious and almost incessant service, and confined to Bristol except for the last five months of his life. The rapidity with which he seized all the topics of conversation then in vogue, whether of politics, literature, or fashion; and when, added to all this mass of reflection, it is remembered that his youthful passions were indulged to excess, faith in such a prodigy may well be suspended, and we should look for some secret agent behind the curtain, if it were not as difficult to believe that any man possessing such a genuine vein of poetry, would have submitted to lie concealed while he actuated a puppet, or would have stooped to prostitute his muse to so many unworthy functions. But nothing in Chatterton can be separated from Chatterton. His noblest flights and his sweetest strains, his grossest ribaldry and his most common-place imitations of the productions of magazines, were all the effervescence of the same ungovernable impulse which, cameleon-like, imbibed the colours of all it looked upon. It was Ossian, or a Saxon monk, or Gray, or Smollet, or Junius; and if it failed most in what it most affected to be, a poet of the 16th century, it was because it could not imitate what had not existed. (w)

CHAUCER, GEOFFREY, the Morning Star of English poetry, was born in London in 1328. His descent appears, from the name, to have been Norman; and his father, though variously described, was most probably a merchant. At what university he studied, is a disputed point which even Mr. Tyrwhitt has left unsettled. Leland and Warton place him at Oxford, without adding any proof. His signature of Philoginett of Cambridge affixed to his first poem, The Court of Love, is brought by other biographers as direct testimony that he studied at the other university; but the signature, it should be remembered, is fictitious in point of name, and might be equally so in point of date.

Leland, who is so often inaccurate, tells us that he studied in France. Mr. Godwin undertakes to prove this doubtful part of his history, from the circumstance of a Parisian education being so commonly given to young Englishmen in those days, and from Chaucer's fluently speaking French. The reader will admit these proofs at his own discretion. The presumption of Chaucer's having studied at the Temple, and the story of his having been fined whilst a student there, for thrashing a friar in Fleet-street, rest also on the weakest authority.

The precise time at which he attracted the notice of Edward the Third, and of his munificent patron John of Gaunt, is not ascertained, but he certainly enjoyed that patronage before his thirty-first year,
as appears from the date of his poem, entitled, *The Dream*, an allegory alluding to the nuptials of John of Gaunt with Blanche heiress of Lancaster. The same poem contains an allusion to the poet's own tender attachment to the lady whom he afterwards married. This was a daughter of Payne de Rouet, king at arms for the province of Guienne. She was maid of honour to Philippa, Queen of Edward III. and youngest sister to Catharine de Rouet, who was first the mistress, and afterwards the wife of John of Gaunt, and by her marriage with that prince, an ancestor of the royal family of England. The supposition of his having been early patronized at the court of Edward, is countenanced by many passages in his poems, describing a residence which coincides with that which tradition has ascribed to him at the royal abode of Woodstock, in the lodge near the park gate. There is some reason to presume that he accompanied his warlike monarch in the invasion of France in 1359, in a military character. From the record of his evidence in a military court, discovered by one of his latest biographers, (Godwin,) we find that he gave evidence to a fact which he had witnessed in France in the capacity of a soldier. The expedition of 1359, however, which terminated in the peace of Bretigne, gave him little opportunity of seeing service, and he certainly never resumed the profession of arms.

A.D. 1367. In his thirty-ninth year he received from Edward the Third a pension of twenty marks per annum, a sum probably equal in effective value to two or three hundred pounds of modern money. In the patent for this annuity, he is styled by the king *Valettus Noster. Valettus,* Mr Tyrwhitt thinks, is a contraction of *vassaletus,* the diminutive of *vassalius.* The name was given, though not as a badge of service, to young men of the highest distinction before they were knighted. Chaucer, however, at the date of that pension, was not young, being thirty-nine years of age. How long he had served the king in that or in any other station, and what particular merits were rewarded by this royal bounty, are points equally unknown. Chaucer, at the time of receiving his first pension, must have been thirty-nine. He did not acquire the rank of scutifer or esquire till five years after, when he was appointed the king's envoy to Genoa. So respectable an appointment seems to imply, that he had established a personal and political character of some importance; but the particular objects of his mission, it has puzzled all his biographers to discover. Mr Godwin, whose life of the poet is a series of suppositions, supposes that it related to commercial objects, and is decidedly of opinion that he visited the northern parts of Italy, and had a conference with Petrarch. But the reality of this interview, pleasing as it is to the imagination, is more than doubtful. It is said to be implied in a passage of one of the *Canterbury Tales,* in which the speaker says, that he learned his story from Petrarch, a learned clerk of Padua. It should be noticed, in the first place, that Chaucer, making one of his pilgrims deduce his tale from Petrarch, does not amount to declaration from himself as author, that he derived it from that source. The story originally belongs to Boccaccio, and was only translated into Latin by Petrarch, and, like the plan of the *Canterbury Tales,* is in all probability borrowed from the same author.

On the other hand, the accurate Tyrwhitt, though he doubts whether Chaucer ever went upon his mission, yet admits, that, supposing him to have been at Genoa, it is to be presumed that he would have seen the first literary character of the age; and it is remarkable that the time of this embassy in 1373, is the precise time at which he could have learned this story from Petrarch at Padua. Neither Petrarch nor his biographers, however, have mentioned the fact, nor did the author of *Memoires pour la Vie de Petrarch* ever fulfil his promise of proving the interview. His genius as a poet, and, we may suppose from the style of his writings, his amenity as a courtier, also kept him in prosperity during the whole of Edward the Third's reign, and indeed during the whole period of John of Gaunt's influence. In 1374, the year after his appointment as envoy, he was presented by the crown with an allowance of a pitcher of wine daily, a grant which was commuted during the succeeding reign to an annuity of twenty marks. He was appointed in the same year to the comptrollership of the customs of wool and skins in the port of London. In the next year he received £104 for the wardship of Sir Edward Stapelgate's heir; and in the following year, some forfeited wool to the value of £71 4s. 6d. In the last year of Edward's reign, he was sent with Sir Guichard Dangle. His situation in the middle part of his life must thus have been opulent and honourable. It was so opulent, he says himself in his *Testament of Love,* as to enable him to maintain a plentiful hospitality. But the picture of his fortune was reversed during a considerable part of the reign of Edward's successor. He was not, it is true, immediately deprived of his comptrollership on the accession of Richard the Second; his pension was renewed to him, and a grant of money made to him in lieu of his daily pitcher of wine. But these favours were obtained by the influence of John of Gaunt, an influence which lasted but during a few years under the new king. We find him, however, in 1382, receiving a grant of comptrollership of small customs in the port of London; with the additional favour, that the new office might be performed by deputy. Neither is it true that he was obliged to receive a royal protection from his creditors within two years from Richard's accession. This error in former biographers, is one of the few things which Mr Godwin proves in his voluminous biography. He was certainly attached, as his patron was, (for a time,) to the opinions of the reformers, which became unpopular at court under Richard. The immediate cause of our poet's misfortunes seems to have been his interfering in a dispute between the court and the city of London, in which Chaucer embraced the civic side. This came to a violent crisis in 1384. John of Northampton, a popular candidate for the mayoralty of London, was supposed to be attached to the tenets of Wickliffe. Richard and his court, who detested the Londoners, were resolved that they should have a mayor of a different description. They succeeded in forcing upon the city another candidate, Sir Nicholas Brembar, and the contest subsided, after some resistance on the part of the popular leaders, which was dignified with the name of a rebellion, in the death of some of them, and the imprisonment of John of Northampton. There is a mystery over this court as it is connected with Chaucer's life; for
through his writings testify that his subsequent exile and misfortunes arose from it, yet we find him, in 1385, permitted to execute his office by deputy, at a time when there is reason to believe that he was in exile on account of his politics. It is certain, however, that he was arrested and committed to the Tower on his return to England. When obliged to fly, he escaped first to Hainault, then to France, and finally to Zealand. While in Zealand, he maintained some of his countrymen who had fled thither on the same account, a liberality which soon exhausted his money. In the mean time, the partizans of his cause whom he left at home, contrived to make his peace, not only without endeavouring to procure him a pardon, but without aiding him in his poverty abroad. On his return home, he suffered a temporary confinement, and in 1386 he was deprived of his two comptrollerships. The coincidence of this date with that of the Duke of Gloucester’s usurpation of power, would lead us to suppose that Glocester was personally more hostile to the poet than the king himself was, whose asperity was probably softened by the good offices of his queen, Anne of Bohemia, the friend of Chaucer, and the subject of his warmest panegyric. In 1388, he was obliged to dispose of his two pensions, which were all the resources left to him by his predecessors. From 1386 to 1389, Richard the Second had been strait of his authority. The latter year was propitious to Chaucer. Before its conclusion, John of Gaunt, now Duke of Lancaster, who afterwards married his sister-in-law, returned from Spain, and from that date he had a more steady protector. Before Lancaster’s arrival, he had procured his liberation from prison, on terms which have been alleged to be disgraceful to his memory. He made a confession of his coadjutors in what was called Northampton’s conspiracy. But in naming them, he implicated no innocent person; and it is evident that they had behaved towards him in the most unprincipled manner.

In the same year, 1389, he was appointed to be clerk of the works at Westminster, and in the year following to the same office at Westminster. His salary amounted to £36, 10s. per annum, a sum (considering the price of provisions in those days,) probably equal in effect to seven hundred pounds of our present paper currency. His resignation of this office brings us to the sixty-third year of the poet’s life. He then retired most probably to Woodstock, and devoted the repose and evening of his life to writing his immortal Canterbury Tales, among those beautiful scenes which had inspired his youthful genius. In 1394, he obtained a pension for life of £20. One of the most curious particulars in the concluding part of his life is, the patent of protection granted to him by Richard the Second, in the year 1398, which has been generally supposed to be a protection against his creditors. But this protection proves, upon examination, to contain no mention of the poet’s debts or creditors; and though it is difficult to suppose that what other sort of protection a man of peaceful pursuits could require, yet it is one of the many problems in his history which remain yet to be solved. The record shows, however, that Chaucer, though now seventy years of age, had once more embarked in public business, although the nature of his employment is not specified. In the autumn of the same year, he received a grant of a yearly ton of wine, we may suppose in lieu of the daily pitcher which had been stopped during his misfortunes. The place appointed for this delivery seems to imply, that his residence was then in London.

The succeeding year, 1399, was marked by the deposition of Richard the Second, and the ascension of Bolingbroke, the son of his patron John of Gaunt, to the English throne. It is creditable to the memory of Henry IV., although he abandoned so many of his father’s friends, that he did not suffer the poetical ornament of the age to be depressed by the revolution. Chaucer’s grants of the annuity and pipe of wine were renewed in the first year of the new reign, and an additional pension of forty merks a year was conferred on him. But he did not live long to enjoy them. He died, according to the inscription on his tomb-stone, in the beginning of the second year of Henry IV., at London, on the 25th of October 1400, and was interred in Westminster Abbey, southcross aisle. The monument to his memory was erected above a century and a half after his decease, by Nicholas Brigham, a gentleman of Oxford, and a warm admirer of his poetry. It stands at the north end of a magnificent recess, formed by four obtuse foliaged arches, and is a plain altar, with three quadrfoils and the same number of shields. The inscription and figures on the back are almost obliterated.

Chaucer, it will be hardly necessary to inform any of our readers, found the poetry of England (if the metrical romances and rhyming chronicles of the Norman school deserve that name) in the rudest state. Of the measures of verse which had been established by his predecessors, he designed only to adopt one, the eight syllable measure, and another still shorter and more imperfect; but the latter he introduces in his Canterbury Tales only as a specimen of the common minstrel style, in derision. He introduced the majestic ten syllable iambic into our language, which, although it may be sometimes found among the hobbling and indetermined measure of older versifiers, evidently occurs only by accident. He found, however, the numbers of the language more defective than its stores of fancy and fiction. Fable and imaginary characters had been already engraved on English minstrelsy, through the joint influence of the troubadours, and of the expansion of intercourse among nations, among whom England had taken a distinguished lead since the period of the first Richard. This increasing intercourse and diffusion of taste and fancy, as well as knowledge, throughout Europe, is to be remarked in the influence which the Italian poets possessed upon Chaucer’s character as a poet, both as it tuned his versification and enriched him with subjects.

Chaucer’s earliest production, The Court of Love, was written at eighteen years of age. There yet existed, as we have already noticed, no form of versification in English that could direct his ear in the stately and regular measure of the prolonged iambic. * * It was reserved for the youthful hand of our poet first to array them in English, and to ornament

* To prevent obscurity, we notice to those who may not know the classical names of metres, that long iambic means our common heroic measure, such as the line,

“Sweet Auburn, loveliest village of the plain.”
them with that inverted form of rhyme which was borrowed from the French and Italians. The Court of Love seems to have derived its name from a custom peculiar to the days of early chivalry, viz. courts or parlements of love. These institutions, whimsical as they appear to a serious age, decided questions of gallantry and attachment that were proposed to them, in the same manner as modern academies pretend to determine questions of literature. The obedience that was paid to them was voluntary, the result of public respect for the arbiters; but the questions argued before them were commonly fanciful. Chaucer's poem reminds us of the institution. It is an allegorical dream, in which the poet supposes himself summoned by Mercury to visit the court of love at Mount Citheron, where he meets with a number of votaries, is introduced to a mistress, and sworn to observe the twenty statutes of the god. These include fidelity to his mistress, implicit belief in her virtues, promptitude to fight, to swear either truth or falsehood for her honour, to say that the crow is white if she says so, and to do the duties of love seven times in a night. The poet objects to this statute alone, and pleads his inability. Among the attendants at the court are placed, with a bold impropriety, but evidently for the sake of contrast, a crowd of monks and friars, and those who lament their obligation to celibacy from other causes. The poet does not leave the court till he forms an assignation with his mistress, and with the celebration of that meeting the poem concludes, "The season is May," and the birds sing a service in concert to the god of love, which, strange to say, is from the Roman Catholic ritual. The nightingale sings, Domine labia; the possinjay, Cavi emarrant; and the turtle dove, Tu autem. The materials of the piece are meagre, extravagant, and ill united. We see, however, in the lover's refusal to the hardest statute of love, and in the deplorable picture of the monks, some promise of the arch and salacious humour which sports so indulgently in the Canterbury Tales. We have been thus particular in noticing the earliest production of our earliest poet.*

His next production, in order of time, is the story of Troilus and Cresside, in which Chaucer has claims on our curiosity, were it only for being the precursor of Shakespeare and Dryden, in telling, though differently, an interesting tale. It is, however, the best of Chaucer's productions next to the Canterbury Tales, and was for ages the favourite of the English nation.† Troilus, one of the sons of Priam, is supposed, during the siege of Troy, to fall in love with a beautiful widow,‡ Cresside, whose father, the poet, in defiance of antique story, makes a Trojan, and supposes to have deserted from his native city to the camp of the Greeks. The Trojan prince sees her in the temple of Minerva, and is irrecoverably smitten with her appearance, naturally lovely, but made more interesting by the grief for her father's desertion. The uncle of Cresside is the bosom-friend of Troilus; he visits him, finds him in despair, and, sacrificing duty to friendship, obtains, by a long train of artifices, the happiness of Troilus from the yielding virtue of Cresside. Calchas, however, sends for his daughter from Troy; she is exchanged for a Greek prisoner; after bidding a secret and tender

* A specimen of the best part of it may not be unacceptable to those who are little invited by its obsolete language to explore an almost unintelligible author. In describing the life of lovers, he thus proceeds:

This is the life of joy that we begin,
Resembling life of heavenly paradise;
Love is elixir of joy and sin,
Love makith hertis lustie || to devise;
Honour and grace have they in every wise,
That ben to lovis law obedient,
Love makith folke beneigne and diligent, Aye stirring them to dreasin vice and shame;
In their degree it makith them honourable,
And sweet it is of love to bear the name,
So that his love be faithful, true, and stable.
Love prunith hym to seemen amiable,
Love hath no faulte there it is exercised,
But sole with them that have all love despised.

† The poet pretends to have borrowed this story from the Latin, which is exceedingly improbable. But should we ascribe its origin, as Mr. Tyrwhitt has done, to Boccaccio, still the merit of much originality, in point of manner would remain to Chaucer. Chaucer himself professes, that he was indebted for the tale of Troilus and Cresside, to his Auctor Lollissis: he declares,

"That of no sentiment I thus endite
But out of Latin in my tongue I write."

Of the writings of this Lolliss nothing is known. He certainly was not the Lollis Urbicus of the 3d century; and though mentioned again by Chaucer in his House of Fame, his existence as a real writer seems still to be questionable. Mr. Warton lays no stress on Chaucer's mention of his Auctor, but from having seen some of the name Italianized in a MS. of the poem which he had perused, he pronounces its origin to have been Italian. Mr. Tyrwhitt directly charges Chaucer with forging the name of Lollis, and concludes, that he borrowed it from the Philobates of Boccaccio. Mr. Godwin again quotes the evidence of Lydgate to controvert Tyrwhitt's opinion; but Mr. Godwin has not observed that Lydgate's evidence goes no way to prove the authenticity of Lollis. Lydgate says, that Chaucer borrowed it from a book called Tropike, in the Lombard tongue. The two assertions of Chaucer and of Lydgate are indeed direct, but they go in opposite directions.

‡ Mr. Warton, when he speaks of this character in Chaucer's poem, does not seem to have attended to several circumstances which, at the outset of the story, distinctly point out Cresside to have been a widow, not a virgin. Mr. Godwin, from the same misapprehension, though he dwells on the real intrigue of the story with great equanimity, is indignantly shocked at a passage which he denominates brutal, in which the poet declares his uncertainty whether Cresside had ever been a mother before her affair with the Trojan prince. There is, however, nothing brutal in this passage: the poet only suggests a doubt whether or not the young widow had been left with a few small children. Cresside speaks of her widowhood in several places. She says on one occasion, when invited to a public amusement, "Let maidens go to dance and yonge wives." And to Dromed, she speaks in direct terms of her former lord, evidently not alluding to Troilus, (with whom all her interviews had been stolen,) but of a plain lawful partner.

"But as to speak of love I wis, she said,
I had a lord to whom I wedded was,
The whose mine heart was all still that he died."
adieu of the prince, and taking an oath of constancy, which, like many other mistresses, she forgets, and repairing to the camp of the Greeks, transfers her affections to Diomed. Troilus learns her infidelity, and dies in despair. The story concludes disagreeably, and is tediously told; but it is interspersed with a number of interesting and deeply pathetic passages. Though the scene and subject are connected with classical and heroic story, the poet describes no pomp nor circumstances of war, but such as are immediately necessary to usher in his hero to the notice of his mistress with better effect, returning victorious from the field; and he seems to describe the temple of Minerva, only for the sake of introducing the beauty in a greater attitude of solemnity. Like the true poet of love, he magnifies the importance of domestic scenes, and neglects war and public circumstances, except where they serve as auxiliaries to that passion which

"Drives ambition with its pomp away; Unless conducive to his ampler way."*

The scenery and names in *Troilus and Cressida* are Trojan, but the sentiments and manners are purely modern and chivalrous. In one place we hear of jousts and tournaments, in another in the parliament of Troy. Cressida is found by a noble anachronism reading the Thebais of Statius during the Trojan war. In the speeches, there are frequent allusions to bishops, scholastic divinity, the devil, and other ideas still more modern than Statius. Next to the length of the poem, the greatest obstacle to our interest in it is an inconsistency between the strength and tenderness, and the lawlessness and secrecy of Troilus's passion. The poet represents no sufficient cause to prevent the Trojan from marrying Cressida. He dies of love for her, and yet declares no honourable passion. This is a departure from nature and probability; the more remarkable in a poet whose characteristic merit is generally adherence to both. Yet this tale of Troy divine, which Sir Philip Sidney adored, and which was once regarded as an ornament of our language, did not fascinate our forefathers without a reason. As an ancient novel in verse, it reminds us very frequently of the minute touches and pathos of Richardson. The confession which Cressida makes of her attachment in the scene of felicity, has been noticed, deservedly, by Warner as exceedingly beautiful.

Cressida all quite* from every dive and tend.*
As she that justly cause had him to twist;
Made him soche feast, it joy was for to sen;
When she his truth and clene intent twist,
And as a tree with many a twist
Bitrent* and writhen is the sweet woodbine,
Gan echo of 'hem in arms other ends.
And as the new abashed nightingale,
That stinith when she beginneth sing,
When that she herish any herdis tale,
Or in the hedges any wight stirring;
And after skir* doth her voice omaturing.

The grief of Troilus at her departure, is most naturally portrayed:

Where is mine own lady, lefe, and dere? Where is her white breast? where is it, where? Where ben her armis, and her eyen clear? That yesterday this time with me were? Now may I weep alone with many a tear, And grasp about I may, but in this place, Save a pilowè, I find nought to embrace.

His sensations on arriving at her house, when, instead of finding her returned, she sees the barred doors and shut windows giving token of her absence, and his Hurrying precipitately from the distracting sight, are well conceived and described:

Therewith when he was ware, and gan behold How shut was every window of the place, As frost, him thought his heart began to cold, For which, with changed dely pale face, Withouten worde he forthe by gan to pace, And as God would, he gan so fast to ride, That no wight his continnance aspire. Then said he thus, O palace desolate! O house of houses, wholum best ydight! O palace empty and disconsolate! O thou lanterne of which quene is 4 the light! O palace whilom day that now art night! Well oughtest thou to fall and I to die.

It would be unprofitable to enter minutely into all the poems of Chaucer, which are numerous as well as individually large. His *Dream*, which is supposed to be an epithalamium on the marriage of John of Gaunt, is an allegory of very childish and grotesque fancy. He dreams of an enchanted island, which is visited by a knight, and invaded by Cupid, who brings a formidable navy, and wounds the queen. The knight departs, after obtaining a promise of marriage from the queen; but returning in a ship, which has the convenient property of enlarging or contracting its dimensions, he finds the queen has changed her mind. The knight commits suicide at the news, and the queen expires. While their bodies are surrounded by mourners, a beautiful bird enters, and sings over the bier of the queen, but returning back, dashes against a window, and falls down lifeless. Another bird enters, and restores the dead one, by putting a seed into its mouth. This furnishes a hint for restoring the knight and queen, who are revived and married with great splendor. Such was the style of allegory that was tolerated in the infancy of our poetry. It certainly appears, at first sight, to have as little connection with John of Gaunt as with John o' Nokes, and to be abundantly foolish.

The *Boke of the Duchess* is another dream, intended to commemorate the sorrow of his patron for the same Lady Blanche, who is heroine of the former story. He dreams that he has been led into a forest by the sound of the hunting horn, and that a dog who comes and fawns upon him, leads him to the

---

* When the final e, which is now silent in our language, but which in Chaucer's poetry seems to be arbitrarily silenced and sounded as it suits his purpose, is pronounced as it is accentuated in the specimens we have quoted, the versification will read as smoothly as much later poetry.
foot of a tree, where he finds a melancholy knight, evidently John of Gaunt, who laments to him for
the loss of his partner. This poem also is dull, but
it contains one description of a forest landscape, in
a very sprightly style. * The Assembly, or the Par-
liament of Birds, is another poem devoted to the
story of his patron’s attachment. It commences with
a lofty abstract from the Somnium Scipionis; and
after describing the parliament, or meeting of birds,
to choose their mates on Valentine’s day, tiresomely
touches the amour of the royal pair under the simi-
ltude of eagles.

The Romant of the Rose, is a fine translation
from the French allegory of John de Meun and Wil-
liam de Lorris, representing the dangers and diffi-
culties of a lover.

The Flower and the Leaf is another allegory, foun-
ded on mysterious allusions to the virtues of the vege-
table world. The plan of the poem is ascribed by
Warton to a French original; and the peculiar style
of French poetry from which it is deduced, is sup-
pessed by the same critic to be that of the Chans
Royaux Balades Rondeaux and Pastoralis, which Frois-
sart and others cultivated as the provengal poetry de-
clined. The fancies with which this poem is filled,
(says the same author,) seem to have taken their rise
from the floral games instituted in France in the
year 1324, which filled the French poetry with im-
ages of this sort. They were founded by Clemen-
tina Isaur, Countess of Thoulouse, and annually cel-
brated in the month of May. She published an edict,
by which she assembled all the poets of France
in artificial arbours, dressed with flowers, and the suc-
cessful poet was rewarded with a flower made in gold.
There were also inferior prizes in silver. This fan-
tastic institution soon became common over the whole
kingdom of France.

The best of Chaucer’s allegories (and we long to
have done with them) is his House of Fame, which
Pope has so elegantly modernized. Warton has in-
juries compared Pope’s imitation to the modern orna-
ments in the venerable pile of Westminster Ab-
ney. Analogies drawn from one art to another, are
unsafe guides in matters of taste, and of all analogies
we deprecate those chiefly which are drawn from
brick and stone. We will not suffer the later poet
to be condemned by so arbitrary a comparison. Pope
has not indeed the merit of originality in his Temple
of Fame; it is doubtful if even Chaucer drew it
from invention or translated it. What is most bold
and pleasing in Chaucer’s piece, is the conception of
the palace of Fame; of the rock of ice on which the
perishable names of grandeur were engraven; his
theory and explanation of the expansion of sounds,
spreading in circles through the air like the rings on
water, when a pebble is cast into it, till it reach the
abode of Fame; the house of Rumour for ever shift-
ing round. These ideas, and the claims of the peti-
tioners at the tribunal of Fame, are modernized by
Pope with an addition, not a loss of dignity. In some
respects, the judgment of Pope has improved upon
the original. Chaucer supposes himself snatched up
to heaven by an immense golden eagle, which addres-
ses him in the names of St James and the Virgin Ma-
ry; but presently quiet the poet’s apprehensions of
being carried off to Dan Jupiter like Ganymede, or
stiffened like Orion, by assuring him that Jove wishes
him to sing of other subjects than of Venus and blind
Cupids, and has ordered him to obtain a sight of the
house of Fame. The philosophy of Fame appears
in Pope with much more propriety coming from the
mouth of the poet himself, than from the beak of a
talkative eagle.

We now come to his immortal Canterbury Tales.
The subject of that work, it will be hardly neces-
sary to inform any reader, is the journey of a
number of travellers, who are going on a pilgrim-
age to Canterbury, and who agree, at the sugges-
tion of a jovial landlord, to tell stories by the way,
with an agreement, that the one who tells the best
story should have a supper at the common expence
on their return. The plan is borrowed from Boc-
caccio, who first introduced in his Decameron
the dramatic form of novel writing; but whatever be the
merit of Boccaccio’s stories, his gentlemen and ladies
in the Decamerone are spiritless portraits compared
to those of Chaucer. The Italian poet’s characters
are true gentlemen and ladies, as similar to each other
as old shillings, from which the polish of society has
erased every stamp of originality. In comparing
the merit of the different tales, Dryden pronounces
the highest panegyric on the Knight’s story, while
those of the Squire and Miller have been honoured
by the preference of Warton. The former has been
immortalized by the notice of Milton himself, viz.
the story of Cambuscan bold. The enumeration of
the pilgrims at the opening of the poem has no rival
in description drawn from familiar life. The groups
of Homer’s heroes, and of Milton’s devils, are more
astonishing, but not more perfect in their kind. The
scene is full without confusion, varied with the ap-
pearance of accident, but with consummate art. Never
were drawn together a company so completely fitted
to be the representatives of the entire state of soci-
ety at one period. A fine unobtrusive but sufficient
contrast is supported between the characters; as be-
tween the demure society of the prioress and the
jovial laxity of the wife of Bath; the rudeness of
the shipman and the polish of the knight, &c.; but it is
a contrast arising out of nature, not an antithesis bet-
raying intention. The dramatic conduct of the
piece deserves uncommon approbation. Among nine-

* The poet describes himself as led into a forest,

Where there were many grene greves,†
Or thick of trees, so full of leaves;
And every tree stood by himself
Fro other well ten feet or twelve.
So great trees and so huge of strength,
Of forty or fifty fathoms length,
All clean withouten bowe or stick,
With croppis broad and eke as thick:

† Greves, groves.

They were not in an inch under
That it was shade o’er all un
And many a harte and many a binte
Was both before me and behind;
Of fawnis, sovris, ‡ buckis, does,
Was full the wood, and many roes
And many squirrillus, that sake
Full high upon the trees and aite.

‡ Sowris, bucks fours years old.

VOL. V. PART II.
and twenty travellers, it would have been unnatural and improbable if some disagreeable humour had not broken out. The introduction of two quarrelling characters, the Sompnour and the Frere, two descriptions of the priesthood which in those days were at deadly enmity, affords both a spirited and amusing break in the lounging sociality of the other pilgrims, and an occasion for the poet to indulge his satire on all parts of the church, by employing its members to ridicule each other. The Frere, intolerant, coarse, and abusive, takes an opportunity of hinting, like a modern Methodist, that the soul of his antagonist is doomed to hell. The Sompnour indignantly, but with far more successful wit and humour, tells a story of a canting hypocritical friar, and exposes the mendicant fraternity to derision. The story is low even to grossness, but is very laughable. Of all the characters, the Wife of Bath is perhaps drawn in the strongest and broadest lines of the poet's humour; and if we could venture to censure Pope for any failure in his imitation of the old bard, it would be in having missed the proper aspect of this incomparable dame.

Chaucer's merits as a poet are great and various, but they are all inferior to his power of delineating living character. His landscapes are pleasant, his feasts and tournaments are picturesque; but his men and women are not inferior even to Shakespeare's in comic spirit and resemblance to nature. He is sometimes pathetic, and Warton gives an instance of his sublimity, but the passage is chiefly borrowed from Statius, and is mixed with much incongruous matter. After such terrible images as

"The slayer of himself yet saw I there,
His heart's blood ybathed had his hair;"

after "Woodnesse laughing in her rage;" after exhibiting the burning of ships, and the desolation of cities, he introduces the "cooke scalded for all his longe lade." But Chaucer lived when taste was in its childhood.

He was the great architect of our versification. He understood the genius of his native language, and adapted it to those structures of rhyme which some whimsical projectors in the age of Queen Elisabeth would have demolished, in order to substitute a Latin form, but which Spenser in his better judgment followed and improved. A groundless objection was made to his style by an old critic, that he introduced cartloads of French words into our language. It is a satisfactory answer to this, that the language of England in his time was deeply intermixed with French. In the reign of Edward the Third, French and English were taught together at schools; and it was usual to make the scholars construe their Latin into French. A Norman-Saxon dialect must have been in fact the accustomed language of the upper classes, and it was to them that Chaucer wrote. Spenser thought differently of his style from the critic to whom we have alluded, when he pronounced it the "Well of English unfeild." The fluctuation of language easily accounts for this being less strictly true at present than 200 years ago. In general his words in a single sentence clearly reach the meaning to which they point, and he is only fatiguing because he multiplies sentences, and spins out descriptions. This, however, like the coarse part of his humour, was more the fault of his age than of himself. While the beauties of style in more refined classics meet and surprise us at every turn, those of Chaucer may be compared to flowers which we collect in a long journey, numerous in the soil, but collected widely aunder. This expression may appear irreverent to those who are enamoured of old English and obsolete spelling, merely because it is old and obsolete; but the reader who sits down to Chaucer, expecting wonders in every page, will find, that though there is much to reward his patience, there is also something to exercise it. (a)

CHECK, or Cheque, in the manufacture of cloth, a very extensive variety of fanciful goods, made from all the different substances used in the manufacture, sometimes separately, and sometimes combined in the same fabric. Checks are made by forming stripes in the warp, either of yarn of different fineness, or of different colours. In the cotton manufacture, handkerchiefs checked of various colours form a very extensive branch of the business, and are distinguished by the general name of pullicate, from the Indian article of which they are imitations. Those which combine the most extensive variety of colours, for the same reason are called Madras pullicates or handkerchiefs. The ground of the Madras handkerchiefs is a pale buff colour, very like that of the plain cotton cloth known by the name of nankeen, or nanquin; and in the real Indian manufacture, the buff ground is not the effect of any chemical process of dyeing or tinging, but the natural colour of the cotton. In the British imitations, the ground of the cloth is woven white, and afterwards tinged before finishing. The most extensive branch of check manufacture, however, is that of coarse kind which is used for shirts by seamen, and exported in very great quantities to the West Indian colonies, for various articles of negro clothing.

From the very great quantities of these coarse stuffs which are annually consumed, it forms a very prominent branch both of the linen and cotton manufacture. The English cotton checks are chiefly manufactured at Blackburn, and other villages in Lancashire; and the principal seat of the check manufacture, especially the coarser kinds, is in Scotland, at the town of Kirkaldy in Fifeshire. The extensive demand for this article, and the coarseness of the fabric, renders it peculiarly an object for those economical improvements by which the exportation of articles of price may be obtained, without preventing those employed in it from obtaining by their labour fair and competent means of subsistence. It seems, for this reason, to be one of the most inviting objects for the application of the recently introduced operations of weaving by power, although, as far as we know or have reason to believe, this has not hitherto been attempted. For this reason, we shall here explain the principles of an invention made some time ago by the author of this article, at the request of a friend who was engaged to a considerable extent in the power weaving

* Spenser seems at one period to have been a convert to the plan of naturalizing the Latin hexameter in our poetry, but he certainly changed his mind.
of plain cloths for printing. It was not put in practice, by the death of the person for whose use it was intended; and other pursuits have hitherto prevented the inventor from taking any steps to bring it into practice.

To fit a loom moved by power to the operations of weaving checks of every description, from the most simple pattern of blue and white, for a seaman's or a negro's shirt, to the most variegated pattern of a Madras handkerchief, it is only necessary to add to the loom a very simple apparatus for moving the various shuttles, so as to work alternately according to the pattern required. This apparatus will be found in Figures 1 and 2. Plate CXL.; and the inventor offers it with the less hesitation or diffidence, because although he admits that it has never been practically applied to this purpose, yet he has used and proved one of a much more complicated and diversified nature, with unequivocal success, and entirely upon a similar principle, in the patent tambouring machinery, where the effect produced was greatly more difficult of accomplishment. The figure is a profile section, taken longitudinally, of the framework of a power loom of that kind which was originally introduced in Cheshire and Lancashire, and is known there by the name of the Stockport loom. In Scotland, it is generally called the Crank loom, from the means by which the motion is communicated. The upper rail, or cape of the loom, is represented at AA, and the hanging part, or, as it is called by weavers, the sword of the lay, at B. Supposing that a pattern combining five colours is required, and that, of course, five different shuttles are requisite, a section of a box with five divisions, distinguished by numerals, will be seen at C. This box is to be placed on a centre pin at 1, and by moving it backward and forward, the separate divisions from 1 to 5 may be successively brought into the working position, that at 5 being represented in that situation. Let D be a wheel of a convenient diameter, with a ratchet wheel on its rim. This wheel may be made of well-seasoned wood; but, although more expensive, cast-iron will be greatly preferable. With the lower part of the box-frame the lever E is connected by a common joint; and by means of two iron pins or studs, the motion for shifting the boxes will be derived by the rotation of the wheel D on its own axis. This motion will be given at each motion of the lay by the hook H, connected with the lever G by two intermediate cranks at L and M. The vibration or oscillatory motion of the lay, generated by the revolution of the crank F, is represented by the two dotted lines drawn from the centre on which it swings. Now when the lay swings forward towards the wheel D, the pin in the end of the lever E will come in contact with the piece of wood or metal which is screwed on the wheel at 3. Let another vibration of the lay between the dotted lines take place, and the piece of wood 4 will be presented to the pin in the end of the lever E. This piece being nearer the circumference of the wheel D than the former, the pin will be sooner stopped; and the lay continuing its motion to the dotted line, it is evident that the frame of boxes must move upon its centre, and the box 4 will then occupy the place which the box 3 now does, and thus the shuttle will be instantaneously changed, without for one second impeding the speed of the loom. When the wheel D is again shifted, the piece 5 will present itself to the pin, and again instantaneously shift the frame to present a new shuttle in the box 5. Let the lever E be lengthened, and another pin placed so as to come in contact with the inside of the second range of pieces on the wheel D, and the boxes will be successively shifted from 5 to 1 in the inverted order of the former shift. This, however, will not be effected when the lay comes forward to the cloth, but when it is again thrown back towards the heddles; and the shift will take place immediately before the shuttle receives the impulse which is to throw it across the cloth. Now a little reflection will make it apparent, that a wheel of this description may be fitted to every possible diversity of pattern, merely by giving the ratchet wheel as many teeth as necessary, and screwing pieces to more either pin between the concentric circles on the wheel which correspond to the box to be presented. If the wheel is made with a number of slotted holes diverging from the centre towards the circumference, the pattern may be very speedily altered from one description to another, and very few wheels will be required for each loom. The spring K will keep the frame of boxes steady in the position where it is placed until a fresh shift is requisite. An apparatus of this kind might be added to any of the power looms now in use; and there seems no reason to doubt that it would fit them for a much more extensive range of work than they have been hitherto applied to.

The small Figure 4. is a profile of the wheel D and lever E, and will further illustrate how the stop pieces act upon the pins at both extremities of the vibration.

It seems rather extraordinary that no plan of this nature has as yet been adopted; and it can only be accounted for by reflecting how very precarious every new invention is; from a variety of causes both in its mechanical and economical relations. The extensive use to which this might be applied, even in its most simple state, for weaving low-priced blue and white checked cloth must be evident, when we reflect that these checks supply the men employed in the navy, amounting to upwards of 130,000, with shirts and trowsers; that most of the labourers and operative mechanics wear the same kind; and that it supplies the negroes in the colonies with their chief and almost only clothing; that it furnishes a very useful part of the dress of females employed in almost every branch of domestic industry; and that, besides being an article of dress, it is also, among the most numerous class of the people, very much in use for bed-hangings, window-curtains, and many other kinds of household furniture. CHELMSFORD

Chelmsford, a bridge, originally built by Maurice, bishop of London, but rebuilt in 1787. The town consists of four principal streets, and possesses several elegant public buildings. The shire hall is a handsome edifice, and contains apartments for the courts of assize and session, and also the corn exchange, and the assembly rooms. Its front, which is built with white stone, has a basement of rustie work, and a pediment sustained by four three square Ionic columns. The church, dedicated to St. Mary, is a large and elegant building. The body of the church was erected in 1803, and in place of the more ancient part, which fell down in 1800. It has a square flint tower at its west end. On the Moulsham side of the Cheemaker stands the county gaol, which was begun in 1773, and contains all those accommodations which are now almost every where extended to persons in confinement. Two extensive barracks have been recently built here, one at the west end of the town, and the other on the south side, both of which can accommodate 4000 troops. At a short distance from the last of these barracks commences the line of embankment, with the batteries and parapets which were erected for the defence of the metropolis. The other public buildings in Chelmsford, are the free grammar school, endowed by Edward VI. in 1552; a charity school for 50 boys, founded in 1713; a charity school for 20 girls, founded in 1714; and a neatly sculptured conduit, (with the figure of a naiad at the top, and several appropriate inscriptions,) to which the water is conveyed from a spring at the distance of a quarter of a mile. At Galleywood Common near Chelmsford, there is a race course, on which three plates are run for annually, and one of them of the value of 100 guineas is given by the queen. Number of houses 822. Population in 1811, 4649; males 2046, females 2603; females employed in trade 533. See Gough’s Additions to Camden’s Britannia, vol. ii. p. 55; and Brayley and Britton’s Beauties of England and Wales, vol. v. p. 256. (J)

CHELONE, a genus of plants of the class Didynamia, and order Angiosperma. See Botany, page 254.

CHELTENHAM, a town of England in Gloucestershire, celebrated principally as a watering place, is situated near the river Chilt, or Chelt, which runs into the Severn at Wainlode. The town is pleasantly situated, and is sheltered on the north-east by the Cotswold Hills, which terminate about two miles to the north-east of Cheltenham. The town consists only of one street, which is about a mile in length, and during the last 20 years the buildings have been progressively improving. The hotel, and the lodging houses, are commodiously and elegantly fitted up; the assembly rooms are large and handsome; and the theatre has been lately completed on an enlarged plan. The church, dedicated to St. Mary, stands to the south of the centre of the town, and is a large building, consisting of a nave, chancel, side aisles, and transept, with a square tower rising from the intersection, and terminating in a lofty octagonal spire, which deviates considerably from a vertical direction. There is in the north transept a beautiful circular window 15 feet in diameter, divided into 33 compartments. There is an ancient stone cross near the church, consisting of a single shaft rising from the centre of a flight of steps. The walls in the church-yard are shaded with double rows of lime trees. The other public institutions are an hospital for six poor men and women; a free school founded in 1574; and the Cheltenham repository established in 1800.

The numerous invalids who resort to Cheltenham, principally between the months of May and November, are supplied from three springs which were discovered at different periods. The medicinal qualities of the Spa were first discovered in 1716. This spring rises about six feet below the surface of a meadow, about half a mile south of the town, and is an excellent purgative chalybeate. It was enclosed by a rail in 1718, and in 1738 a brick pavilion on five arches was built over the well; a convenient room was fitted up for the reception of the company, several walks were formed, and a long avenue of lime trees was planted. Another spring was discovered in 1788 at the depth of 50 feet, more copious than the former, and possessing all its medical virtues. A third spring was discovered by Dr. Thomas Jameson in 1803, which contains a greater proportion of sulphureous gas than any of the rest. Population of the town and parish in 1811, 8325. See Brayley and Britton’s Beauties of England and Wales, vol. v. p. 675; and Tour in Wales, in Philip’s Coll. of Voy. vol. iv. p. 17. (w)
